Cancer patients are particularly vulnerable to serious COVID-19 related morbidity and mortality due to a combination of disease and therapy-related effects. Available vaccines are highly effective, but initial supply limitations forced difficult patient prioritization decisions. Advisory Committee on Immunization Practices guidelines recommended that states prioritize patients from 65-74 and patients from 16-64 with high risk-conditions (including cancer) in phase 1c. However, this group encompassed 129 million people nationally forcing many states to sub-prioritize. The proportion of states that elected to follow phase 1c recommendations and include all 16+ patients with a cancer diagnosis (vaccine-eligible age) in the same tier as patients over 65 is unknown.*Methods and Materials In late February 2021, we identified every states' COVID vaccination webpage through keyword-based internet search and attempted to identify information about vaccination for cancer patients. The primary endpoint was the proportion of states simultaneously vaccinating patients with cancer and patients over the age of 65. Secondary endpoints included the proportion of states identifying a cancer diagnosis as a criteria for vaccination and the proportion specifically defining a qualifying cancer diagnosis. Descriptive statistics including proportions and frequency counts were performed.*Results 43 states included cancer as a criteria for vaccination with 8 precisely defining a qualifying cancer diagnosis and 17 giving patients with cancer and patients aged 65-74 the same immunization priority. There was no relationship between per capita cancer prevalence and vaccine prioritization decisions. Finding detailed vaccination information required significant computer literacy, as it routinely required navigation through multiple webpage subdomains.*Conclusions Although the majority of states included cancer as a criteria for vaccination, during the supply-constrained vaccination phase, over four-fifths did not clearly define a cancer diagnosis meeting criteria and nearly two-thirds did not give the recommended equal priority to cancer patients and patients aged 65 to 74. Policy interventions in future waves requiring boosters, or in other pandemics, should ensure timely vaccination of vulnerable populations to better mitigate disparities.*Clinical Relevance/Application Nearly 2/3 of states did not follow guidelines to prioritize vaccinating patients with cancer risking unnecessary morbidity and mortality, as this population is particularly vulnerable to COVID-19. Policy interventions in future waves requiring boosters, or in other pandemics, should ensure timely vaccination of vulnerable populations to better mitigate disparities.

RESULTS

43 states included cancer as a criteria for vaccination with 8 precisely defining a qualifying cancer diagnosis and 17 giving patients with cancer and patients aged 65-74 the same immunization priority. There was no relationship between per capita cancer prevalence and vaccine prioritization decisions. Finding detailed vaccination information required significant computer literacy, as it routinely required navigation through multiple webpage subdomains.

CLINICAL RELEVANCE/APPLICATION

Nearly 2/3 of states did not follow guidelines to prioritize vaccinating patients with cancer risking unnecessary morbidity and mortality, as this population is particularly vulnerable to COVID-19. Policy interventions in future waves requiring boosters, or in other pandemics, should ensure timely vaccination of vulnerable populations to better mitigate disparities.

SSRO04-3   Dosimetric Comparison In Risk-adapted Robotic SBRT For Ultra-central Lung Tumors Between Monte Carlo And Ray Trace Dose Calculations: A Preliminary Study In 16 Patients

Participants
Hong Xiang, PhD, Lancaster, Pennsylvania (*Presenter*) Nothing to Disclose

PURPOSE

SBRT for ultra-central lung tumors (UCLTs) has been an area of caution in clinical practices where several risk-adapted fractionation schemes are used to mitigate the high risk from severe toxicity to fatal complications. The accuracy of dose calculation and reporting may have a more direct impact on the outcome and toxicity. This study focuses on UCLTs cases exclusively with organs-at-risk (OARs) either in direct contact or overlap with the target volumes. Key dosimetric differences between Monte Carlo (MC) and Ray Trace (RAT) dose calculations are characterized.*Methods and Materials Risk-adapted SBRT plans for 16 patients with ultra-central lung tumors are generated in CyberKnife Precision TPS system either by reducing the dose per fraction for a 5-fraction SBRT per RTOG-0813 or by two alternative SBRT schemes of 750cGyx8 and 400cGyx15. Each plan is optimized using RAT algorithm to cover 95% or higher of the PTV with priority given to meeting the OAR constraints. All plans are re-calculated with MC algorithm under the same number of beams, beam directions and number of monitor units. Dosimetric comparisons are made between the two dose calculations, including D95% for PTV, mean and minimum dose for PTV and IGTV.

DVHs values of D0.03 cc and D xx cc for OARs are also compared, including the primary bronchial trees, esophagus, heart, aorta-great-vessels.*Results Comparing to MC, RAT is observed to overestimate the dose to the target volumes of PTV and IGTV, and in most of the cases also overestimates the dose to the OARs. The D95% for PTV is 10.6% (median) higher (range 2.8% to 22.2%). The mean and minimum dose to the PTV are 10.1% (median) higher (range 3.2% to 26.2%) and 8.3% (median) higher (range -7.7% to 20.8%). The mean and minimum dose to the IGTV are 8.3% (median) higher (range 2.3% to 16.9%) and 7.3% (median) higher (range 0.4 to 16.6%). The D0.03cc and D4cc (or D10cc) for the bronchi are 7.1% (median) higher (range 6.2% to 9.1%) and 6.6% (median) higher (range -20.4% to 12.3%). The differences in D0.03cc (other than bronchi), D5cc (esophagus), D10cc-or-15cc (heart) and D10cc (aorta-great-vessel) are around 3-5% (median) and range -0.8% to 13.9%.*Conclusions In risk-adapted robotic SBRT plans for ultra-central lung tumors, we observed significant differences in reported dose to target volumes and organs-at-risk, especially for the bronchi, between Monte Carlo and Ray-Trace dose calculations. Such differences provide critical inputs in evaluating case-specific risk and benefit associated with the current SBRT fractionation schemes.*Clinical Relevance/Application Dose calculation accuracy is most critical in SBRT for ultra-central lung tumors, which have not been explicitly addressed in the RTOG 0813 publications and CyberKnife-based lung SBRT literature to date.

RESULTS

Comparing to MC, RAT is observed to overestimate the dose to the target volumes of PTV and IGTV, and in most of the cases also overestimates the dose to the OARs. The D95% for PTV is 10.6% (median) higher (range 2.8% to 22.2%). The mean and minimum dose to the PTV are 10.1% (median) higher (range 3.2% to 26.2%) and 8.3% (median) higher (range -7.7% to 20.8%). The mean and minimum dose to the IGTV are 8.3% (median) higher (range 2.3% to 16.9%) and 7.3% (median) higher (range 0.4 to 16.6%). The D0.03cc and D4cc (or D10cc) for the bronchi are 7.1% (median) higher (range 6.2% to 9.1%) and 6.6% (median) higher (range -20.4% to 12.3%). The differences in D0.03cc (other than bronchi), D5cc (esophagus), D10cc-or-15cc (heart) and D10cc (aorta-great-vessel) are around 3-5% (median) and range -0.8% to 13.9%.

CLINICAL RELEVANCE/APPLICATION

Dose calculation accuracy is most critical in SBRT for ultra-central lung tumors, which have not been explicitly addressed in the RTOG 0813 publications and CyberKnife-based lung SBRT literature to date.

SSRO04-4 Association Of Non-Cancerous Features On Radiotherapy Planning CT Scans With Overall Survival In Patients With Stage I Non-Small Cell Lung Cancer

Participants
Ismail Tahir, MBBCh, Boston, Massachusetts (*Presenter*) Nothing to Disclose

PURPOSE

To explore the association between non-cancerous features on CT scans obtained for radiation therapy planning and overall survival (OS) in patients with lung cancer. We hypothesized that Agatston score, pulmonary artery to aorta (PA:Ao) ratio, and sarcopenia are associated with OS.*Methods and Materials This retrospective single-center study included consecutive patients with stage I non-small cell lung cancer treated with stereotactic body radiotherapy from 2009-2017. Two independent analysts measured Agatston score, PA:Ao ratio, and skeletal muscle cross-sectional area by threshold-based segmentation at the level of the T10 vertebral body on axial 2.5 mm thick CT images (140kV, 21-139 mA, 99% without intravenous contrast). Sarcopenia was defined using sex-specific cut-offs for cross-sectional muscle area divided by height2 that were established in an independent cohort. Associations with OS were measured using univariate (unadjusted hazard ratio, uHR) and multivariate Cox proportional hazards regression (adjusted HR, aHR) adjusted for age and Eastern Cooperative Oncology Group (ECOG) status.*Results Of 206 patients [121 females (58.7%), mean age 74.2±9.2 years], most were ECOG status 1 [n = 96 (46.6%); ECOG status =2 n = 67 (32.5%)], respectively]. 83 patients died after a median clinical follow-up of 39.7 months (IQR 27.2-53.5); median survival was 59.7 months (95%CI 55.7-68.6). The median Agatston score was 199 (IQR 9.0-711.5) and the mean PA:Ao ratio was 0.81±0.12. 62 patients (30.1%) met criteria for sarcopenia. PA:Ao ratio per 1-SD increase (uHR 1.18, p=0.097; aHR=1.35, p=0.007) and ECOG status =2 (uHR=2.06, p=0.027; aHR=2.13, p=0.027) were most strongly associated with worse OS. Sarcopenia was only borderline significant in the multivariate analysis (uHR=1.44, p=0.11; aHR =1.62, p=0.046). Agatston score 10-400 (uHR=1.50, p=0.14; aHR=1.54, p=0.15) and >400 (uHR=1.35, p=0.30; aHR=1.31, p=0.38) was not associated with OS, as was age (uHR=1.01, p=0.29; aHR=1.01, p=0.31).*Conclusions Following radiation therapy, higher PA:Ao ratio on RT-planning CT scans is associated with worse OS in patients with stage I non-small cell lung cancer, independent of age, ECOG status, Agatston score, and sarcopenia.*Clinical Relevance/Application The PA:Ao ratio is readily quantifiable on radiation planning images and may improve clinical decision-making for patients with stage I non-small lung cancer.

RESULTS

Of 206 patients [121 females (58.7%), mean age 74.2±9.2 years], most were ECOG status 1 [n = 96 (46.6%); ECOG status =2 n = 67 (32.5%)], respectively]. 83 patients died after a median clinical follow-up of 39.7 months (IQR 27.2-53.5); median survival was 59.7 months (95%CI 55.7-68.6). The median Agatston score was 199 (IQR 9.0-711.5) and the mean PA:Ao ratio was 0.81±0.12. 62 patients (30.1%) met criteria for sarcopenia. PA:Ao ratio per 1-SD increase (uHR 1.18, p=0.097; aHR=1.35, p=0.007) and ECOG status =2 (uHR=2.06, p=0.027; aHR=2.13, p=0.027) were most strongly associated with worse OS. Sarcopenia was only borderline significant in the multivariate analysis (uHR=1.44, p=0.11; aHR =1.62, p=0.046). Agatston score 10-400 (uHR=1.50, p=0.14; aHR=1.54, p=0.15) and >400 (uHR=1.35, p=0.30; aHR=1.31, p=0.38) was not associated with OS, as was age (uHR=1.01, p=0.29; aHR=1.01, p=0.31).

CLINICAL RELEVANCE/APPLICATION

The PA:Ao ratio is readily quantifiable on radiation planning images and may improve clinical decision-making for patients with stage I non-small lung cancer.

SSRO04-5 Advanced MRI For Characterizing Myocardial Contractility Pattern In Small-animal Model Of Radiation Induced Cardiotoxicity

Participants
El-Sayed Ibrahim, PhD, Milwaukee, Wisconsin (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the capability of advanced MRI parameters of heart mechanics for early detection of radiation therapy (RT)-induced cardiotoxicity in a rat model of lung cancer RT, with end goal to help with risk stratification and treatment management to avoid cardiovascular complications.*Methods and Materials Adult salt-sensitive (SS) rats received whole-heart radiation (24Gy; 1

fraction) and were imaged with MRI at 8wk and 10wk post-RT and the results compared to sham treated rats (n=18). The MRI images were analyzed to measure regional peak systolic strain, based on which the percentage of normally contracting myocardium (%Contractility) was determined based on AHA 17-segment model, where a myocardial segment is considered normally contracting if its peak systolic strain exceeds the average value from all studied segments. %Contractility measurements were compared to ejection fraction (EF) and peak strain in different rat groups. Furthermore, ventricular torsion, diastolic strain rate, and mechanical dyssynchrony were measured.*Results EF and myocardial mass paradoxically increased post-RT. However, peak systolic strain and %Contractility significantly decreased post-RT. Specifically, %Contractility showed continuous decrease post-RT. This can be explained by the nonlinear inverse relationship between EF and %Contractility, in which %Contractility spanned a wide range of measurements between 20% and 100% for rats in different groups despite normal EF (>55%) for all rats. When comparing %Contractility to corresponding peak strain values in different rats, %Contractility showed more reduction post-RT than did the strain values. Furthermore, %Contractility showed more significant reduction post-RT than other MRI parameters, including ventricular torsion, early-diastolic strain rate, and mechanical dyssynchrony.*Conclusions %Contractility is a sensitive marker for early detection of RT-induced subclinical cardiac dysfunction before global function is affected and is more sensitive than peak systolic strain and other MRI cardiac biomarkers. The increase in EF and mass post-RT could be explained by undergoing ventricular remodeling during sub/acute phase of cardiotoxicity.*Clinical Relevance/Application %Contractility is sensitive marker for early detection of RT-induced cardiotoxicity which would help with risk stratification and treatment management to avoid cardiac complications and heart failure.

RESULTS

EF and myocardial mass paradoxically increased post-RT. However, peak systolic strain and %Contractility significantly decreased post-RT. Specifically, %Contractility showed continuous decrease post-RT. This can be explained by the nonlinear inverse relationship between EF and %Contractility, in which %Contractility spanned a wide range of measurements between 20% and 100% for rats in different groups despite normal EF (>55%) for all rats. When comparing %Contractility to corresponding peak strain values in different rats, %Contractility showed more reduction post-RT than did the strain values. Furthermore, %Contractility showed more significant reduction post-RT than other MRI parameters, including ventricular torsion, early-diastolic strain rate, and mechanical dyssynchrony.

CLINICAL RELEVANCE/APPLICATION

%Contractility is sensitive marker for early detection of RT-induced cardiotoxicity which would help with risk stratification and treatment management to avoid cardiac complications and heart failure.

SSRO04-6 A Prognostic Radiomic Model For NSCLC Patients At An Early Stage Treated With SBRT

Participants
Marco Bertolini, Reggio Emilia, Italy (*Presenter*) Nothing to Disclose

PURPOSE

This study aimed to evaluate the prognostic role of a radiomic model by using healthy and tumour tissues in a multimodal imaging cohort of early stage non-small cell lung cancer (NCSLC) patients treated with Stereotactic Radiation Therapy (SRT).*Methods and Materials We selected a set of NSCLC 65 lesions in two retrospective early stage patients' cohorts treated in two institutions with SRT, analyzed on an IEC-approved protocol. Gross Tumor Volume (GTV) was separately delineated on the available images (simulation CT, 18F-FDG PET/CT) by two experienced radiation oncologists. For each GTV, thirteen healthy control volumes (HCVs) were created by locating and shifting duplicated GTV volumes in the contralateral lung. 1502 features were extracted using pyradiomics for each region of interest (ROI). Our novel harmonization process was computed from the difference between GTV and mean HCV features divided by its standard deviation. Least absolute shrinkage and selection operator (LASSO) regression was used for feature selection. Receiver operating characteristic (ROC) curves were used to test the predictive performance of the resulting model using 5-fold cross-validation. The main endpoint of the study was 2-year local progression-free survival (LPFS).*Results Cohort patients' median age was 76 year (51-87 years). Median PFS was 21.0 months (2.0-107.8). Through LASSO selection, 5 image-filtered features were used to build a linear SVM model using the original features and our harmonized values, respectively showing an AUC of 0.78 (CI 0.69-0.87) and 0.89 (CI 0.77-0.95). Original features model failed to stratify the population in 2 distinct groups with 2-years PFS of 44.6% (CI 30.6%-65.0%) and 60.0% (CI 50.9%-90.8%) (log-rank test p-value=0.063), while our harmonized features model stratified the population in two groups with 2-years PFS of 26.2% (CI 13.7%-50.0%) and 81.9% (CI 68.7%-97.7%) (log-rank test p-value=0.00028), as shown in the figure.*Conclusions This study showed that the model based on our new proposed feature harmonization could increase the prognostic ability of radiomic studies.*Clinical Relevance/Application Local relapse disease risk stratification in patients with early stage NSCLC is still an unsolved clinical question. Our radiomic model could help the physician in this task.

RESULTS

Cohort patients' median age was 76 year (51-87 years). Median PFS was 21.0 months (2.0-107.8). Through LASSO selection, 5 image-filtered features were used to build a linear SVM model using the original features and our harmonized values, respectively showing an AUC of 0.78 (CI 0.69-0.87) and 0.89 (CI 0.77-0.95). Original features model failed to stratify the population in 2 distinct groups with 2-years PFS of 44.6% (CI 30.6%-65.0%) and 60.0% (CI 50.9%-90.8%) (log-rank test p-value=0.063), while our harmonized features model stratified the population in two groups with 2-years PFS of 26.2% (CI 13.7%-50.0%) and 81.9% (CI 68.7%-97.7%) (log-rank test p-value=0.00028), as shown in the figure.

CLINICAL RELEVANCE/APPLICATION

Local relapse disease risk stratification in patients with early stage NSCLC is still an unsolved clinical question. Our radiomic model could help the physician in this task.

SSCA05-3   Hepatosteatosis And Atherosclerotic Plaque On Coronary Computed Tomography Angiography

Participants
Michelle Williams, MBCHB, BSC, Kelso, United Kingdom (*Presenter*) Speaker bureau for Canon Medical Systems and Siemens Healthineers.

PURPOSE

Cardiovascular mortality is common among patients with non-alcoholic fatty liver disease (NAFLD), but the underlying mechanisms for this association are uncertain. This study assesses the association between NAFLD and quantitative atherosclerotic plaque burden on CT.*Methods and Materials In this post-hoc analysis of computed tomography (CT) performed in the Scottish COmputed Tomography of the HEART (SCOT-HEART) trial, hepatosteatosis (<40 Hounsfield units) and coronary artery calcium score were measured on non-contrast CT. Coronary artery stenoses were subsequently assessed on coronary computed tomography angiography (CCTA) and classified as normal, non-obstructive or obstructive disease. Quantitative plaque burden (plaque to vessel volume, %) was assessed for total plaque, non-calcified plaque, calcified plaque and low-attenuation plaque.*Results Images from 1726 patients (mean age 58 ± 9 years, 56% male) were suitable for analysis. Patients with hepatosteatosis (n=155, 9%) had a higher body-mass index, were more likely to have hypertension or diabetes mellitus, and had higher cardiovascular risk scores (p<0.001 for all). They had increased coronary artery calcium scores (43 [interquartile interval 0 to 273] Agatston units versus 19 [0 to 225] AU, p=0.046), prevalence of non-obstructive disease (48% versus 37%, p=0.02) and low-attenuation plaque burden (5.11 [0.00 to 7.16]% versus 4.07 [0 to 6.84]%, p=0.035). However, these associations were not independent of established cardiovascular risk factors. Over a median of 4.7 years, there was no difference in the occurrence of myocardial infarction between those with and without hepatosteatosis (2% versus 2%, p=0.706).*Conclusions Hepatosteatosis on CT is associated with an increased prevalence of cardiovascular risk factors but does not independently affect coronary artery disease on CT or the frequency of subsequent myocardial infarction.*Clinical Relevance/Application Hepatosteatosis is a common finding on CT and is associated with other cardiovascular risk factors. However, its presence in patients with symptoms of coronary artery disease should not influence management.

RESULTS

Images from 1726 patients (mean age 58 ± 9 years, 56% male) were suitable for analysis. Patients with hepatosteatosis (n=155, 9%) had a higher body-mass index, were more likely to have hypertension or diabetes mellitus, and had higher cardiovascular risk scores (p<0.001 for all). They had increased coronary artery calcium scores (43 [interquartile interval 0 to 273] Agatston units versus 19 [0 to 225] AU, p=0.046), prevalence of non-obstructive disease (48% versus 37%, p=0.02) and low-attenuation plaque burden (5.11 [0.00 to 7.16]% versus 4.07 [0 to 6.84]%, p=0.035). However, these associations were not independent of established cardiovascular risk factors. Over a median of 4.7 years, there was no difference in the occurrence of myocardial infarction between those with and without hepatosteatosis (2% versus 2%, p=0.706).

CLINICAL RELEVANCE/APPLICATION

Hepatosteatosis is a common finding on CT and is associated with other cardiovascular risk factors. However, its presence in patients with symptoms of coronary artery disease should not influence management.

SSCA05-6   Prediction Of Acute Coronary Syndrome Based On Myocardial Mass At-risk Using Coronary Computed Tomography Angiography

Participants
Shant Malkasian, BS, Irvine, California (*Presenter*) Nothing to Disclose

PURPOSE

This study assessed the relationship of myocardial mass at-risk (MMAR) to coronary artery lesions of differing angiographic stenosis, composition, and remodeling.*Methods and Materials From the multicenter, international ICONIC study, 62 patients suspected of coronary artery disease (CAD) underwent coronary CT angiography imaging (CCTA) and follow-up for acute coronary syndrome (ACS), comprising 31 patients who would experience future ACS matched to 31 patients who would not experience future ACS by propensity scoring of age, gender, CAD risk factors. MMAR was calculated distal to each lesion using the minimum-cost path technique, as the percent of left ventricle myocardium subtended by a lesion. Left ventricle myocardial segmentation and coronary centerlines were used to calculate MMAR distal to all identifiable coronary lesions. Coronary artery lesions were classified as

obstructive (>50% stenosis) and high-risk (2 or more of the following: remodeling index = 1.1, intra-plaque intensity <30 HU, or intra-plaque calcification < 3.3 mm3).*Results Mean MMAR was 68.5±24.3%, 18.7±24.0%, and 11.6±20.6%, for all lesions, lesions with high-risk plaque (HRP), and lesions with diameter stenosis >50% (DS50). Mean MMAR of all lesions was 62.3±24.3% in patients not experiencing ACS and 74.6±23.0% in patients experiencing ACS ACS (p=0.04). Mean MMAR of HRP lesions was 11.4±18.2% in patients not experiencing ACS and 26.0±27.1% in patients experiencing ACS (p=0.02). Mean aggregated MMAR of obstructive lesions were 7.3±19.2% in patients not experiencing ACS and 15.9±21.3% experiencing ACS (p=0.10). Time-restriction survival analysis was performed for occurrence of ACS within 2 years following CCTA imaging, with cutoffs for survival of 82.03%, 7.02%, and 27.01% for MMAR distal to all, high-risk, and obstructive lesions, respectively. The difference in survival time was 0.50 years (p=0.02), 0.40 years (p=0.02), and 0.62 years (p=0.13) for MMAR distal to all, high-risk, and obstructive CAD lesions, respectively.*Conclusions MMAR distal to HRP lesions was significantly larger in patients with ACS, while MMAR distal to obstructive lesions was not clinically significant.*Clinical Relevance/Application MMAR may provide clinically important assessment of CAD burden and improve risk stratification of patients for occurrence of ACS.

RESULTS

Mean MMAR was 68.5±24.3%, 18.7±24.0%, and 11.6±20.6%, for all lesions, lesions with high-risk plaque (HRP), and lesions with diameter stenosis >50% (DS50). Mean MMAR of all lesions was 62.3±24.3% in patients not experiencing ACS and 74.6±23.0% in patients experiencing ACS ACS (p=0.04). Mean MMAR of HRP lesions was 11.4±18.2% in patients not experiencing ACS and 26.0±27.1% in patients experiencing ACS (p=0.02). Mean aggregated MMAR of obstructive lesions were 7.3±19.2% in patients not experiencing ACS and 15.9±21.3% experiencing ACS (p=0.10). Time-restriction survival analysis was performed for occurrence of ACS within 2 years following CCTA imaging, with cutoffs for survival of 82.03%, 7.02%, and 27.01% for MMAR distal to all, high-risk, and obstructive lesions, respectively. The difference in survival time was 0.50 years (p=0.02), 0.40 years (p=0.02), and 0.62 years (p=0.13) for MMAR distal to all, high-risk, and obstructive CAD lesions, respectively.

CLINICAL RELEVANCE/APPLICATION

MMAR may provide clinically important assessment of CAD burden and improve risk stratification of patients for occurrence of ACS.

SSGI01-1   **Development And External Validation Of A Combined Model Using Radiomics And Radiologist Assessment For Predicting Rectal Cancer Treatment Response On MRI**

Participants
Natally Horvat, MD, PhD, New York, New York (*Presenter*) Nothing to Disclose

PURPOSE

To develop and externally validate a combined model using magnetic resonance imaging (MRI)-based radiomics combined with radiologist subjective semantic assessment on restaging rectal MRI in predicting pathological complete response (pCR) in patients with locally advanced rectal cancer (LARC) after neoadjuvant treatment.*Methods and Materials In this IRB-approved study consecutive patients with LARC who underwent neoadjuvant therapy were retrospectively included from two institutions from different countries. Two radiologists (R1 and R2), from each institution, evaluated restaging MRI and classified patients as showing clinical complete or partial response in consensus. A texture classifier (n=33 features) was trained (internal dataset) and validated (external dataset) and also combined with radiological semantic assessment. MRI harmonization using histogram standardization was performed.*Results 114 patients from Institution 1 (41% female; median age=55 years) and 50 from Institution 2 (52% female; median age=64.5) were included. Homogeneity (135°, 1.414) and energy of Gabor (180°, 1.414) were among the top predictive features. In the testing set, accuracy for R1 assessment combined with the texture classifier was 88% (95% CI: 0.76-1.00), and for R2 combined with radiomics features, 85% (95% CI: 0.71-0.99), which were significantly improved over individual reader assessment (68% and 70%, and P=0.01 and 0.04, respectively). MRI harmonization did not reduce the variability of specific features.*Conclusions The combined radiomics texture classifier and radiologist qualitative assessment model was accurate in predicting pCR in patients with LARC after neoadjuvant therapy.*Clinical Relevance/Application Few radiomics algorithm were externally validated, none of them using post-treatment rectal MRI features combined with qualitative radiologist assessment and also none of them with patients from different countries. There is a multidisciplinary effort to improve the accuracy of clinical complete response diagnosis after neoadjuvant treatment, because those patients may be eligible for a non-surgical watch-and-wait approach.

RESULTS

114 patients from Institution 1 (41% female; median age=55 years) and 50 from Institution 2 (52% female; median age=64.5) were included. Homogeneity (135°, 1.414) and energy of Gabor (180°, 1.414) were among the top predictive features. In the testing set, accuracy for R1 assessment combined with the texture classifier was 88% (95% CI: 0.76-1.00), and for R2 combined with radiomics features, 85% (95% CI: 0.71-0.99), which were significantly improved over individual reader assessment (68% and 70%, and P=0.01 and 0.04, respectively). MRI harmonization did not reduce the variability of specific features.

CLINICAL RELEVANCE/APPLICATION

Few radiomics algorithm were externally validated, none of them using post-treatment rectal MRI features combined with qualitative radiologist assessment and also none of them with patients from different countries. There is a multidisciplinary effort to improve the accuracy of clinical complete response diagnosis after neoadjuvant treatment, because those patients may be eligible for a non-surgical watch-and-wait approach.

SSGI01-2   **Diagnostic Accuracy Of MRI For Detecting Tumor Deposits In Staging Of Primary Rectal Cancer**

Participants
Agatha Stanek, MD, Montreal, Quebec (*Presenter*) Nothing to Disclose

PURPOSE

Tumor deposits (TD) are an adverse prognostic indicator in rectal cancer. This study aimed to assess accuracy of MRI in differentiating TD from lymph nodes (LN).*Methods and Materials Following IRB approval, pathologically proven rectal MRI's between 2014-2020 were evaluated (n=394). An expert reader randomized cases into a blinded database with individually marked TD and LN. Four readers, all with less than 5 years' experience individually assessed these labeled structures. Variables assessed included: short and long axis size (mm); T2 signal characteristic, signal on DWI and ADC, contours (irregular or smooth), shape (irregular, ovoid, round), disruption of a vein, whether the structure ran along/tapered/ neither by a vein; distance from the tumor; distance to the MRF; involvement of the MRF; and if the structure was a TD or LN.*Results 105 sessions were created with 46 TD structures and 56 LN structures for individual assessment (n=420). The intraclass correlation coefficient (ICC) demonstrated substantial agreement for long axis dimension (0.87, 95% CI 0.83-0.90), short axis dimension (0.89, 95% CI 0.85 - 0.92), distance from the tumor (0.74, 95% CI 0.66-0.80), and distance to the MRF (0.63, 95% CI 0.51-0.74), (all p&lt0.001). The Kappa estimates showed moderate to substantial agreement for structure discontinuity from the tumor (0.61, 95% CI 0.54-0.69), structure interrupting the course of a vein (0.40, 95% CI 0.33-0.48), contour (0.55, 95% CI 0.47-0.63), and TD/ LN identification (0.57, 95% CI 0.49 - 0.65),

(all p&lt0.001). TD were discontinuous from the primary tumor in 79% of cases and continuous in 21% of cases, whereas LN were discontinuous in 98% of cases and continuous in 1.6% of cases. TD tapering into the vein was identified in 60% of cases and interrupted the course of a vein in 76% of cases. TD were correctly identified in 80% of cases and LN were correctly identified in 69.3% of cases.*Conclusions Tumor deposits demonstrate distinct MRI features including their continuity with the primary tumor, direct tapering, and interruption of nearby veins. These morphologic features can be used in the identification of TD on MRI, which have prognostic implications.*Clinical Relevance/Application Morphologic MRI features of tumor deposits are not adequately delineated in the current TNM staging system for rectal cancer despite their prognostic implications. This study confirms the use of specific morphological characteristics on MRI in the correct identification of tumor deposits versus lymph nodes.

RESULTS

105 sessions were created with 46 TD structures and 56 LN structures for individual assessment (n=420). The intraclass correlation coefficient (ICC) demonstrated substantial agreement for long axis dimension (0.87, 95% CI 0.83-0.90), short axis dimension (0.89, 95% CI 0.85 - 0.92), distance from the tumor (0.74, 95% CI 0.66-0.80), and distance to the MRF (0.63, 95% CI 0.51-0.74), (all p&lt0.001). The Kappa estimates showed moderate to substantial agreement for structure discontinuity from the tumor (0.61, 95% CI 0.54-0.69), structure interrupting the course of a vein (0.40, 95% CI 0.33-0.48), contour (0.55, 95% CI 0.47-0.63), and TD/ LN identification (0.57, 95% CI 0.49 - 0.65), (all p&lt0.001). TD were discontinuous from the primary tumor in 79% of cases and continuous in 21% of cases, whereas LN were discontinuous in 98% of cases and continuous in 1.6% of cases. TD tapering into the vein was identified in 60% of cases and interrupted the course of a vein in 76% of cases. TD were correctly identified in 80% of cases and LN were correctly identified in 69.3% of cases.

CLINICAL RELEVANCE/APPLICATION

Morphologic MRI features of tumor deposits are not adequately delineated in the current TNM staging system for rectal cancer despite their prognostic implications. This study confirms the use of specific morphological characteristics on MRI in the correct identification of tumor deposits versus lymph nodes.

SSGI01-3   Can Radiologic Features Predict Hepatocellular Carcinoma Genetic Subtypes Relevant To Prognosis And Treatment Response?

Participants
Xiaoyang Liu, MD, PhD, Boston, Massachusetts (*Presenter*) Nothing to Disclose

PURPOSE

To correlate MRI features with genetic mutations of hepatocellular carcinoma (HCC) that have implications for prognosis and treatment in patients with and without cirrhosis.*Methods and Materials Next generation sequencing of 447 HCC implicated genes was performed on 52 pathology-proven HCC tumors from patients with (n=32) or without (n=20) cirrhosis. 38 patients underwent pre-biopsy/resection multiphase contrast enhanced MRI, which were retrospectively reviewed by two abdominal radiologists for features including tumor size, margin definition, arterial hyperenhancement, washout, capsule, peritumoral enhancement (focal/patchy parenchymal blush contiguous or within 1 cm of the tumor and persisting in venous phases), intra-tumoral fat, and tumor-in-vein. Diagnostic performance was calculated. Fisher's exact test was used to correlate genetic subtypes with imaging features and cirrhotic status.*Results CTNNB1 mutation was more likely to occur in HCC tumors from cirrhotic livers (16/32, 50%) than in non-cirrhotic livers (4/20, 20%) (p=.0419). The CTNNB1 mutation was strongly correlated with peritumoral enhancement on MRI (p=.0026), with substantial inter-reader agreement (kappa=.72) for this imaging feature. The accuracy of peritumoral enhancement for predicting CTNNB1 mutation was 79% (sensitivity 62%, specificity 88%). TP53 mutation was correlated with a poorly defined tumor margin on MRI (p=.0258). The accuracy of poorly defined tumor margin for predicting TP53 mutation was 74% (sensitivity 58%, specificity 81%). Intra-tumoral fat was more commonly associated with HCC in non-cirrhotic than in cirrhotic livers (p=.0086).*Conclusions Peritumoral enhancement on MRI strongly correlated with CTNNB1 mutation of HCC tumors. A poorly defined tumor margin on MRI correlated with TP53 mutation. These imaging features were accurate in predicting these genetic subtypes of HCC. The incidence of these mutations differed for HCC tumors in cirrhotic versus non-cirrhotic livers.*Clinical Relevance/Application TP53 and CTNNB1 are common and mutually exclusive mutations in HCC. CTNNB1 mutation favors well-differentiated histology, better prognosis, but worse response to immunotherapy; the TP53 mutation favors better response to immunotherapy, but worse response to tyrosine kinase inhibitor therapy. This study links specific MRI features to these genetic subtypes of HCC. If validated by further study, these MRI features may be useful in predicting genetic subtypes and guiding treatment decisions for patients with HCC.

RESULTS

CTNNB1 mutation was more likely to occur in HCC tumors from cirrhotic livers (16/32, 50%) than in non-cirrhotic livers (4/20, 20%) (p=.0419). The CTNNB1 mutation was strongly correlated with peritumoral enhancement on MRI (p=.0026), with substantial inter-reader agreement (kappa=.72) for this imaging feature. The accuracy of peritumoral enhancement for predicting CTNNB1 mutation was 79% (sensitivity 62%, specificity 88%). TP53 mutation was correlated with a poorly defined tumor margin on MRI (p=.0258). The accuracy of poorly defined tumor margin for predicting TP53 mutation was 74% (sensitivity 58%, specificity 81%). Intra-tumoral fat was more commonly associated with HCC in non-cirrhotic than in cirrhotic livers (p=.0086).

CLINICAL RELEVANCE/APPLICATION

TP53 and CTNNB1 are common and mutually exclusive mutations in HCC. CTNNB1 mutation favors well-differentiated histology, better prognosis, but worse response to immunotherapy; the TP53 mutation favors better response to immunotherapy, but worse response to tyrosine kinase inhibitor therapy. This study links specific MRI features to these genetic subtypes of HCC. If validated by further study, these MRI features may be useful in predicting genetic subtypes and guiding treatment decisions for patients with HCC.

SSGI01-4   Convolutional Neural Networks For The Differentiation Of Benign And Premalignant Colorectal Polyps Detected By CT Colonography

Participants
Sergio Grosu, MD, Munich, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Machine learning-based differentiation of premalignant and benign colorectal polyps detected by CT colonography (CTC) using convolutional neural networks (CNN).*Methods and Materials In this retrospective analysis of an average risk colorectal cancer screening sample, polyps of all size categories and morphologies were manually segmented on stool tagged supine and prone CTC

images and classified as benign (hyperplastic polyp or regular mucosa) or premalignant (adenoma) according to histopathology. Two CNN-based models were trained to predict the polyp class (benign vs premalignant). Model SEG was trained on 3D CTC image subvolumes covering individual polyps and additionally polyp segmentation masks. Model noSEG was solely trained on the CTC subvolumes. Diagnostic performance of both models for the determination of premalignant from benign was then validated in an external multicenter test sample (The Cancer Imaging Archive). The operating point for both models was selected individually to maximize the respective Youden-Index.*Results The training set consisted of 107 colorectal polyps in 63 patients (mean age: 63±8 years, 40 men) comprising 169 polyp segmentations. The external test set included 77 polyps in 59 patients comprising 118 polyp segmentations. Model SEG achieved a ROC-AUC of 0.83, sensitivity of 66%, and specificity of 92% on the external test set for determination of premalignant from benign polyps. Model noSEG yielded a ROC-AUC of 0.75, sensitivity of 65%, and specificity of 79% on the external test set.*Conclusions In this proof-of-concept study, CNN-based image analysis allowed for the differentiation of premalignant and benign colorectal polyps with CTC. As this method did not necessarily require manual polyp segmentation it has the potential to facilitate the identification of high-risk polyps as an automated second reader.*Clinical Relevance/Application CNN potentially improve the diagnostic accuracy of CTC in colorectal cancer screening by allowing for a more precise selection of patients who would benefit from endoscopic polypectomy.

RESULTS

The training set consisted of 107 colorectal polyps in 63 patients (mean age: 63±8 years, 40 men) comprising 169 polyp segmentations. The external test set included 77 polyps in 59 patients comprising 118 polyp segmentations. Model SEG achieved a ROC-AUC of 0.83, sensitivity of 66%, and specificity of 92% on the external test set for determination of premalignant from benign polyps. Model noSEG yielded a ROC-AUC of 0.75, sensitivity of 65%, and specificity of 79% on the external test set.

CLINICAL RELEVANCE/APPLICATION

CNN potentially improve the diagnostic accuracy of CTC in colorectal cancer screening by allowing for a more precise selection of patients who would benefit from endoscopic polypectomy.

SSGI01-5   Added Value Of Multiparametric PET/MRI In Staging Of Rectal Cancer

Participants
Alexander Herold, MD, Vienna, Austria (*Presenter*) Nothing to Disclose

PURPOSE

Positron emission tomography/magnetic resonance imaging (PET/MRI) has emerged as a ,,one-stop shop" examination in staging of colon and rectal cancer (RC) and various other neoplastic disorders. The purpose of this study was to determine, whether multiparametric PET/MRI can improve locoregional staging of untreated rectal cancer.*Methods and Materials In this retrospective study, 48 patients with primary RC were included, who underwent multiparametric 2-Deoxy-2-[18F] fluoroglucose (FDG) PET/MRI, followed by surgical resection and no further pretreatment. T and N staging was performed on standard T2w- sequences by two readers. Various parameters were extracted from the multiparametric protocol, consisting of diffusion-weighted (DWI), perfusion imaging and PET sequences, and were compared to the histopathological and radiological staging.Statistical analysis (median, mean, 90th percentile and interquartile range [IQR] of parametric data), ROC curve analysis and multivariate regression analysis was performed for correlation with clinical and histological parameters such as pT, pN-Staging, lymph node ratio (LNR) and lymphatic invasion (L).*Results Locally advanced tumors (T3N+ and higher) exhibited significantly higher metabolic tumor volume (MTV, T3N+: AUC= 0.796, p=0.001) and total lesion glycolysis (TLG). Rate constant (kep) was associated with increased lymph node ratio (AUC=0.780, p=0.043) as well as with lymphatic invasion (AUC=0.765, p= 0.01). In the multivariate regression analysis, a combination of MTV and kep best predicted locally advanced RC (HR=1.053, p=0.009), with a sensitivity and accuracy of 78.6% and 72.3% respectively, which was superior to standard anatomical assessment.*Conclusions Multiparametric PET-MRI including dynamic contrast-enhanced MR Perfusion provides additional information on RC tumor biology and tumor involvement of the lymphatic system. This can improve identification of locally advanced tumors and hence help in treatment stratification.*Clinical Relevance/Application Improvement of locoregional staging in untreated rectal cancer and thus possibly impacting treatment decisions regarding neoadjuvant therapy.

RESULTS

Locally advanced tumors (T3N+ and higher) exhibited significantly higher metabolic tumor volume (MTV, T3N+: AUC= 0.796, p=0.001) and total lesion glycolysis (TLG). Rate constant (kep) was associated with increased lymph node ratio (AUC=0.780, p=0.043) as well as with lymphatic invasion (AUC=0.765, p= 0.01). In the multivariate regression analysis, a combination of MTV and kep best predicted locally advanced RC (HR=1.053, p=0.009), with a sensitivity and accuracy of 78.6% and 72.3% respectively, which was superior to standard anatomical assessment.

CLINICAL RELEVANCE/APPLICATION

Improvement of locoregional staging in untreated rectal cancer and thus possibly impacting treatment decisions regarding neoadjuvant therapy.

SSGI01-6   A New Proposal For Secondary Surveillance Following Local Ablative Therapy Of HCC: Alternating MRI And CEUS

Participants
Stephanie Wilson, MD, Calgary, Alberta (*Presenter*) Equipment support, Koninklijke Philips NV;Equipment support, Siemens AG;Equipment support, Samsung Electronics Co, Ltd;Research support, Samsung Electronics Co, Ltd;

PURPOSE

A high recurrence rate following ablative therapy of hepatocellular carcinoma (HCC) necessitates routine follow-up imaging (secondary surveillance) to facilitate early re-treatment. We evaluate our unique secondary surveillance algorithm (with use of alternating MRI and CEUS) by assessment of the relative diagnostic accuracy of MRI and CEUS in detection of residual/recurrent tumor. Potential benefits of alternating surveillance are compared to the use of MRI alone.*Methods and Materials This prospective observational IRB approved study included 231 patients with 354 treated tumors between January 2017 and June 2020. Treated lesions underwent secondary surveillance for a minimum of 7 months and up to 3 years, median follow-up 14 months. Secondary surveillance involved MRI performed at 1 month after treatment, followed by CEUS and MRI at alternate 3 month intervals (i.e., CEUS at month 4, MRI at month 7, etc.), for a total of 2 years. An equivocal finding on one imaging modality triggered expeditious evaluation with the alternate modality. Arterial phase hyperenhancement and washout comprise the classic features of recurrent tumor on both modalities.*Results A total of 746 MRI and 712 CEUS examinations were performed, and a total of 184 tumor

recurrences detected, MRI (n=82) and CEUS (n=102) (p = 0.19). There was no difference in the sensitivity (71.0-85.0% and 80.9-92.0%), specificity (97.4-99.2% and 98.5-99.9%), and area under the ROC curve (0.85-0.92 and 0.91-0.96) between MRI and CEUS respectively. 23 of 82 recurrent tumors identified on MRI were equivocal and confirmed with expedited CEUS. 9 equivocal cases on MRI were disproved by expedited CEUS. On CEUS, 1 of the 102 recurrent tumors was equivocal and confirmed on MRI, and 2 equivocal CEUS cases were disproved by MRI.*Conclusions MRI and CEUS performed similarly in our secondary surveillance algorithm for HCC in their ability to detect tumor recurrence, and showed no significant difference in their relative diagnostic test accuracy measures. Of greater interest, equivocal results on MRI (typically due to difficulty in distinguishing tumor recurrence from post-treatment change/shunting) were either confirmed or disproven by CEUS in all cases.*Clinical Relevance/Application Secondary surveillance of treated HCC with alternating MRI and CEUS shows equivalent performance of each modality. CEUS resolves equivocal MRI and optimally demonstrates APHE and washout in tumor recurrence.

RESULTS

A total of 746 MRI and 712 CEUS examinations were performed, and a total of 184 tumor recurrences detected, MRI (n=82) and CEUS (n=102) (p = 0.19). There was no difference in the sensitivity (71.0-85.0% and 80.9-92.0%), specificity (97.4-99.2% and 98.5-99.9%), and area under the ROC curve (0.85-0.92 and 0.91-0.96) between MRI and CEUS respectively. 23 of 82 recurrent tumors identified on MRI were equivocal and confirmed with expedited CEUS. 9 equivocal cases on MRI were disproved by expedited CEUS. On CEUS, 1 of the 102 recurrent tumors was equivocal and confirmed on MRI, and 2 equivocal CEUS cases were disproved by MRI.

CLINICAL RELEVANCE/APPLICATION

Secondary surveillance of treated HCC with alternating MRI and CEUS shows equivalent performance of each modality. CEUS resolves equivocal MRI and optimally demonstrates APHE and washout in tumor recurrence.

SSPH10-1 Low-energy Virtual Monoenergetic Imaging With The Synergy Of Two Algorithms -prior Knowledge Aware Iterative Denoising And Convolutional Neural Network Based Direct Conversion

Participants
Hao Gong, PhD, Rochester,, Minnesota (*Presenter*) Nothing to Disclose

PURPOSE

Low keV virtual monoenergetic imaging (VMI) can boost iodine contrast signal and improve the differentiation of soft tissue. Yet, the quality of conventional VMI synthesis (including commercial VMI technique) is largely limited by the amplified image noise and artifacts at low energy levels. In this work, we aim to address these limitations by exploiting the synergistic effects of a CNN based VMI method and a prior knowledge aware iterative denoising (PKAID) technique.*Methods and Materials A CNN-based method was developed to directly convert multi-energy CT images into VMIs. The CNN used an in-house structure with customized inception blocks, and in-house-designed loss functions. The network was trained using the phantom images with tissue mimicking materials and iodine contrast media. Training set was generated using image patches of those phantom materials, paired with the corresponding theoretical CT numbers as labels. Numerical phantom materials with a variety of mass densities were simulated to increase the amount of training data. To further improve the image quality, multi-energy CT images were further denoised using PKAID prior to feed into the trained CNN for VMI synthesis. PKAID achieved noise reduction by exploiting spatial redundancy between high-noise thin-slice images and low-noise thick-slice images. The proposed method was tested on patient images of different types of exams (contrast and non-contrast), body parts (head and abdomen), and multi-energy platforms (a dual-source dual energy CT, DECT; and an investigational photon counting detector CT, PCD-CT). Contrast, noise, and contrast to noise ratio (CNR) were measured and compared to commercial VMIs.*Results Compared to commercial VMI, the CNN (with and without PKAID) substantially reduced image noise, and blooming and beam-hardening artifacts in both non-contrast head and contrast-enhanced abdomen CT exams. Without PKAID, CNN can still yield ~66% lower noise and up to 2.8 fold CNR improvement. The synergistic method consistently achieved further noise reduction and CNR improvement: brain tissue in DECT - noise reduction ~72%, CNR improvement ~50%; abdominal muscle and adipose in PCD-CT - noise reduction ~70%, CNR improvement ~3.4 fold.*Conclusions The presented synergistic method substantially improves the image quality of low keV VMIs through reduction of image noise and artifacts, with a CNR improvement up to 3.4 fold compared to current commercial solution.*Clinical Relevance/Application Conventional low keV VMI has limited quality for diagnostic applications. The presented method has the potential of improving the diagnostic quality and clinical adoption of low keV VMI.

RESULTS

Compared to commercial VMI, the CNN (with and without PKAID) substantially reduced image noise, and blooming and beam-hardening artifacts in both non-contrast head and contrast-enhanced abdomen CT exams. Without PKAID, CNN can still yield ~66% lower noise and up to 2.8 fold CNR improvement. The synergistic method consistently achieved further noise reduction and CNR improvement: brain tissue in DECT - noise reduction ~72%, CNR improvement ~50%; abdominal muscle and adipose in PCD-CT - noise reduction ~70%, CNR improvement ~3.4 fold.

CLINICAL RELEVANCE/APPLICATION

Conventional low keV VMI has limited quality for diagnostic applications. The presented method has the potential of improving the diagnostic quality and clinical adoption of low keV VMI.

SSPH10-2 Extraction Of Spectral CT Information From Single-kV CT Scans By Deep Learning

Participants
Yinsheng Li, PhD, Madison, Wisconsin (*Presenter*) Nothing to Disclose

PURPOSE

There is a long-standing technical limitation associated with conventional single-kV CT imaging: anatomical structures with different material compositions may have the same CT number, thereby limiting the ability to differentiate and classify different tissue types and contrast agents. In this work, an artificial intelligence based method was developed to extract the desired spectral CT information from a conventional single-kV CT acquisition.*Methods and Materials A deep neural network, Deep-En-Chroma, was developed to mine the encoded spectral information in the recorded signals using an energy-integrating detector. A dedicated module in Deep-En-Chroma was developed to extract the corresponding effective energy for each measured datum. This effective energy was then used to guide the decomposition of a conventional CT image into material basis images. To train the model, human subject data acquired from the hardware based dual-energy CT acquisitions were curated to generate 4,043 pairs of training data which consists of the conventional high-kV image and the corresponding material basis images. The trained model was applied to 1,526 individual high-kV image slices to produce the corresponding material basis image for comparison. The results of Deep-En-

Chroma were compared against the corresponding clinical gold standard DECT images. The Bland-Altman statistical analysis method was used to analyze results over 9,100 randomly selected ROIs from 1,526 image slices.*Results 1) Image objects with similar CT numbers in single-kV CT images can be well differentiated using the Deep-En-Chroma material basis images. 2) Quantitative accuracy of the material basis images from Deep-En-Chroma and single-kV acquisition closely match those of the DECT images over the entire test cohort. 3) For iodine basis images, the mean difference between Deep-En-Chroma and DECT is -0.25 with a tight agreement limits of [-0.75 mg/ml, +0.24 mg/ml]. 4) For the water basis images, the mean difference is 0.0 with a tight agreement limits of [-0.01 g/ml, 0.01 g/ml].*Conclusions The Deep-En-Chroma method provides a new way to generate spectral CT imaging from a single-kV scan with high quantitative accuracy.*Clinical Relevance/Application This new paradigm enables conventional CT scanners to be equipped with a spectral-resolving capability for the accurate quantification of material compositions to improve the diagnostic accuracy in modern precision medicine.

RESULTS

1) Image objects with similar CT numbers in single-kV CT images can be well differentiated using the Deep-En-Chroma material basis images. 2) Quantitative accuracy of the material basis images from Deep-En-Chroma and single-kV acquisition closely match those of the DECT images over the entire test cohort. 3) For iodine basis images, the mean difference between Deep-En-Chroma and DECT is -0.25 with a tight agreement limits of [-0.75 mg/ml, +0.24 mg/ml]. 4) For the water basis images, the mean difference is 0.0 with a tight agreement limits of [-0.01 g/ml, 0.01 g/ml].

CLINICAL RELEVANCE/APPLICATION

This new paradigm enables conventional CT scanners to be equipped with a spectral-resolving capability for the accurate quantification of material compositions to improve the diagnostic accuracy in modern precision medicine.

SSPH10-3   Real-time, Personalized Estimation Of CT Organ Dose From Scout Images

Participants
Adam S. Wang, PhD, Stanford, California (*Presenter*) Research support, General Electric Company;Research support, Siemens AG;Research collaboration, Varex Imaging Corporation

PURPOSE

To develop an automated tool for providing accurate and real-time patient-specific, organ-specific CT doses from scout views, which could be used to prospectively guide CT acquisition.*Methods and Materials An end-to-end deep-learning model was designed, namely Scout-Net, to predict the CT dose of organs-of-interest from input frontal and lateral views. The Scout-Net model facilitates joint learning of the dose prediction at six different organs (lung, kidneys, liver, spleen, pancreas, bladder) and patient body through two basic modules: a generic feature learning module and individual dose learning modules. An automated pipeline was also developed to establish reference organ doses leveraging the publicly available MC-GPU (V1.3) and an AutoSeg (context-encoder U-Net). MC-GPU was modified to model a realistic CT system, including bowtie filtration and anode heel effect. The methods were validated using an internal dataset of 112 (80 train and 32 test) adult body scans, acquired from Revolution CT scanners (GE Healthcare), paired with frontal and lateral scouts. The CT scan range, which users select prior to scanning, was also input to the model so that dose is calculated for the relevant range.*Results The best model was saved on a validation set of 5% (4 scans) from the train set and mean relative errors were calculated on the test set after ten runs. Scout-Net predicts patient body dose with 6.26%± 0.03 (0.56mGy± 0.03) error and the six organ doses with 10.25%± 0.4 (0.75mGy± 0.02) error on average. Approximately 9% overall performance gain was observed with the incorporation of scan range, and physically consistent augmentations (vertical flip and Gaussian noise) further improved the model performance (by 14% in body dose). In addition to the accurate estimation of patient body and organ doses, Scout-Net facilitates massive gain in runtime and computing resources. Compared to CT-based retrospective estimation (MC-GPU and AutoSeg) which takes approximately 200 s per scan, only 11 ms with GPU (16 ms in CPU) is required for the prospective dose estimation by the Scout-Net model.*Conclusions A novel deep learning-based CT organ dose estimation method (Scout-Net) was developed which is capable of calculating organ dose distribution prospectively before acquiring the CT exam. Compared with CT-based dose estimation, Scout-Net demonstrates the correct prediction of the prospective dose report at the patient body and six different organs from the scout views, with improved generalization and execution speed.*Clinical Relevance/Application We present a new means of estimating organ doses aimed at improving CT acquisition to potentially facilitate the reduction of radiation dose by guiding the automatic exposure control to balance dose and image quality.

RESULTS

The best model was saved on a validation set of 5% (4 scans) from the train set and mean relative errors were calculated on the test set after ten runs. Scout-Net predicts patient body dose with 6.26%± 0.03 (0.56mGy± 0.03) error and the six organ doses with 10.25%± 0.4 (0.75mGy± 0.02) error on average. Approximately 9% overall performance gain was observed with the incorporation of scan range, and physically consistent augmentations (vertical flip and Gaussian noise) further improved the model performance (by 14% in body dose). In addition to the accurate estimation of patient body and organ doses, Scout-Net facilitates massive gain in runtime and computing resources. Compared to CT-based retrospective estimation (MC-GPU and AutoSeg) which takes approximately 200 s per scan, only 11 ms with GPU (16 ms in CPU) is required for the prospective dose estimation by the Scout-Net model.

CLINICAL RELEVANCE/APPLICATION

We present a new means of estimating organ doses aimed at improving CT acquisition to potentially facilitate the reduction of radiation dose by guiding the automatic exposure control to balance dose and image quality.

SSPH10-4   Simultaneous CT Angiography And CT Venography Using Dual-contrast-agent Multi-energy CT: An Animal Feasibility Study

Participants
Zhongxing Zhou, Rochester, Minnesota (*Presenter*) Nothing to Disclose

PURPOSE

To develop a dual-contrast-agent multi-energy CT (MECT) technique to simultaneously image and differentiate arteries and veins in a single scan, and to explore its feasibility in a swine model using a triple-beam MECT system.*Methods and Materials The triple-beam MECT system was implemented on a dual-source CT platform by mounting a z-axis split filter (0.05 mm Au, 0.6 mm Sn) on Tube A. The x-ray beam configuration of 70/Au120/Sn120 kV was used to provide optimal spectral performance for material delineation. A dual-contrast scanning protocol was developed for simultaneously acquiring two phases of vascular enhancement,

with iodine and gadolinium corresponding to the arterial enhancement (CT angiography (CTA)) and venous enhancement (CT venography (CTV)), respectively. The quantification accuracy of iodine and gadolinium was evaluated using a water phantom containing multiple concentrations of iodine and gadolinium contrast agents. A test bolus scan was performed in the swine head/neck region to determine the contrast enhancement profiles in arteries and veins, based on which the injection timing for the two agents was calculated. A gadolinium contrast bolus (Gadavist, 80 mL, 10 mL/s) was intravenously injected, followed 12 s later by an iodine contrast bolus (Omnipaque 350, 40 mL, 5 mL/s). A MECT scan was performed 12 s after initiation of the iodine contrast injection. Material decomposition was performed to separate iodine and gadolinium, which corresponded to CTA and CTV images, respectively.*Results Iodine and gadolinium samples were accurately quantified in the phantom experiment with root-mean-square-error (RMSE) of 1.58 mg/cc for iodine and 1.33 mg/cc for gadolinium. In the swine experiment, common carotid arteries containing iodine and internal/external jugular veins containing gadolinium could be clearly delineated from each other. Fine vessels such as cephalic veins and branches of external jugular veins could be visualized but clarity was impacted by image noise.*Conclusions The feasibility of simultaneous CTA and CTV imaging in MECT using a dual-contrast-agent (iodine and gadolinium) injection protocol was demonstrated in a swine study.*Clinical Relevance/Application A MECT scan using dual-contrast-agent injections provides perfectly registered images of arteries and veins from a single CT scan, providing a more complete description of the vascular system.

RESULTS

Iodine and gadolinium samples were accurately quantified in the phantom experiment with root-mean-square-error (RMSE) of 1.58 mg/cc for iodine and 1.33 mg/cc for gadolinium. In the swine experiment, common carotid arteries containing iodine and internal/external jugular veins containing gadolinium could be clearly delineated from each other. Fine vessels such as cephalic veins and branches of external jugular veins could be visualized but clarity was impacted by image noise.

CLINICAL RELEVANCE/APPLICATION

A MECT scan using dual-contrast-agent injections provides perfectly registered images of arteries and veins from a single CT scan, providing a more complete description of the vascular system.

SSNR06-1 **External Validation Of The Brain Tumour And Reporting System (BTRADS) Score In Multidisciplinary Management Of Post-treatment Gliomas**

Participants
Kamaxi Trivedi, MD,MBBS, Mumbai, India (*Presenter*) Nothing to Disclose

PURPOSE

BTRADS is a structured reporting system proposed by the Emory neuroradiology group to increase the value of the report to the ordering clinician, and provide greater clarity to patients with brain tumors. This study is an external independent validation of the BTRADS scoring system and mainly addresses interobserver variability and evaluation of its efficacy in correctly predicting the multidisciplinary meeting (MDM) decision.*Methods and Materials Retrospective observational study- IEC approved. Sample size:100 Inclusion criteria: All post-operative patients receiving adjuvant therapy (RT ± TMZ) as per hospital protocol and under routine clinical surveillance. Exclusion criteria: Paediatric (= 18 years) brain tumours. Two independent, dedicated neuro-radiologists (RD1 and RD2) were blinded and analysed the consecutive post-treatment MRIs of 100 patients with post-treatment gliomas and gave a score as per the BTRADS to each patient, at two separate sittings. Patients in whom the allotted scores were different were then resolved by discussion and a final "consensus" score given, These scores were then correlated with the MDM decision.*Results Intraclass correlation coefficients showed low interobserver variabilities of the BTRADS scores between RD1 and RD2 and both with consensus as well. The intraclass correlation coefficients was 0.934 (95% CI: 0.901, 0.956) between RD1 and RD2, 0.981 (95% CI: 0.972, 0.988) between RD1 and consensus, and 0.962 (95% CI: 0.944, 0.975) between RD2 and consensus. The overall agreement rate between RD1 and RD2 was 62.7%, with kappa of 0.67. The agreement rate between the RD1 and consensus was 83.3% with a kappa of 0.85. The agreement rate between RD2 and consensus was 69.3% with a kappa of 0.79. Among radiologists, agreement was highest for score 2 and lowest was for score 3B. The consensus with MDM recommendation linked to each score was 97.9% (in total 94 cases) with only 2.1%(2 cases) showing disagreement. Both of these cases were scored 3A.*Conclusions Our study reveals that the BTRADS system shows low inter-reader variability between radiologists. Overall agreement is good, but variation rates increase with category 3b and 3c patients which may be harder to correctly interpret. This is an expected finding because this category likely represents patients who are either pseudo-progression or true progression. The table of interpretation categories tied to suggested management decisions was also quite effective and showed significant match with decisions taken by our treating oncologists.*Clinical Relevance/Application The BTRADS system is independently and externally validated to have good agreement between reporting radiologists, and the allotted scores can be tied to management recommendations.

RESULTS

Intraclass correlation coefficients showed low interobserver variabilities of the BTRADS scores between RD1 and RD2 and both with consensus as well. The intraclass correlation coefficients was 0.934 (95% CI: 0.901, 0.956) between RD1 and RD2, 0.981 (95% CI: 0.972, 0.988) between RD1 and consensus, and 0.962 (95% CI: 0.944, 0.975) between RD2 and consensus. The overall agreement rate between RD1 and RD2 was 62.7%, with kappa of 0.67. The agreement rate between the RD1 and consensus was 83.3% with a kappa of 0.85. The agreement rate between RD2 and consensus was 69.3% with a kappa of 0.79. Among radiologists, agreement was highest for score 2 and lowest was for score 3B. The consensus with MDM recommendation linked to each score was 97.9% (in total 94 cases) with only 2.1%(2 cases) showing disagreement. Both of these cases were scored 3A.

CLINICAL RELEVANCE/APPLICATION

The BTRADS system is independently and externally validated to have good agreement between reporting radiologists, and the allotted scores can be tied to management recommendations.

SSNR06-2 **Lost To Follow-up: A Nationwide Analysis Of Transient Ischemic Attack Patients Discharged From Emergency Departments With Incomplete Imaging Work-up**

Participants
Vincent M. Timpone, MD, Denver, Colorado (*Presenter*) Research Consultant, iSchemaView, Inc

PURPOSE

Imaging guidelines for Transient Ischemic Attack(TIA) recommend patients receive urgent brain and neurovascular imaging, preferably within 24 hours of symptom onset. It has been previously demonstrated that a majority of TIA patients discharged from the emergency department(ED) without hospital admission do not complete a recommended TIA imaging work-up during their ED encounter. The purpose of this study was to determine the percentage of patients discharged from ED with incomplete imaging work-up that are able to complete recommended imaging following discharge.*Methods and Materials We analyzed 24 months of data of the Medicare 5% database from 2017-2018. Patients diagnosed and discharged from EDs with TIA were identified using ICD-10 codes, and imaging performed was identified using CPT codes. Incomplete imaging work-up was defined as an encounter

without cross-sectional brain, brain-vascular and neck-vascular imaging performed at time of initial ED encounter, or within the subsequent 30-days post ED discharge. A multivariable logistic regression analysis was performed to determine significant associations with incomplete TIA imaging work-up.*Results 4,814 TIA encounters were included in our analysis. 2,802(58.2%) of patients had a complete TIA imaging work-up during their ED encounter. Of the 2,012 of patients discharged from EDs with incomplete imaging, 568(28.2%) had completed imaging during the subsequent 30-days post ED discharge. For TIA imaging work-ups completed post ED discharge, median time to completion was 5 days. Odds of incomplete TIA imaging work up at 30-days post ED discharge were increased in Black patients(OR 3.00[1.86-4.82]), older patients(85+ years; OR 2.61[1.88-3.62]), and large hospitals(400+ beds; OR 2.11[1.36-3.28]).*Conclusions Most patients discharged from EDs with incomplete TIA imaging work-up do not complete recommended imaging within 30 days post discharge. Odds of incomplete imaging are increased in Black patients, older patients, and large hospitals.*Clinical Relevance/Application Future efforts should be directed to improve access to timely imaging of TIA so that modifiable risk factors for future stroke can be identified and treated.

RESULTS

4,814 TIA encounters were included in our analysis. 2,802(58.2%) of patients had a complete TIA imaging work-up during their ED encounter. Of the 2,012 of patients discharged from EDs with incomplete imaging, 568(28.2%) had completed imaging during the subsequent 30-days post ED discharge. For TIA imaging work-ups completed post ED discharge, median time to completion was 5 days. Odds of incomplete TIA imaging work up at 30-days post ED discharge were increased in Black patients(OR 3.00[1.86-4.82]), older patients(85+ years; OR 2.61[1.88-3.62]), and large hospitals(400+ beds; OR 2.11[1.36-3.28]).

CLINICAL RELEVANCE/APPLICATION

Future efforts should be directed to improve access to timely imaging of TIA so that modifiable risk factors for future stroke can be identified and treated.

SSNR06-3 Computed Tomography Texture Analysis Of Carotid Plaque As Predictor Of Unfavorable Outcome After Carotid Artery Stenting: A Preliminary Study

Participants
Davide Colombi, MD, Piacenza, Italy (*Presenter*) Nothing to Disclose

PURPOSE

to test the association between textural features of stenotic plaque at carotid bifurcation derived by using open-source software (3D Slicer software; https://www.slicer.org) on computed tomography angiography (CTA) and unfavorable outcome after carotid artery stenting (CAS)*Methods and Materials The study included patients who underwent CAS from January 2010 to January 2021 for carotid bifurcation or internal carotid artery (ICA) stenotic plaque. Exclusion criteria were as follows: (1) absence of supra-aortic vessels CTA within 6 months before the procedure; (2) unsuccessful CAS; (3) unsuccessful software analysis. The study included 172 patients (men 112/172, 65%; median age, 77 years-old, interquartile range, 70-82 years-old). Carotid stenosis was symptomatic (ipsilateral neurologic ischemic event within 6 months before procedure) in 90/172 (52%) patients. All patients underwent CTA of the supraortic vessels and image datasets were reconstructed axially using medium-soft kernel at 1.5-2 mm slice thickness. Carotid plaques were manually segmented at CTA; mean, standard deviation, kurtosis, and skewness of the carotid plaque were derived by the analysis of the density histogram performed by the Radiomics extension (Computational Imaging & Bioinformatics Lab, Harvard Medical School; Boston, Massachusetts, USA) of the open-source 3D Slicer software.Multiple logistic regression analysis was used to examine the association between potential prognostic variables and unfavorable outcome, defined as occurrence of periprocedural (within 30 days following CAS) death or myocardial infarction and any ipsilateral stroke after CAS. Receiver operating characteristic (ROC) curve analysis and the calculation of the area under the ROC (AUC) were used to assess the performance for predicting unfavorable outcome*Results Patients without unfavorable outcome were similar to the remaining patients for demographics, comorbidities, and anatomic features. Patients with unfavorable outcome showed an higher rate of ulcerated plaque (58% vs 30%, P=0.029) and lower plaque kurtosis (5.37 vs 5.84, P=0.048).Among textural features, kurtosis was an independent predictor of unfavorable outcome (odds ratio 0.77; confidence interval: 0.61-0.96; P=0.021). The predictive model for unfavorable outcome including CTA textural features outperformed the model without textural features (AUC 0.856 vs 0.803, P=0.004)*Conclusions In patients with stenotic plaque at carotid bifurcation, kurtosis of the CTA density histogram is an independent predictor of unfavorable outcome*Clinical Relevance/Application Textural analysis of stenotic carotid plaque at CT could be helpful for the risk stratification of unfavorable outcome after carotid artery stenting

RESULTS

Patients without unfavorable outcome were similar to the remaining patients for demographics, comorbidities, and anatomic features. Patients with unfavorable outcome showed an higher rate of ulcerated plaque (58% vs 30%, P=0.029) and lower plaque kurtosis (5.37 vs 5.84, P=0.048).Among textural features, kurtosis was an independent predictor of unfavorable outcome (odds ratio 0.77; confidence interval: 0.61-0.96; P=0.021). The predictive model for unfavorable outcome including CTA textural features outperformed the model without textural features (AUC 0.856 vs 0.803, P=0.004)

CLINICAL RELEVANCE/APPLICATION

Textural analysis of stenotic carotid plaque at CT could be helpful for the risk stratification of unfavorable outcome after carotid artery stenting

SSNR06-4 Admission CT Radiomic Signatures Are Stronger Predictors Of Long-term Outcome And Baseline Clinical Severity Than Hematoma Volume In Patients With Intracerebral Hemorrhage (ICH)

Participants
Stefan Haider, New Haven, Connecticut (*Presenter*) Nothing to Disclose

PURPOSE

Only 40% of ICH patients regain functional independence while there is yet no effective treatment - highlighting the importance of early risk stratification for personalized treatment decisions and enrollment in clinical trials. To date, hematoma volume is the most widely used and strongest imaging predictor of clinical outcome. We investigated the utility of ICH radiomics in predicting the severity of clinical symptoms at admission and long-term functional outcome.*Methods and Materials Utilizing the dataset gathered by the "Antihypertensive Treatment of Acute Cerebral Hemorrhage II" trial, we extracted a set of n=1130 radiomics features reflecting hematoma shape, density and texture from hematoma lesions of n=895 patients on admission non-contrast CT. Subjects were randomly allocated to a discovery (n=448) and independent validation cohort (n=447). Following exclusion of features with low inter- and intra-rater reproducibility and high multicollinearity, we generated separate "radiomics signatures" associated with

admission GCS, admission NIHSS, and 3-month follow-up modified Rankin scale (mRS) scores using LASSO-regularized ordinal logistic regression models in the discovery cohort. Features with non-zero coefficients were linearly combined and weighted by their respective coefficients to devise the signatures. Spearman's correlation (rho) between radiomics signatures and target scores was compared with the correlation between ICH volume and target scores.*Results Radiomics signatures, compared to ICH volume, demonstrated significantly stronger correlation with GCS (rho=0.47 vs 0.44, p=0.008), NIHSS (0.69 vs 0.57, p<0.001), and mRS scores (0.44 vs 0.32, p<0.001) in the discovery cohort. Similarly, in independent validation, the radiomics signatures exhibited significantly stronger association with GCS (0.43 vs 0.41, p=0.02), NIHSS (0.64 vs 0.56, p<0.001), and mRS scores (0.43 vs 0.33, p<0.001). The mRS radiomics signature was an independent predictor of long-term disability in multiple regression analysis adjusted for admission GCS and NIHSS scores with p<0.001 in both cohorts.*Conclusions ICH radiomics signatures derived from admission non-contrast CTs provide stronger imaging correlates for clinical presentation and long-term outcome than the hematoma volume alone.*Clinical Relevance/Application Our results suggest admission CT radiomics signatures may aid risk assessment, treatment triage, and prognostication in ICH patients beyond hematoma volume.

RESULTS

Radiomics signatures, compared to ICH volume, demonstrated significantly stronger correlation with GCS (rho=0.47 vs 0.44, p=0.008), NIHSS (0.69 vs 0.57, p<0.001), and mRS scores (0.44 vs 0.32, p<0.001) in the discovery cohort. Similarly, in independent validation, the radiomics signatures exhibited significantly stronger association with GCS (0.43 vs 0.41, p=0.02), NIHSS (0.64 vs 0.56, p<0.001), and mRS scores (0.43 vs 0.33, p<0.001). The mRS radiomics signature was an independent predictor of long-term disability in multiple regression analysis adjusted for admission GCS and NIHSS scores with p<0.001 in both cohorts.

CLINICAL RELEVANCE/APPLICATION

Our results suggest admission CT radiomics signatures may aid risk assessment, treatment triage, and prognostication in ICH patients beyond hematoma volume.

SSNR06-5   Retrospective Multicenter Study Of The Neuroimaging Incidence Of CNS Complications In Hospitalized COVID-19 Positive Patients

Participants
Scott H. Faro, MD, Collingswood, New Jersey (*Presenter*) Nothing to Disclose

PURPOSE

We sought to determine the incidence of acute neuroimaging (NI) findings in hospitalized Covid-19 infected patients in 6 US and 4 European University hospitals.*Methods and Materials Retrospective multicenter study of Covid-19 positive patients admitted (September 2019-June 2020) in 11 institutions was conducted out of which data from 10 institutions were included. Data analysis from remaining 1 institute is in progress. Inclusion criteria: age>18, confirmed diagnosis of Covid-19 infection, acute neuroimaging findings not attributable to any cause other than Covid-19 on CT or MRI brain. Patients were verified by board certified neuroradiologists. Total incidences were calculated for overall and specific neuroimaging findings in Covid-19 positive patients and in those who underwent NI.*Results 24,315 Covid-19 positive patients were reviewed in 8 centers. Total acute NI incidence in patients who underwent NI was 436/4409 (9.8%) in 10 centers with 279 MRI and 157 CT including 287/3762 (7.62%) in USA and 149/647 (23%) in Europe. Total acute NI positive findings incidence in all Covid-19 positive hospitalized patients was 259/24315 (1.06%) in 8 centers including 0.7% in the US and 2.06% in Europe. Average patient age was 66 ± 12 years across institutions. In those who underwent NI, incidence of ischemic stroke was 6.2% followed by intracranial hemorrhage (3.72%), encephalitis (0.47%), deep sinus thrombosis (0.22%) and, ADEM (0.18%). White matter involvement was seen in 5.8% of NI. The most common distribution was unilateral (5.73%) followed by bilateral asymmetric (3.04%). Most common lobes affected were the frontal (5.35%) and parietal lobes (4.9%). *Conclusions We demonstrated an overall incidence of CNS complications in Covid-19 positive patients who underwent NI to be 9.8% including 7.62% in the US and 23% in Europe. Incidence of all positive NI in all hospitalized Covid-19 patients was 1.06% including 0.7% in the US and 2.06% in Europe. We also defined the incidence in a variety of NI abnormalities in USA and Europe.*Clinical Relevance/Application In a large international multi-institutional cohort, incidence and distribution of acute neuroimaging findings helped to characterize the neurological complications of Covid-19 thereby assisting in understanding the full extent of this disease process.

RESULTS

24,315 Covid-19 positive patients were reviewed in 8 centers. Total acute NI incidence in patients who underwent NI was 436/4409 (9.8%) in 10 centers with 279 MRI and 157 CT including 287/3762 (7.62%) in USA and 149/647 (23%) in Europe. Total acute NI positive findings incidence in all Covid-19 positive hospitalized patients was 259/24315 (1.06%) in 8 centers including 0.7% in the US and 2.06% in Europe. Average patient age was 66 ± 12 years across institutions. In those who underwent NI, incidence of ischemic stroke was 6.2% followed by intracranial hemorrhage (3.72%), encephalitis (0.47%), deep sinus thrombosis (0.22%) and, ADEM (0.18%). White matter involvement was seen in 5.8% of NI. The most common distribution was unilateral (5.73%) followed by bilateral asymmetric (3.04%). Most common lobes affected were the frontal (5.35%) and parietal lobes (4.9%).

CLINICAL RELEVANCE/APPLICATION

In a large international multi-institutional cohort, incidence and distribution of acute neuroimaging findings helped to characterize the neurological complications of Covid-19 thereby assisting in understanding the full extent of this disease process.

SSNR06-6   White Matter Hyperintensities And Silent Brain Infarcts In Aortic Valve Repair: Preliminary Results Of The Pearl Study

Participants
Moreno Zanardo, MSc, San Donato Milanese, Italy (*Presenter*) Nothing to Disclose

PURPOSE

We assessed white matter hyperintensities (WMH) burden, a biomarker of chronic cerebrovascular disease, and quantified ischemic lesions at diffusion-weighted magnetic resonance imaging (DW-MRI) in patients who underwent either surgical aortic valve replacement (SAVR) or transcatheter aortic valve implantation (TAVI). We aimed at enquiring whether an association between chronic cerebrovascular disease and acute ischaemia in aortic valve repair patients could be found.*Methods and Materials In this prospective study, patients underwent a 1.5-T brain MRI within seven days from TAVI or SAVR. We used the semi-quantitative Fazekas scale to classify patients into three classes of severity (low-intermediate-high) of chronic cerebrovascular disease. WMHs and DW-MRI positive lesions were quantified using a semi-automated segmentation method based on local intensity thresholds.*Results Fifteen patients were enrolled (9 SAVR, 6 TAVI). Nine (60%) patients had at least one visible lesion at DW-MRI:

five (83%) in the TAVI group and four (44%) in the SAVR group. TAVI patients had significantly higher volumes of DW-MRI lesions (P = 0.036). Also, TAVI patients had more severe chronic cerebrovascular disease than SAVR patients, albeit not significantly (P = 0.057 for Fazekas grade; P = 0.145 for WMH volume). We found a statistically significant difference in the distribution of volumes of DW-MRI lesions across the three Fazekas severity groups (p=0.027), with patients with higher Fazekas grade having higher DW-MRI lesions volume (Spearman's ? = 0.538; P = 0.039). When considering only patients with at least one lesion at DW-MRI, the association between total WMH volume and DW-MRI lesions volume was also strongly significant (Spearman's ? = 0.476; P = 0.002).*Conclusions Patients with more severe chronic cerebrovascular disease burden had significantly more ischamic lesions after TAVI/SAVR than those with a low WMH burden.*Clinical Relevance/Application The WMH burden may enable risk-stratification of patients who undergo TAVI/SAVR and identify those that would benefit most from the adoption of neuroprotective devices.

RESULTS

Fifteen patients were enrolled (9 SAVR, 6 TAVI). Nine (60%) patients had at least one visible lesion at DW-MRI: five (83%) in the TAVI group and four (44%) in the SAVR group. TAVI patients had significantly higher volumes of DW-MRI lesions (P = 0.036). Also, TAVI patients had more severe chronic cerebrovascular disease than SAVR patients, albeit not significantly (P = 0.057 for Fazekas grade; P = 0.145 for WMH volume). We found a statistically significant difference in the distribution of volumes of DW-MRI lesions across the three Fazekas severity groups (p=0.027), with patients with higher Fazekas grade having higher DW-MRI lesions volume (Spearman's ? = 0.538; P = 0.039). When considering only patients with at least one lesion at DW-MRI, the association between total WMH volume and DW-MRI lesions volume was also strongly significant (Spearman's ? = 0.476; P = 0.002).

CLINICAL RELEVANCE/APPLICATION

The WMH burden may enable risk-stratification of patients who undergo TAVI/SAVR and identify those that would benefit most from the adoption of neuroprotective devices.

SSVA03-1 Influence Of The Comorbidities On The Dissection And Rupture Rate Of The Thoracic Aortic Aneurysm

Participants
Rokas Liubauskas, MD, Boston, Massachusetts (*Presenter*) Nothing to Disclose

PURPOSE

Patients with thoracic aortic aneurysm (TAA) are currently being followed by imaging and treated according to guidelines based primarily on aneurysmal size. Association between comorbidities and aortic diameter, aortic aneurysm rupture (AAR), and/or dissection (AAD) was assessed.*Methods and Materials Single-center IRB-approved study of patients with a TAA who underwent computed tomography between October 4th, 2002, and February 18th, 2021. Demographic and comorbidity data were recorded. For this study, TAA rupture or dissection was defined as an aortic event. Associations between aortic events and the prevalence of coronary artery disease (CAD), chronic kidney disease (CKD), COPD, hyperlipidemia, hypertension, peripheral artery disease (PAD), prediabetes & diabetes mellitus (DM group), obesity, and smoking, and initial aortic diameter were investigated. Chi-squared test was used to assess association of comorbidities with AAR and AAD.*Results 6269 patients were included. 4102 (65%) male, median age 71 (IQR 63 - 80). Prevalence of the comorbidities were: CAD - 21% (1344), CKD - 20% (1223), COPD - 13% (802), hyperlipidemia - 31% (1954), hypertension - 46% (2886), PAD - 8% (474), DM group - 29% (1844), obesity - 26% (1648), smoking - 15% (942). The incidence of aortic events was 4.5% (282/6269). The aortic event rate was higher in every comorbidity group compared to patients without it, statistically significantly in patients with hypertension ($p < 0.0001$), PAD ($p < 0.0001$), CAD ($p=0.002$), CKD ($p < 0.0001$), hyperlipidemia ($p < 0.0001$), DM group ($p=0.0005$), smoking ($p < 0.0001$). The aortic event rate was especially high in patients with hypertension (7% vs 2% in patients without it), PAD (9% vs 4%), and smoking (7% vs 4%). Specificity for an aortic event varied among comorbidities, with the following comorbidities exhibiting specificity > 0.80: CKD (0.81), COPD (0.87), PAD (0.93), smoking (0.85). Assessment of the event rate based on the initial aortic diameter and presence of comorbidities showed that hypertension, PAD, and smoking are significant independent predictors, but there was no significant interaction between comorbidities and the initial diameter. I.e. the association between the aortic event and the comorbidities is similar in patients regardless of the initial aortic diameter.*Conclusions Hypertension, PAD, and smoking history substantially increase the risk for TAA rupture or dissection, as compared to patients without these comorbidities. Comorbidities influence the risk of these events equally, regardless of initial TAA diameter.*Clinical Relevance/Application The presence of certain comorbidities might influence the decision regarding the frequency of imaging follow-up and timing of surgical intervention.

RESULTS

6269 patients were included. 4102 (65%) male, median age 71 (IQR 63 - 80). Prevalence of the comorbidities were: CAD - 21% (1344), CKD - 20% (1223), COPD - 13% (802), hyperlipidemia - 31% (1954), hypertension - 46% (2886), PAD - 8% (474), DM group - 29% (1844), obesity - 26% (1648), smoking - 15% (942). The incidence of aortic events was 4.5% (282/6269). The aortic event rate was higher in every comorbidity group compared to patients without it, statistically significantly in patients with hypertension ($p < 0.0001$), PAD ($p < 0.0001$), CAD ($p=0.002$), CKD ($p < 0.0001$), hyperlipidemia ($p < 0.0001$), DM group ($p=0.0005$), smoking ($p < 0.0001$). The aortic event rate was especially high in patients with hypertension (7% vs 2% in patients without it), PAD (9% vs 4%), and smoking (7% vs 4%). Specificity for an aortic event varied among comorbidities, with the following comorbidities exhibiting specificity > 0.80: CKD (0.81), COPD (0.87), PAD (0.93), smoking (0.85). Assessment of the event rate based on the initial aortic diameter and presence of comorbidities showed that hypertension, PAD, and smoking are significant independent predictors, but there was no significant interaction between comorbidities and the initial diameter. I.e. the association between the aortic event and the comorbidities is similar in patients regardless of the initial aortic diameter.

CLINICAL RELEVANCE/APPLICATION

The presence of certain comorbidities might influence the decision regarding the frequency of imaging follow-up and timing of surgical intervention.

SSVA03-2 Perfusion DSA Of The Abdominal Aorta During EVAR: A Work-in-progress

Participants
Stavros Charalambous, Heraklion Crete, Greece (*Presenter*) Nothing to Disclose

PURPOSE

To present a novel perfusion-based digital subtraction angiography (DSA) technique to assess the perfusion of the aneurysm sac in the presence of an endoleak during endovascular aneurysm repair (EVAR).*Methods and Materials Eight patients (all males; median age 78y) who underwent EVAR for infra-renal abdominal aortic aneurysm (AAA) were examined with perfusion DSA after detection of endoleak with standard DSA. For perfusion DSA (SmartPerfusion; Philips Healthcare), a standardized protocol was used with a 5-

Fr diagnostic catheter placed at the level of supra-renal abdominal aorta. Perfusion images were obtained from the level of renal arteries to the external iliac arteries after injection of 30mL of iodinated contrast media at a flow rate of 15mL/s. Subsequent perfusion images were automatically reconstructed on a dedicate workstation. Eight different perfusion indices were investigated, i.e. arrival time (AT), time to peak (TTP), wash in rate (WiR), wash out rate (WoR), mean transit time (MTT), width (Wid), peak density (PD) and area under curve (AUC). To assess the perfusion of the aneurysm sac, a region of interest (ROI) was placed within the aneurysm sac to determine the time-density curve, reflecting the actual perfusion of the AAA in time.*Results Completion DSA revealed type-II endoleak in all patients and this finding was confirmed by follow-up CT examination. A wide range of perfusion indices was presented to all study participants. In particular, the median value with interquartile range differences of all examined indices were as follow: AT (3.7; 1.3-6.1), TTP (10.35; 4.9-16.9), WiR (35.2; 22.9-73.6), WoR (17.1; 10.1-30.9), MTT (11.5; 6.4-18.7), Wid (11.1; 9.4-13.3), PD (1492.6; 901-2073) and AUC (48558.9; 24503.6-71501.6). The median dose-area-product (DAP) associated with the perfusion DSA study was significant lower than the median total DAP reported by the entire EVAR procedure (69.9 vs 200 Gy.cm2, respectively; p<0.01).*Conclusions Perfusion DSA represents a promising real-time diagnostic tool for the accurate diagnosis, early determination and clinical significance of endoleaks after EVAR.*Clinical Relevance/Application The wide range that was recorded in all perfusion indices may indicate that different endoleaks present variable hemodynamic characteristics, and thus, may be associated with a variable prognosis.

RESULTS

Completion DSA revealed type-II endoleak in all patients and this finding was confirmed by follow-up CT examination. A wide range of perfusion indices was presented to all study participants. In particular, the median value with interquartile range differences of all examined indices were as follow: AT (3.7; 1.3-6.1), TTP (10.35; 4.9-16.9), WiR (35.2; 22.9-73.6), WoR (17.1; 10.1-30.9), MTT (11.5; 6.4-18.7), Wid (11.1; 9.4-13.3), PD (1492.6; 901-2073) and AUC (48558.9; 24503.6-71501.6). The median dose-area-product (DAP) associated with the perfusion DSA study was significant lower than the median total DAP reported by the entire EVAR procedure (69.9 vs 200 Gy.cm2, respectively; p<0.01).

CLINICAL RELEVANCE/APPLICATION

The wide range that was recorded in all perfusion indices may indicate that different endoleaks present variable hemodynamic characteristics, and thus, may be associated with a variable prognosis.

SSVA03-3   BAY1747846: A Novel Tetrameric, Macrocyclic Gadolinium-based Contrast Agent With A High Relaxivity For CE-MRI

Participants
Hubertus Pietsch, PhD, Berlin, Germany (*Presenter*) Employee, Bayer AG

PURPOSE

BAY1747846 is a novel tetrameric, macrocyclic gadolinium (Gd)-based contrast agent (GBCA) exhibiting high stability and high relaxivity, providing the possibility of substantially lowering the Gd dose for CE-MR imaging. This study aims to characterize the key physico-chemical and pharmacokinetic properties as well as features for use in CE-MRI.*Methods and Materials The T1-relaxivity of BAY1747846 was determined at 1.41T. The complex stability was analyzed in human serum over 15 days (pH 7.5, 37°C). Pharmacokinetic studies were performed in rats. MR imaging was investigated in healthy Goettingen minipigs on a clinical 1.5T MR system using routine clinical imaging procedures for MR Angiography (MRA). In time-resolved MRA (TWIST) 2 different doses of BAY1747846 (0.025 and 0.03 mmol Gd/kg) were compared to the clinical standard dose (0.1 mmol Gd/kg) of gadoterate meglumine and gadobutrol.*Results BAY1747846 with its tetrameric structure shows pronounced T1-relaxivity (r1: 47.2 mM-1·s-1 per molecule corresponding to 11.8 mM-1·s-1 per Gd at 1.41T in human plasma). Due to the high kinetic inertness of the chelate no release of Gd was observed during 15 days under physiological conditions. Pharmacokinetics showed fast distribution into extracellular space and essentially complete renal elimination in an unchanged form, as also known for other macrocyclic GBCAs. The evaluation of MRI demonstrated similar signal enhancement profiles for BAY1747846 at approximately 70% reduced Gd dose compared to the approved macrocyclic GBCAs (gadobutrol and gadoterate meglumine) administered at the standard dose.*Conclusions BAY1747846, a next generation, macrocyclic GBCA offers a high relaxivity which allows a substantial reduction of the Gd dose, while ensuring high stability of macrocyclic GBCA. The signal enhancements in 4D-MRA at relevantly reduced Gd dose was similar compared to the marketed GBCAs gadoterate meglumine and gadobutrol at a standard dose.*Clinical Relevance/Application Health authorities recommend the lowest approved dose to be utilized and to limit repeated exposures of GBCAs. BAY1747846 will enable a substantial Gd dose reduction compared to the standard GBCA dose as of today.

RESULTS

BAY1747846 with its tetrameric structure shows pronounced T1-relaxivity (r1: 47.2 mM-1·s-1 per molecule corresponding to 11.8 mM-1·s-1 per Gd at 1.41T in human plasma). Due to the high kinetic inertness of the chelate no release of Gd was observed during 15 days under physiological conditions. Pharmacokinetics showed fast distribution into extracellular space and essentially complete renal elimination in an unchanged form, as also known for other macrocyclic GBCAs. The evaluation of MRI demonstrated similar signal enhancement profiles for BAY1747846 at approximately 70% reduced Gd dose compared to the approved macrocyclic GBCAs (gadobutrol and gadoterate meglumine) administered at the standard dose.

CLINICAL RELEVANCE/APPLICATION

Health authorities recommend the lowest approved dose to be utilized and to limit repeated exposures of GBCAs. BAY1747846 will enable a substantial Gd dose reduction compared to the standard GBCA dose as of today.

SSVA03-4   False Lumen Regurgitant Fraction At Entry Tear Predicts Adverse Aorta-related Events In Type B Aortic Dissection

Participants
Bradley Allen, MD, Chicago, Illinois (*Presenter*) Consultant, Circle Cardiovascular Imaging Inc;Speaker, Medscape, LLC

PURPOSE

Prior studies suggest false lumen (FL) regurgitant fraction (RF) (%flow from FL retrograde to true lumen) at the entry tear (ET) in descending aortic dissection (DAD) correlates with aorta growth, but it is not clear how this relates to patient outcomes. This study compares both 4D flow MRI-derived in vivo FL RF and aorta diameters in DAD patients with and without adverse aorta-related outcomes (AARO - defined as aortic intervention or aorta-related mortality).*Methods and Materials DAD patients were retrospectively identified from a cohort of patients with MRA of the thoracic aorta with 4D flow under an IRB-approved protocol. Patients with prior descending aorta intervention were excluded. 4D flow was evaluated in dedicated clinical software (cvi42, Circle,

Calgary). The ET was identified by a cardiovascular radiologist who was blinded to AARO status. An analysis plane was placed orthogonal to the direction of antegrade flow at the ET and a region of interest encompassing ET flow was manually drawn at each phase. The same radiologist measured the maximal diameter of the descending aorta (DAo) and false lumen (FLD) on the standard MRA. Group-wise differences between morphologic and hemodynamic parameters were compared using Kruskal Wallis test. A combined model of significant parameters was created using multivariate linear regression. ROC analysis was used to compare AARO classification of individual parameters and the combined model.*Results A total of 31 patients met inclusion criteria, including n = 8 AARO patients (26%, 57±6 years-old, 5/3 M/F) and n = 23 non-AARO patients (74%, 62±14 years-old, 14/9 M/F). Follow-up interval for non-AARO was 2.5±2.6 years and time-to-AARO was 0.9±0.7 years. A total of 14 patients had prior type A dissection repair and 6 patients had connective tissue disease. AARO patients had larger DAo (51±6 mm vs. 42±8 mm, p = 0.01), FLD (48±6 mm vs. 39±7 mm, p = 0.004), and FL RF (47±39% vs. 15±20%, p = 0.006). The combined model included DAo, FLD, FL RF (R = 0.55, p = 0.02) and exhibited the highest AUC (0.86) relative to individual parameters alone (DAo: 0.82, FLD: 0.85, FL RF: 0.74).*Conclusions DAo, FLD, and FL RF are increased in DAD patients with AARO. Since most surgery decisions are heavily influenced by aortic diameter, it is difficult to discern the true added value of FL RF in this retrospective study, but our findings support the hypothesis that a combination of hemodynamic and morphologic parameters has the potential to improve prospective risk-stratification.*Clinical Relevance/Application Incorporating in vivo 4D flow MRI entry tear hemodynamics in combination with standard morphologic features (i.e. aortic diameter) may improve risk-stratification and treatment selection in descending aortic dissection patients.

RESULTS

A total of 31 patients met inclusion criteria, including n = 8 AARO patients (26%, 57±6 years-old, 5/3 M/F) and n = 23 non-AARO patients (74%, 62±14 years-old, 14/9 M/F). Follow-up interval for non-AARO was 2.5±2.6 years and time-to-AARO was 0.9±0.7 years. A total of 14 patients had prior type A dissection repair and 6 patients had connective tissue disease. AARO patients had larger DAo (51±6 mm vs. 42±8 mm, p = 0.01), FLD (48±6 mm vs. 39±7 mm, p = 0.004), and FL RF (47±39% vs. 15±20%, p = 0.006). The combined model included DAo, FLD, FL RF (R = 0.55, p = 0.02) and exhibited the highest AUC (0.86) relative to individual parameters alone (DAo: 0.82, FLD: 0.85, FL RF: 0.74).

CLINICAL RELEVANCE/APPLICATION

Incorporating in vivo 4D flow MRI entry tear hemodynamics in combination with standard morphologic features (i.e. aortic diameter) may improve risk-stratification and treatment selection in descending aortic dissection patients.

SSVA03-5 Accuracy Of Non-contrast Magnetic Resonance Angiography Using Inflow-sensitive Inversion Recovery (IFIR) Technique For Upper Abdominal Arterial Vessels Evaluation: Comparison With Contrast-enhanced Magnetic Resonance Angiography And Computed Tomography Angiography

Participants
Marco Porta, MD, Senago, Italy (*Presenter*) Nothing to Disclose

PURPOSE

Inflow-sensitive inversion recovery (IFIR) is a technique recently introduced to perform unenhanced Magnetic Resonance Angiography (MRA). The aim of our study is to retrospectively determine the accuracy of IFIR-MRA in the evaluation of main upper abdominal arteries, compared to Contrast Enhanced-MRA (CE-MRA) and Computed Tomography Angiography (CTA).*Methods and Materials Seventy patients underwent upper abdomen IFIR-MRA in different clinical settings. Qualitative comparison with CE-MRA (65 patients) and CTA (39 patients) was performed by using a 4-point scale. Celiac trunk (CA), common-proper-left-right hepatic artery (C-P-L-R-HA), left gastric artery (LGA), gastroduodenal artery (GA), splenic artery (SA), renal arteries (RA) and superior mesenteric artery (SMA) were assessed.*Results IFIR-MRA images were better rated in comparison with CE-MRA. Particularly, all arteries obtained a statistically significant higher qualitative rating value (all p<0.05). IFIR-MRA and CE-MRA exhibited acceptable intraclass correlation coefficients (ICC) values for CA, C-L-R-HA, and SMA (ICC 0.507, 0.591, 0.615, 0.570, 0.525). IFIR-MRA and CTA showed significant correlations in C-P-L-R-HA (Tau=0.362, 0.261, 0.308, 0.307, respectively; p<0.05) and both RA (Tau=0.279, p<0.05).*Conclusions Compared to CE-MRA, IFIR-MRA demonstrated a higher image quality in the main upper abdomen arterial vessels assessment. In particular LHA and RHA branches could be better visualized with IFIR sequences. This suggests the possibility to routinely integrate non-contrast IFIR-MRA in upper abdomen MR studies, especially in liver transplant patients.*Clinical Relevance/Application IFIR-MRA is a reliable diagnostic tool for the evaluation of abdominal vessels architecture in those patients with contraindication to contrast media injection

RESULTS

IFIR-MRA images were better rated in comparison with CE-MRA. Particularly, all arteries obtained a statistically significant higher qualitative rating value (all p<0.05). IFIR-MRA and CE-MRA exhibited acceptable intraclass correlation coefficients (ICC) values for CA, C-L-R-HA, and SMA (ICC 0.507, 0.591, 0.615, 0.570, 0.525). IFIR-MRA and CTA showed significant correlations in C-P-L-R-HA (Tau=0.362, 0.261, 0.308, 0.307, respectively; p<0.05) and both RA (Tau=0.279, p<0.05).

CLINICAL RELEVANCE/APPLICATION

IFIR-MRA is a reliable diagnostic tool for the evaluation of abdominal vessels architecture in those patients with contraindication to contrast media injection

SSVA03-6 Baseline 4D Flow-derived In Vivo Kinetic Energy Stratifies Descending Aorta Dissection Patients With Enlarging Aortas

Participants
Stanley Chu, Chicago, Illinois (*Presenter*) Nothing to Disclose

PURPOSE

Increasing aorta diameter is associated with increasing morbidity, mortality, and need for surgical or endovascular intervention in patients with descending aorta dissection. Imaging-based risk-stratification has focused on baseline aortic diameter and growth, but aorta hemodynamics (flow and pressure) in both the true and false lumen (TL and FL) may provide additional information. Our study used 4D flow MRI to quantify the in vivo volumetric TL and FL kinetic energy (KE - a marker of dynamic pressure) to determine their relationship with aortic diameter change.*Methods and Materials Using an IRB approved protocol, we retrospectively identified descending aorta (DAo) dissection patients with thoracic aorta MRA including 4D flow MRI and follow-up aorta imaging (MRA or CTA) at least 3 months later. Patients with prior DAo intervention were excluded. The FL and TL were manually segmented

from 4D flow MRI data (Mimics, Materialise, Belgium). Total kinetic energy throughout the cardiac cycle was quantified in MatLab (MathWorks, USA) using the formula KE = 0.5 x ? x dV x v(t)2, with ? the blood density assumed as 1060 kg/m3, dV the unit voxel volume, and v(t) the velocity magnitude, and then summed over the entire volume and cardiac cycle. Maximal DAo diameters of the index MRA and follow-up study were measured by an experienced cardiovascular radiologist. Groups were divided based on growth rate >3 mm/year. Index aortic diameter, TL KE, FL KE, and the KE ratio (FL KE/TL KE) were compared between groups using the Mann-Whitney U test.*Results A total of 17 patients met inclusion criteria (age: 59 ± 11 years, M/F: 12/5, n = 3 with connective tissue disease, n = 9 prior type A repair), with n = 5 in the aortic growth group and n = 12 in the non-growth group. There was no difference in index aortic diameters (p = .08), FL KE (p = .28), or TL KE (p = .38), but the KE ratio was significantly higher (larger ratio FL KE to TL KE) in the aortic growth group (p = 0.04).*Conclusions The ratio of FL KE to TL KE may reflect the relative differences in FL and TL dynamic pressure and was larger in aortic growth patients on index imaging. The baseline aortic diameter, which is commonly used for risk-stratification, was not statistically different between these groups. This result demonstrates the potential role of in vivo hemodynamic assessment for improved risk-stratification of descending aorta dissection.*Clinical Relevance/Application Prospectively identifying descending aorta dissection patients at-risk of adverse aortic remodeling has important treatment implications and in vivo true and false lumen kinetic energy may aid in risk-stratification.

RESULTS

A total of 17 patients met inclusion criteria (age: 59 ± 11 years, M/F: 12/5, n = 3 with connective tissue disease, n = 9 prior type A repair), with n = 5 in the aortic growth group and n = 12 in the non-growth group. There was no difference in index aortic diameters (p = .08), FL KE (p = .28), or TL KE (p = .38), but the KE ratio was significantly higher (larger ratio FL KE to TL KE) in the aortic growth group (p = 0.04).

CLINICAL RELEVANCE/APPLICATION

Prospectively identifying descending aorta dissection patients at-risk of adverse aortic remodeling has important treatment implications and in vivo true and false lumen kinetic energy may aid in risk-stratification.

SSPH14-1 Diagnostic Performance Of Whole-body Ultra-low Dose Computed Tomography For Detection Of Mechanical Ventriculoperitoneal Shunt Complications: A Retrospective Analysis

Participants
Saif Afat, MD, Tuebingen, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the diagnostic performance of Whole-Body Ultra Low-Dose computed tomography (WB-ULD-CT) for detecting mechanical ventriculoperitoneal (VP)-Shunt complications.*Methods and Materials This study included 186 patients (median age: 54,8 y; 18-88 y; 101 female) who underwent WB-ULD-CT (100 kVp; reference tube current, 10 mAs). Two radiologists independently reviewed the images for the presence/absence of VP-Shunt complications, overall image quality, and diagnostic confidence. On a five-point Likert scale, readers scored image quality (1= very low, 5= very high) and diagnostic confidence (1= low confidence, 5= very high confidence). Sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV) were calculated for WB-ULD-CT compared to final clinical diagnosis as a reference standard. Radiation dose estimation of WB-ULD-CT was calculated and compared to the radiation dose of radiographic shunt series.*Results Thirty-four of the 186 included patients had confirmed mechanical VP-Shunt complications. All positive patients were correctly identified on WB-ULD-CT by both readers. No false positive or false negative cases were recorded by any of the readers, yielding a sensitivity of 100 % (95% CI, 87.3%, 100%), a specificity of 100 % (95% CI, 96.9%, 100%), and a perfect agreement (? = 1). WB-ULD-CT revealed a high PPV and NPV of 100%. Shunt-specific image quality was rated very high (median score, 5 range, 5-5). Diagnostic confidence was rated very high (median score, 5; range, 5-5). Interobserver agreement was substantial for image quality (? = 0.73) and for diagnostic confidence (? = 0.78). The mean radiation dose of WB-ULD-CT was significantly lower than radiation dose of conventional radiographic shunt series (0.67 ± 0.4 mSv vs. 1.57 ± 0.6 mSv, 95% CI: 0.79-1.0, p<0.001)*Conclusions WB-ULD-CT allows detection of VP-Shunt complications with excellent diagnostic accuracy and diagnostic confidence.*Clinical Relevance/Application WB-ULD-CT can potentially replace the radiographic shunt series as a new ''gold standard''

RESULTS

Thirty-four of the 186 included patients had confirmed mechanical VP-Shunt complications. All positive patients were correctly identified on WB-ULD-CT by both readers. No false positive or false negative cases were recorded by any of the readers, yielding a sensitivity of 100 % (95% CI, 87.3%, 100%), a specificity of 100 % (95% CI, 96.9%, 100%), and a perfect agreement (? = 1). WB-ULD-CT revealed a high PPV and NPV of 100%. Shunt-specific image quality was rated very high (median score, 5 range, 5-5). Diagnostic confidence was rated very high (median score, 5; range, 5-5). Interobserver agreement was substantial for image quality (? = 0.73) and for diagnostic confidence (? = 0.78). The mean radiation dose of WB-ULD-CT was significantly lower than radiation dose of conventional radiographic shunt series (0.67 ± 0.4 mSv vs. 1.57 ± 0.6 mSv, 95% CI: 0.79-1.0, p<0.001)

CLINICAL RELEVANCE/APPLICATION

WB-ULD-CT can potentially replace the radiographic shunt series as a new ''gold standard''

SSPH14-2 Creating Individualized Learner Models: Predicting Missed Liver Metastases From CT Images Using Deep Convolutional Neural Networks

Participants
Scott Hsieh, Rochester, Minnesota (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this work was to use deep convolutional neural networks (CNNs) to predict radiologist performance for detecting hepatic metastases from contrast-enhanced CT images. Individualized prediction of difficult lesions may allow targeted training of idiosyncratic weaknesses.*Methods and Materials 10 subspecialized abdominal radiologists, blinded to clinical and imaging information, marked all suspected metastases in a multi-reader-multi-case study of 102 CT liver scans at multiple radiation dose levels. A reference reader marked metastatic and benign lesions according to predefined reference criteria. 51 of 102 patients had 124 hepatic metastases that were assigned binary labels of "detected" or "missed" by individual readers. These labeled images were used to train CNNs, which included a preprocessing pipeline of up-sampling, data augmentation, transfer learning, and dropout to reduce overfitting. The reader performance data was partitioned into 5 folds for five-fold cross-validation. We compared generalized and individualized prediction of missed lesions. In the generalized prediction, the CNN was trained with labels of "detected" if found by more than 25% of all readers or "missed" otherwise. In the individualized prediction, the CNN was trained with labels derived only from a single radiologist.*Results Reader sensitivity ranged from 67.3% to 93.0%. Individualized CNNs obtained an average area under the receiver operating characteristic curve (AUC) of 0.82 (+/- 0.04) in categorizing lesions as missed or detected by the 10 readers across the test sets for each fold. The generalized CNN obtained an average AUC of 0.74 (+/- 0.04).*Conclusions Deep CNNs may be used to create generalized or individualized learner models to predict which hepatic metastases may be missed by an

individual abdominal radiologist. An individualized CNN provides higher performance than a generalized CNN in predicting reader-specific lesion detectability but requires substantial training data for each reader. In situations where this training data cannot be collected, a generalized CNN may be an efficient method for identifying metastases that could be used for radiologist training.*Clinical Relevance/Application The ability to accurately identify liver metastases missed by many radiologists as well as individual radiologists may be used to improve reader performance and reduce interobserver variability.

RESULTS

Reader sensitivity ranged from 67.3% to 93.0%. Individualized CNNs obtained an average area under the receiver operating characteristic curve (AUC) of 0.82 (+/- 0.04) in categorizing lesions as missed or detected by the 10 readers across the test sets for each fold. The generalized CNN obtained an average AUC of 0.74 (+/- 0.04).

CLINICAL RELEVANCE/APPLICATION

The ability to accurately identify liver metastases missed by many radiologists as well as individual radiologists may be used to improve reader performance and reduce interobserver variability.

SSPH14-3   Impact Of Multiplanar Reformations On CT Image Quality With Model-based Iterative And Deep Learning Reconstructions: A Task-based Phantom Study

Participants
Damien Racine, Lausanne, Switzerland (*Presenter*) Nothing to Disclose

PURPOSE

In daily clinical practice, multiplanar CT reformations are routinely used for diagnostic purposes. Recent introduction of deep learning image reconstruction algorithms allowed for a significant dose reduction while preserving the objective image quality in the axial plane. The purpose of this work was to evaluate detailed physical metrics and detectability of simulated cervical spine disc herniations in the coronal and sagittal planes compared with axial images.*Methods and Materials A custom cubic phantom was scanned on the Apex GE CT scanner with a dedicated cervical spine protocol at CTDIvol of 17, 10, 5 and 2.5mGy. Images were reconstructed in the axial, coronal and sagittal planes with a standard kernel using two reconstruction algorithms at several strength levels: model-based iterative (ASiR-V 0%, 50% and 100%) and deep learning image reconstruction (True Fidelity (TF) low, medium and high). Task-based transfer function (TTF) and noise power spectrum (NPS) were computed to estimate spatial resolution and noise properties of the images in all three planes. Detectability indexes of simulated disc herniations (|?HU| = 50) were calculated using the nonprewhitening with eye filter model observer.*Results At all dose levels and with all reconstruction algorithms, spatial resolution decreased in the coronal and sagittal planes compared with axial images. Conversely, noise magnitude increased when switching from axial to coronal or sagittal reformations. Overall, TF outperformed ASiR-V in all image reconstruction planes. For the task of simulated disc herniations, detectability indexes were significantly higher in the axial than in coronal or sagittal planes. Moreover, increasing TF strength level substantially enhanced detectability at any dose level in all three image reconstruction planes.*Conclusions CT images acquired in the same conditions but reconstructed in different planes exhibit differences in spatial resolution and noise power spectrum, ultimately affecting lesion detectability.*Clinical Relevance/Application While clinically useful, multiplanar reformations should be used with caution with model-based iterative and deep learning image reconstructions as lesion detectability is intrinsically reduced.

RESULTS

At all dose levels and with all reconstruction algorithms, spatial resolution decreased in the coronal and sagittal planes compared with axial images. Conversely, noise magnitude increased when switching from axial to coronal or sagittal reformations. Overall, TF outperformed ASiR-V in all image reconstruction planes. For the task of simulated disc herniations, detectability indexes were significantly higher in the axial than in coronal or sagittal planes. Moreover, increasing TF strength level substantially enhanced detectability at any dose level in all three image reconstruction planes.

CLINICAL RELEVANCE/APPLICATION

While clinically useful, multiplanar reformations should be used with caution with model-based iterative and deep learning image reconstructions as lesion detectability is intrinsically reduced.

SSPH14-4   Radiologist, Workstation, And Image Features Affecting Liver Metastasis Detection Performance In Abdominal CT

Participants
Scott Hsieh, Rochester, Minnesota (*Presenter*) Nothing to Disclose

PURPOSE

Radiologist readers detect lesions in an imaging dataset by navigating stacks of images - scrolling, windowing, and zooming - while systematically examining the entire volume. We sought to determine if some patterns of navigation were associated with higher performance.*Methods and Materials After IRB approval, 25 readers (9 subspecialized abdominal radiologists, 5 non-abdominal subspecialists, 11 residents/fellows) interpreted 40 portal phase abdominal CT exams selected to contain challenging lesions. Metastases were independently confirmed by histopathology or progression. Radiologists marked suspected liver metastases, rating confidence (1-100). A custom workstation measured scrolling in coronal and axial dimensions, viewing time in coronal and axial dimensions, choice of window width and level, use of zoom, and total interpretation time. Performance was quantified using overall sensitivity as well as the area under the jackknife-adjusted free ROC (JAFROC) curve. A confidence matrix was constructed describing the confidence rating for each reader. This matrix was analyzed using a clustergram, a hierarchical clustering algorithm traditionally applied in genetics, to discover patterns of false negatives.*Results There were 91 metastases (mean size 1.4 cm) in 30 patients. 10 of 40 patients had no metastases. The mean number of reader markings over all 40 exams was 134 (range 73-208) with a mean interpretation time of 6.3 ± 3.1 minutes per case. Mean ± SD JAFROC was 77 ± 3%, 69 ± 7%, 71 ± 3% for abdominal specialists, non-abdominal staff, and trainees, respectively (differences between groups, p < 0.01), with sensitivity being 85 ± 8%, 83 ± 11% and 83 ± 10%, and false positive count being 57 ± 30, 56 ± 18, and 60 ± 25 across all 40 exams. Time in liver windows, time spent looking at coronal images, and total number of marks correlated with improved sensitivity (p < 0.05), but not use of zoom or subspecialized training. The clustering analysis identified groups of metastases that were better or not as well detected by abdominal subspecialists.*Conclusions Subspecialized training and practice correlated with improved JAFROC scores. Abdominal subspecialists appear to be no better at detecting possible liver metastases, but once detected, they exhibited better judgment at rating risk of malignancy.*Clinical Relevance/Application Certain patterns of image navigation are associated with higher sensitivity in the task of liver metastasis detection. Subspecialists are able to attain higher performance through better judgment of

malignancy probability.

RESULTS

There were 91 metastases (mean size 1.4 cm) in 30 patients. 10 of 40 patients had no metastases. The mean number of reader markings over all 40 exams was 134 (range 73-208) with a mean interpretation time of 6.3 ± 3.1 minutes per case. Mean $\pm$ SD JAFROC was $77 \pm 3\%$, $69 \pm 7\%$, $71 \pm 3\%$ for abdominal specialists, non-abdominal staff, and trainees, respectively (differences between groups, $p < 0.01$), with sensitivity being $85 \pm 8\%$, $83 \pm 11\%$ and $83 \pm 10\%$, and false positive count being 57 ± 30, 56 ± 18, and 60 ± 25 across all 40 exams. Time in liver windows, time spent looking at coronal images, and total number of marks correlated with improved sensitivity ($p < 0.05$), but not use of zoom or subspecialized training. The clustering analysis identified groups of metastases that were better or not as well detected by abdominal subspecialists.

CLINICAL RELEVANCE/APPLICATION

Certain patterns of image navigation are associated with higher sensitivity in the task of liver metastasis detection. Subspecialists are able to attain higher performance through better judgment of malignancy probability.

SSPH14-5 CT Image Quality Optimization In The Age Of Deep Learning: A 3-way Tradeoff Among Noise Magnitude, Noise Texture, And Structure Similarity

Participants
Kai Yang, PhD, Boston, Massachusetts (*Presenter*) Research Consultant, Malcova, LLC.

PURPOSE

To evaluate the performance of different quantitative image quality metrics when comparing CT reconstruction algorithms including deep-learning image reconstruction (DLIR, True Fidelity, GE), filtered back-projection (FBP), and iterative reconstruction (ASiR-V).*Methods and Materials Axial CT scans of an anthropomorphic phantom (Kyoto Kagaku CTU-41) were acquired from a GE Revolution scanner using three different protocols: brain routine, abdomen pelvis routine, and chest routine, with four different dose levels ranging from scanner max power, to 100%, 50%, and 25% of protocol default dose. CT slices were reconstructed using two slice thicknesses, five strength levels of ASiR-V (0% for FBP, 10%, 40%, 80%, and 100%) and three levels of DLIR (low, medium, and high). 2D noise power spectrum (NPS) was estimated through Fourier analysis of difference images by subtracting two matching images from two repeated scans. Structure similarity index (SSIM) was determined using the max dose level FBP recon as the ground truth. Noise variance (overall noise magnitude), s2, frequency location of the 1D NPS peak (surrogate of noise texture), fpeak, and the mean SSIM (similarity to the ground truth), SSIMmean, were used as three quantitative metrics to compare image quality, which depended on anatomical region, protocol, algorithm, dose level, and slice thickness.*Results Noise magnitude, s2, had a strong ($R2>0.99$) power law relationship with dose level for all algorithms, with the exponent around -0.65, was reduced by 66% changing from 1.25 mm to 5 mm slice thickness, and by 8% for each 10% of increment of ASiR-V strength and by 24% for each increment of DLIR level from FBP. For abdomen and chest protocol, fpeak gradually shifted from 0.3 (FBP) to 0.15 mm-1 (ASiR-V 100%) with increasing ASiR-V strength, but maintained at about 0.3 mm-1 for different DLIR levels, indicating conservation of spatial resolution. However, fpeak shifted down for the brain protocol with increasing DLIR levels. For the 25% dose scans, 100% ASiR-V had SSIMmean (0.84 for brain and 0.63 for abdomen) values higher than all three levels of DLIR (0.76, 0.79, 0.82 for brain and 0.38, 0.45, 0.55 for abdomen), indicating higher similarity to ground truth.*Conclusions Three quantitative metrics were assessed with CT images of realistic anatomic structures. The unique behavior of DLIR was demonstrated and compared to ASiR-V and FBP.*Clinical Relevance/Application This study demonstrated trade-offs between noise magnitude, noise texture, and structural similarity when evaluating advanced noise-reduction reconstruction algorithms, including DLIR and ASiR-V.

RESULTS

Noise magnitude, s2, had a strong ($R2>0.99$) power law relationship with dose level for all algorithms, with the exponent around -0.65, was reduced by 66% changing from 1.25 mm to 5 mm slice thickness, and by 8% for each 10% of increment of ASiR-V strength and by 24% for each increment of DLIR level from FBP. For abdomen and chest protocol, fpeak gradually shifted from 0.3 (FBP) to 0.15 mm-1 (ASiR-V 100%) with increasing ASiR-V strength, but maintained at about 0.3 mm-1 for different DLIR levels, indicating conservation of spatial resolution. However, fpeak shifted down for the brain protocol with increasing DLIR levels. For the 25% dose scans, 100% ASiR-V had SSIMmean (0.84 for brain and 0.63 for abdomen) values higher than all three levels of DLIR (0.76, 0.79, 0.82 for brain and 0.38, 0.45, 0.55 for abdomen), indicating higher similarity to ground truth.

CLINICAL RELEVANCE/APPLICATION

This study demonstrated trade-offs between noise magnitude, noise texture, and structural similarity when evaluating advanced noise-reduction reconstruction algorithms, including DLIR and ASiR-V.

SSPH14-6 Nonlinear Image Quality Assessment Of Deep Learning Algorithms: Beyond Traditional Image-independent Measures

Participants
Junyuan Li, Baltimore, Maryland (*Presenter*) Nothing to Disclose

PURPOSE

The nonlinear nature of deep learning algorithms has presented challenges to comprehensive evaluation of imaging performance. Traditional image quality metrics have often been evaluated in an image-independent manner and do not adequately capture the various dependencies of deep learning algorithms. In this work, we propose a perturbation response analysis framework to evaluate the nonlinear transfer characteristics of such algorithms.*Methods and Materials The framework was applied to a deep learning denoising algorithm for low dose lung CT. We systematically inserted lesion perturbations of various sizes, contrasts, and shapes into different locations of an example thorax image. Perturbation response was computed as the difference between the mean denoised image over 100 repeats with and without the perturbation. From these responses, we performed a threshold segmentation of lesions and generated radiomics transfer maps of various lesions features including size, contrast, and spiculation index. Furthermore, we evaluated noise transfer using variance and covariance around the perturbations. These transfer characteristics were compared with linear FBP reconstructions.*Results The perturbation response of a spherical lesion in both lung and soft tissue (heart) exhibit nonlinear dependencies on the size and contrast of the perturbation itself. Both visual inspection and the contrast transfer maps confirm a location dependency, with lower contrast recovery in the heart region. Similarly, for spiculated lesions, lesion shape is not faithfully represented for lesions below a certain size and contrast. In noise analysis, FBP shows smoothly varying variance maps while the deep learning algorithm produces high variances around the edges of both anatomy and the lesion perturbations.*Conclusions The perturbation response analysis framework provides a systematic way to probe the performance of

image- and stimuli-dependent deep learning algorithms. The radiomics transfer maps enables quantitative characterization of the various dependencies that determine whether clinically relevant lesion features can be faithfully represented.*Clinical Relevance/Application This work proposes an analysis framework that allows quantitative assessment of deep learning algorithms, forming the basis for algorithm optimization for clinically relevant diagnostic features.

RESULTS

The perturbation response of a spherical lesion in both lung and soft tissue (heart) exhibit nonlinear dependencies on the size and contrast of the perturbation itself. Both visual inspection and the contrast transfer maps confirm a location dependency, with lower contrast recovery in the heart region. Similarly, for spiculated lesions, lesion shape is not faithfully represented for lesions below a certain size and contrast. In noise analysis, FBP shows smoothly varying variance maps while the deep learning algorithm produces high variances around the edges of both anatomy and the lesion perturbations.

CLINICAL RELEVANCE/APPLICATION

This work proposes an analysis framework that allows quantitative assessment of deep learning algorithms, forming the basis for algorithm optimization for clinically relevant diagnostic features.

SSIR01-1   Non-invasive Molecular Imaging Allows Characterization Of The Immune Response Following Hepatic Radiofrequency Ablation (RFA) In A Mouse Model

Participants
Jessica Santana, MD, New Haven, Connecticut (*Presenter*) Nothing to Disclose

PURPOSE

To establish molecular magnetic resonance imaging (MRI) instruments for non-invasive characterization of the immune response to hepatic RFA in a mouse model.*Methods and Materials 72 C57BL/6 wild type mice underwent a standardized RFA (21G 5mm monopolar RF probe at 70 °C for 5 minutes) to generate a white coagulation zone of 6-7mm in diameter. CD68+ Macrophage infiltration in the transitional zone (TZ) was characterized with immunohistochemistry (IHC) 24 hours, 72 hours, 7 days, and 14 days post-ablation (n = 24). A subsequent ablated set of animals was injected with rhodamine-labeled superparamagnetic iron oxide nanoparticles (SPION) for non-invasive visualization of iron uptake by phagocytes using T2*-weighted imaging in a horizontal-bore 9.4 Tesla MRI scanner. Similarly, a separate group of RF ablated mice received 160Gadolinium (160Gad)-labeled CD68 antibody for longitudinal imaging of M1-macrophages using T1-weighted MR sequence. Radiological-pathological comparison was performed using Prussian-blue staining, immunofluorescence of rhodamine, imaging mass cytometry, and IHC staining of CD68 cell marker. Statistical analysis included two-tailed t test and Bonferroni test.*Results RFA induced periablational infiltration (206.92 μm ± 12.2 in diameter) of CD68+ macrophages (p<0.01) peaking at 7 days post-ablation compared to untreated lobe. T2*-weighted MRI with SPION contrast demonstrated curvilinear T2-signal in the periablational rim (measuring 186 μm ± 16.9). Imaging findings were referenced with histopathology, confirming accumulation of iron-labeled macrophages in the TZ. Similarly, T1-weighted MRI with 160Gad-CD68 antibody showed specific curvilinear signal in the TZ (164 μm ± 3.6 in diameter) corresponding to spatial signal distribution patterns detected by IMC. Quantitative analysis of signal intensity changes on both T2-SPIONs- and T1-160Gad-enhanced MRI showed a progressive loss in relative signal intensity ratio (rSI ratio) observed in the TZ over time*Conclusions Both SPION-enhanced T2*-weighted and 160Gad-enhanced T1-weighted MRI allows for non-invasive monitoring of macrophages, demonstrating the feasibility of this model as an investigational platform for the study of immune cell sub-populations in a locally inflamed part of the liver following RF*Clinical Relevance/Application Reproducible in vivo methods designed to bridge the dynamic nature of macrophage response and RFA therapy outcomes would ultimately allow real-time monitoring and modulation of its clinical side-effect

SSIR01-4   Hepatic Hypertrophy And Molecular Response Following Portal Vein Embolization Using Two Different Embolic Agents: A Comparative Study In Swine With Cirrhotic And Normal Underlying Liver.

Participants
Tom Kuhn, New Haven, Connecticut (*Presenter*) Nothing to Disclose

PURPOSE

Portal vein embolization (PVE) is the worldwide standard of care for liver cancer patients with an inadequate future liver remnant (FLR). Till now, there have been no large animal studies ever studying the hypertrophy potential & molecular effects of PVE using embolic agents in a cirrhotic background & comparing them to a normal liver.*Methods and Materials After Institutional Animal Care and Use Committee (IACUC) approval, 14 Yorkshire pigs were separated into a cirrhotic (CG) & non-cirrhotic group (NCG) & then further subgrouped into one using N-butyl cyanoacrylate (NBCA) & the other using microspheres & coils (MC); each subgroup

consisted of three animals & one control for NCG & CG each. The CG received a 3:1 Lipiodol & Ethanol mix intraarterially, developing biopsy-confirmed cirrhosis after four weeks. All animals then received a baseline contrast-Computed tomography (CT), PVE including pre- & post-PVE pressure measurements, and a Cone beam-CT post-procedure. Animals underwent follow-up imaging two & four weeks post-PVE, and manual volumetry was performed. After euthanization, histological liver samples were stained for CD3, CD16, KI67 & Caspase 3. Statistical analyses were performed using t-test comparing means of two groups or one-way-ANOVA analysis for multi-comparisons.*Results Standardized FLR% (sFLR%) two weeks post-PVE was 58.43% (SD:3.66%), 52.24% (SD:0.88%); 46.02% (SD:2.24%), and 47.24% (SD:0.40%) for MC in a normal vs. cirrhotic liver & NBCA in a normal vs. cirrhotic liver, respectively. sFLR% four weeks post-PVE was 60.48% (SD:3.88%), 54.85% (SD:0.83%); 60.35% (SD:3.45%), and 54.15% (SD:0.95%). Absolute sFLR% increase four weeks post-PVE was 18.82% (p<0.01) in the NCG vs. 10.93% (p<0.01) in the CG. Quantified signal intensity for CD3 & CD16 in the NCG vs. CG was 51.07 vs. 61.90 (p<0.01) & 43.70 vs. 53.81 (p<0.01). Signal intensity for KI67 in the embolized vs. non-embolized lobe comparing the NCG vs. CG was 47.55 vs. 70.29 (p<0.01) & 36.38 vs. 44.86 (p<0.01). Signal intensity for Caspase 3 in the embolized vs. non-embolized lobe comparing the NCG vs. CG was 62.10 vs. 52.10 (p<0.01) & 83.68 vs. 63.89 (p<0.01). Technical successful PVE was achieved in all animals.*Conclusions Our study showed that the use of microspheres and coils is preferred to NBCA when a substantial and rapid FLR increase is needed, both in cirrhotic and non-cirrhotic liver.*Clinical Relevance/Application Cirrhotic liver cancer patients, giving their nature of a reduced liver function and decreased regenerative potential, are particularly relying on a rapid and sustained FLR volume increase, giving them the possibility of curative care.

RESULTS

Standardized FLR% (sFLR%) two weeks post-PVE was 58.43% (SD:3.66%), 52.24% (SD:0.88%); 46.02% (SD:2.24%), and 47.24% (SD:0.40%) for MC in a normal vs. cirrhotic liver & NBCA in a normal vs. cirrhotic liver, respectively. sFLR% four weeks post-PVE was 60.48% (SD:3.88%), 54.85% (SD:0.83%); 60.35% (SD:3.45%), and 54.15% (SD:0.95%). Absolute sFLR% increase four weeks post-PVE was 18.82% (p<0.01) in the NCG vs. 10.93% (p<0.01) in the CG. Quantified signal intensity for CD3 & CD16 in the NCG vs. CG was 51.07 vs. 61.90 (p<0.01) & 43.70 vs. 53.81 (p<0.01). Signal intensity for KI67 in the embolized vs. non-embolized lobe comparing the NCG vs. CG was 47.55 vs. 70.29 (p<0.01) & 36.38 vs. 44.86 (p<0.01). Signal intensity for Caspase 3 in the embolized vs. non-embolized lobe comparing the NCG vs. CG was 62.10 vs. 52.10 (p<0.01) & 83.68 vs. 63.89 (p<0.01). Technical successful PVE was achieved in all animals.

CLINICAL RELEVANCE/APPLICATION

Cirrhotic liver cancer patients, giving their nature of a reduced liver function and decreased regenerative potential, are particularly relying on a rapid and sustained FLR volume increase, giving them the possibility of curative care.

SSIR01-5 Functional MRI Directed CT-guided Biopsies Of Focal Bone Lesions Can Improve Diagnostic Yield And Feasibility For Next Generation Tumor Sequencing In Cancer Patients

Participants
Ricardo Donners, MD, Basel, Switzerland (*Presenter*) Nothing to Disclose

PURPOSE

To determine whether functional MRI-directed lesion targeting for CT-guided bone biopsies in tumor patients can increase diagnostic and next generation sequencing (NGS) success rates.*Methods and Materials 113 CT-guided bone biopsies were performed by interventional radiologists (3/2013 to 2/2021) at our center. In 64 cases, contemporaneous diffusion-weighted MRI (DWI), apparent diffusion coefficient (ADC) and relative fat-fraction (rFF) images calculated from 2-point T1w Dixon MRI were available and retrospectively evaluated. In each patient, the biopsy tract was delineated on the biopsy CT and the ROI transferred via in-house software to corresponding slices on the ADC and rFF maps to record its mean, median, maximum, minimum, 10th and 90th centile values. On the same image sections, the targeted lesion was delineated on ADC and rFF and histogram parameters as above were exported. The signal intensity (SI) of the biopsied bone was visually classified on DWI and rFF as low or high SI. Chi² and unpaired T-tests were used to compare parameters between tumor positive/negative biopsies and feasible/non-feasible NGS, with p-values <0.05 deemed statistically significant.*Results There was no statistical difference between the ADC or rFF histogram parameters from the biopsy tract ROIs of positive/negative biopsies (each p> 0.068) or in NGS feasibility/non-feasibility (each p >0.433). Lesion analyses revealed lower mean ADC in tumor positive (834 ± 206 µm2/s) compared with negative biopsies (1002 ±305 µm2/s, p =0.031). Maximum rFF was lower in lesions where NGS was feasible (37 ±15%) compared with lesions where it failed (62 ±21%, p =0.008). A 41.5% maximum rFF value distinguished between NGS suitable and unsuitable areas with 73% sensitivity and 100% specificity. Biopsy tracts that were visually low in rFF SI, with high b50 and b900 SI and no T2 shine-through had 97% diagnostic success and 89% NGS feasibility rate (p < 0.001). These characteristics increased the likelihood for a positive biopsy outcome 13.6-fold.*Conclusions Functional MRI using DWI and rFF can help to improve the success of CT-guided bone biopsies and should be considered as part of the interventional workup.*Clinical Relevance/Application Bone metastases are common, but biopsy success rates are relatively poor. Pre-biopsy MRI using DWI and rFF may improve successful diagnosis and tumor NGS analysis.

RESULTS

There was no statistical difference between the ADC or rFF histogram parameters from the biopsy tract ROIs of positive/negative biopsies (each p> 0.068) or in NGS feasibility/non-feasibility (each p >0.433). Lesion analyses revealed lower mean ADC in tumor positive (834 ± 206 µm2/s) compared with negative biopsies (1002 ±305 µm2/s, p =0.031). Maximum rFF was lower in lesions where NGS was feasible (37 ±15%) compared with lesions where it failed (62 ±21%, p =0.008). A 41.5% maximum rFF value distinguished between NGS suitable and unsuitable areas with 73% sensitivity and 100% specificity. Biopsy tracts that were visually low in rFF SI, with high b50 and b900 SI and no T2 shine-through had 97% diagnostic success and 89% NGS feasibility rate (p < 0.001). These characteristics increased the likelihood for a positive biopsy outcome 13.6-fold.

CLINICAL RELEVANCE/APPLICATION

Bone metastases are common, but biopsy success rates are relatively poor. Pre-biopsy MRI using DWI and rFF may improve successful diagnosis and tumor NGS analysis.

SSIR01-6 Feasibility And Accuracy Of A Hands-free Robotic System For CT-guided Percutaneous Needle Insertion And Steering

Participants
Sebastian Flacke, MD, Burlington, Massachusetts (*Presenter*) Consultant, BTG International Ltd;Consultant, Surefire Medical, Inc;Consultant, Koninklijke Philips NV;Consultant, XACT Robotics Ltd

PURPOSE

To assess feasibility and accuracy of CT-guided needle insertion and steering for clinical biopsies using a novel, hands-free robotic system balancing system accuracy with duration of procedure and radiation dose.*Methods and Materials A prospective, multi-center study was conducted upon 60 clinically indicated biopsies of abdominal lesions at two centers (Center 1 n=26; Center 2 n=34). CT datasets were obtained for planning and controlled needle placement (insertion and steering) of 17-19g trocar needles using a patient-mounted, hands-free CT-guided robotic system with 5° freedom. Planning included target selection, skin entry point selection, linear or non-linear trajectory recommendation and predetermined checkpoints where additional imaging was performed to permit stepwise correction of needle trajectory. Success rate of robotic needle insertion and steering, needle tip to target distance, number of checkpoints used, number of trajectory corrections, procedure duration and effective radiation dose were recorded and compared between Centers. Significance level a was set to p=0.05.*Results 54 of 60 procedures (90%) were completed by the robot with positioning the trocar needle successfully on target. In the remaining 6 patients the procedure was manually performed by the operator due to technical failure (n=3) or patient related factors (n=3). Average lesion size was 2.7±1.8cm with a lesion depth from skin level of 8.6±2.6cm without differences between Centers (n.s.). Overall accuracy (needle tip to target distance) was 1.71±1.51 (0.05-7.20) mm with an accuracy of 2.06±1.45 mm at Center 1 and 1.45±1.52 mm at Center 2 (n.s.). Center 1 used a significant higher number of checkpoints (4.8 ±0.8) and performed target adjustments in 14 of 23 (61%) needle placements compared to Center 2 with 1.8±0.6 checkpoints and 8 of 31 target adjustments (26%), (p<0.001). Accordingly, insertion and steering duration from skin entry to target varied between Center 1 and 2 with 13.3min±4.2min and 5.6min±2.7min, respectively (p<0.001). Average DLP for the entire procedure was 1157±825 mGycm with a slightly lower average at Center 2 (1031±724 mGycm) compared to Center 1(1328 ±933 mGycm) (n.s.).*Conclusions Accurate needle targeting within 2mm error can be achieved in patients when using a hands-free CT-guided robotic system. Variation in the number of checkpoints did not affect system accuracy but related to shorter insertion and steering times and may contribute to lower radiation dose.*Clinical Relevance/Application Highly accurate needle insertion and steering using a hands-free CT-guided robotic system may facilitate difficult needle placement and enhance performance of less experienced interventionalists.

RESULTS

54 of 60 procedures (90%) were completed by the robot with positioning the trocar needle successfully on target. In the remaining 6 patients the procedure was manually performed by the operator due to technical failure (n=3) or patient related factors (n=3). Average lesion size was 2.7±1.8cm with a lesion depth from skin level of 8.6±2.6cm without differences between Centers (n.s.). Overall accuracy (needle tip to target distance) was 1.71±1.51 (0.05-7.20) mm with an accuracy of 2.06±1.45 mm at Center 1 and 1.45±1.52 mm at Center 2 (n.s.). Center 1 used a significant higher number of checkpoints (4.8 ±0.8) and performed target adjustments in 14 of 23 (61%) needle placements compared to Center 2 with 1.8±0.6 checkpoints and 8 of 31 target adjustments (26%), (p<0.001). Accordingly, insertion and steering duration from skin entry to target varied between Center 1 and 2 with 13.3min±4.2min and 5.6min±2.7min, respectively (p<0.001). Average DLP for the entire procedure was 1157±825 mGycm with a slightly lower average at Center 2 (1031±724 mGycm) compared to Center 1(1328 ±933 mGycm) (n.s.).

CLINICAL RELEVANCE/APPLICATION

Highly accurate needle insertion and steering using a hands-free CT-guided robotic system may facilitate difficult needle placement and enhance performance of less experienced interventionalists.

SPR-NPM-1 **Rad Bootcamp: Radiology, Equity, ; Inclusion - A Longitudinal Program Created Through A Multi-institutional Collaboration Diversifying The Radiology Pipeline And Providing Tools For Success**

Participants
Adlai Grayson, BSC, Kissimmee, Florida (*Presenter*) Nothing to Disclose

PURPOSE

Radiology suffers from low numbers of individuals identifying as underrepresented in medicine (URM). This can affect the cultural competency of the field and its ability to identify, understand, and address health disparities for underserved communities, especially those people that are members of communities of color.*Methods and Materials We present the rationale, design, and implementation of a multi-institutional intervention to increase URMs applying into radiology residencies. Rad Boot Camp: Radiology, Equity, Inclusion, is a free, open-to-all longitudinal program created through a collaboration among Massachusetts General Hospital, Emory Healthcare, and Vanderbilt Health with the support of the Student National Medical Association, Latino Medical Student Association, and Association of Native American Medical Students. The initiative consists of three focused interventions: education, mentorship, and research. Rad Bootcamp is structured as quarterly seminars with representation from diverse radiology leaders to provide information and resources supporting success in radiology. Using an end-user design, students inform seminar topics through surveys and participation on the steering committee. We surveyed students before and after the first seminar in October 2020 to evaluate the impact.*Results 180 medical students from 142 unique medical schools worldwide completed the first pre-seminar survey (20% Black, 17% Latinx, 33% Asian). They represented 21 countries, with the majority (72%) coming from the United States. Regarding exposure, 76.7% previously interacted with either a diagnostic or interventional radiologist. Most students had a Diagnostic Radiology (DR) or Interventional Radiology (IR) clerkships at their home institution, 77% and 48%, respectively. Fewer students had access to virtual DR (26%) or IR rotations (3%). Future topics of interest included research, life skills, global radiology, health disparities, and innovation. 150 students (83.3%) were interested in mentorship. Of the 180 registrants, 32 completed a post-event survey. There was a significant increase in comfort with preparing personal statements, electronic application entries, learning about programs, interviewing virtually, and reaching out to residents and program directors.*Conclusions Multi-institutional diversity efforts provide tools to URM students pursuing Radiology careers, encouraging the diversification of the pipeline.*Clinical Relevance/Application Using virtual educational tools extends our reach to more medical students. This model serves our increasingly diverse society and patient population through multi-institutional collaboration and support of students by diversifying the Radiology workforce.

RESULTS

180 medical students from 142 unique medical schools worldwide completed the first pre-seminar survey (20% Black, 17% Latinx, 33% Asian). They represented 21 countries, with the majority (72%) coming from the United States. Regarding exposure, 76.7% previously interacted with either a diagnostic or interventional radiologist. Most students had a Diagnostic Radiology (DR) or Interventional Radiology (IR) clerkships at their home institution, 77% and 48%, respectively. Fewer students had access to virtual DR (26%) or IR rotations (3%). Future topics of interest included research, life skills, global radiology, health disparities, and innovation. 150 students (83.3%) were interested in mentorship. Of the 180 registrants, 32 completed a post-event survey. There was a significant increase in comfort with preparing personal statements, electronic application entries, learning about programs, interviewing virtually, and reaching out to residents and program directors.

CLINICAL RELEVANCE/APPLICATION

Using virtual educational tools extends our reach to more medical students. This model serves our increasingly diverse society and patient population through multi-institutional collaboration and support of students by diversifying the Radiology workforce.

SPR-NPM-2 **Virtual Waiting Room ; Digitized Pre-procedure Forms: Radiology Workflow Innovations Driven By The COVID-19 Pandemic**

Participants
Vishal Desai, MD, Philadelphia, Pennsylvania (*Presenter*) Nothing to Disclose

PURPOSE

The COVID-19 pandemic has required drastic changes at imaging centers, including waiting room adaptations and changes to patient flow. We piloted a new app-based "virtual waiting room" (VWR) and digitized pre-procedure screening forms to meet new safety demands while optimizing patient throughput.*Methods and Materials VWR was piloted at our busiest outpatient imaging center beginning with MRI patients in Jul 2020. This tool enabled SMS reminders, virtual check-in when patients are within a preset radius, and pre-appointment completion of screening forms. After virtual check-in patients are notified when the center is ready and bypass the traditional waiting room. Patients were sent a voluntary survey to evaluate the VWR process. Screening forms for a subset were compared for completeness vs hand-written forms. Analytics were later integrated to assess impact on wait times.*Results 1749 MRI patients utilized VWR for SMS reminders. 226 patients opted for virtual check-in from Oct 2020-Apr 2021, with average virtual check in 23.5 min prior to scheduled appointment time (SD 28; traditional check-in=29.7±25 min; p=.001). Mean wait time until the center was ready to begin the MRI was 5.5 min (SD 13; traditional check-in=10.6±12 min; p=.0003). VWR

patients began their appointment on average 12.6 minutes before the scheduled time (SD 16; traditional check-in=2.7 min after ± 10; p<.0001). Survey results were received from 236 patients. Satisfaction rate was high - 92% would use VWR again and 93% felt communication was clear. 86% utilized VWR to prefill screening forms. No significant difference in responses among each age group. Most patients prefilled 2 forms prior to their appointment. Among the 41 VWR patients who had knee MRI, form completeness on the digital knee questionnaire was 100% for required fields. A control group of 20 knee MRI patients with hand-written forms had 72% completeness of required fields (p=.0004) with illegible responses in 10% of free response fields. *Conclusions Accelerated innovation during the pandemic led to the launch of VWR, which enhances social distancing without sacrificing appointment slots, has reduced wait times, and improves form completion via digitization. The tool was very well-received by survey respondents with a large majority planning to use it for future appointments. Continued analytics and survey review will allow us to optimize appointment time slots, enhance the VWR platform, and roll it out across our enterprise.*Clinical Relevance/Application VWR enhances patient safety, reduces wait times, improves form completion and has high patient satisfaction. Additional appointment time slot optimization and enterprise-wide rollout will allow for improved patient throughput and patient experience.

RESULTS

1749 MRI patients utilized VWR for SMS reminders. 226 patients opted for virtual check-in from Oct 2020-Apr 2021, with average virtual check in 23.5 min prior to scheduled appointment time (SD 28; traditional check-in=29.7±25 min; p=.001). Mean wait time until the center was ready to begin the MRI was 5.5 min (SD 13; traditional check-in=10.6±12 min; p=.0003). VWR patients began their appointment on average 12.6 minutes before the scheduled time (SD 16; traditional check-in=2.7 min after ± 10; p<.0001). Survey results were received from 236 patients. Satisfaction rate was high - 92% would use VWR again and 93% felt communication was clear. 86% utilized VWR to prefill screening forms. No significant difference in responses among each age group. Most patients prefilled 2 forms prior to their appointment. Among the 41 VWR patients who had knee MRI, form completeness on the digital knee questionnaire was 100% for required fields. A control group of 20 knee MRI patients with hand-written forms had 72% completeness of required fields (p=.0004) with illegible responses in 10% of free response fields.

CLINICAL RELEVANCE/APPLICATION

VWR enhances patient safety, reduces wait times, improves form completion and has high patient satisfaction. Additional appointment time slot optimization and enterprise-wide rollout will allow for improved patient throughput and patient experience.

SPR-NPM-3 Utilization Of Supplemental Screening Breast MRI In Diverse High Risk Populations

Participants
Dayna Levin, MD, Philadelphia, Pennsylvania (*Presenter*) Nothing to Disclose

PURPOSE

Early detection of breast cancer reduces mortality. Breast MRI increases detection in high risk women and is more sensitive than mammography and ultrasound. The ACR endorses annual MRI screening for high risk women. Our study estimates the utilization of screening MRI within high risk populations and determines characteristics associated with high risk screening compliance.*Methods and Materials We conducted a retrospective, IRB compliant, study using patient data from 3 breast imaging centers in our urban based academic practice. Data was extracted form the EHR to determine numbers of patients with elevated Gail scores presenting for mammographic evaluation who had an MRI performed within the following 2-year period (2016 and 2017 study years). A multiple logistic regression model was performed on 2431 patients to assess MRI exam compliance association with income, race and age.*Results In our study, less than 20% of high risk patients received indicated supplemental MRI screening. In the 2 year period following a mammogram in 2016 and 2017, between 2.2% (n=90) and 7.8% (n=102) of high risk black patients and between 0% (n=11) and 33% (n=8) of high risk Hispanic patients received MRI screening. Patients with median income over $150,000 are 27% more likely to utilize MRI (OR: 1.27, 95% CI: (1.01,1.60), whereas patients with median income less than $50,000 are 54% less likely to utilize MRI (OR: 0.46, 95% CI: (0.27,0.74). Asian and Black patients are 88% and 70% less likely to get an MRI compared to non-Hispanic White patients respectively (OR_Asian: 0.12, 95% CI: (0.01,0.55); OR_Black: 0.30, 95% CI: (0.14,0.58). Patients over 50 are 36% less likely to get supplemental screening MRI exams than those under 50 (OR: 0.64, 95% CI: (0.50,0.81).*Conclusions Screening high risk women with mammography plus MRI improves the detection of early breast cancer and overall survival and has been shown to be cost effective. However, our study from three academic breast imaging centers in a large urban/suburban area shows low compliance with recommended MRI screening, particularly among racial and ethnic minority populations and lower income populations. Understanding current adherence to screening guidelines provides an opportunity to improve MRI screening in all high risk patients.*Clinical Relevance/Application Innovative methods can be leverage to improve supplemental screening rates in high risk patients and address a significant health care disparity. These include outreach to primary physicians and high risk patients as well as creating integrated advisories within the EHR. Leveraging behavioral economic principles can provide a useful framework to improve supplemental screening. Finally, radiology based patient centered care clinics could be implemented.

RESULTS

In our study, less than 20% of high risk patients received indicated supplemental MRI screening. In the 2 year period following a mammogram in 2016 and 2017, between 2.2% (n=90) and 7.8% (n=102) of high risk black patients and between 0% (n=11) and 33% (n=8) of high risk Hispanic patients received MRI screening. Patients with median income over $150,000 are 27% more likely to utilize MRI (OR: 1.27, 95% CI: (1.01,1.60), whereas patients with median income less than $50,000 are 54% less likely to utilize MRI (OR: 0.46, 95% CI: (0.27,0.74). Asian and Black patients are 88% and 70% less likely to get an MRI compared to non-Hispanic White patients respectively (OR_Asian: 0.12, 95% CI: (0.01,0.55); OR_Black: 0.30, 95% CI: (0.14,0.58). Patients over 50 are 36% less likely to get supplemental screening MRI exams than those under 50 (OR: 0.64, 95% CI: (0.50,0.81).

CLINICAL RELEVANCE/APPLICATION

Innovative methods can be leverage to improve supplemental screening rates in high risk patients and address a significant health care disparity. These include outreach to primary physicians and high risk patients as well as creating integrated advisories within the EHR. Leveraging behavioral economic principles can provide a useful framework to improve supplemental screening. Finally, radiology based patient centered care clinics could be implemented.

SPR-NPM-5 Outcomes Of Incidental Lung Nodules With Structured Impressions And Electronic Tracking: Further Needs For Closing The Loop

Participants
Barun Bagga, MBBS, New York, New York (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate factors affecting follow-up for incidental lung nodules (ILN) found on CT, including structured reporting and electronic health record tracking.*Methods and Materials Patients of a large urban health system with ILN before and after implementation of structured Fleischner recommendations and electronic tracking were sampled randomly (from 2014, 2018). Cohorts were compared for appropriate follow-up completion and no follow-up despite indication, within 2 years of the index test. Multivariable logistic regression and competing risks analysis were used to assess appropriate follow-up and loss to follow-up. Independent variables included use of structured recommendations/tracking, age, sex, race, ethnicity, setting of the index test (inpatient, outpatient, Emergency), smoking history, and nodule features.*Results 1,301 patients met final inclusion criteria, including 255 before and 1,046 after structured recommendations/tracking. In univariate analysis, structured reporting was associated with higher rates of appropriate follow-up completion among those who followed up, 75.0% vs. 56.6% (p<0.001), and less frequent loss to follow-up, 29.5 % vs 40% (p=0.002). The largest differences in follow-up were in ILNs =8 mm in the outpatient setting (both variables p<0.001). All non-white races had significantly lower rates of appropriate follow-up than white patients (p=0.009) and mean age of patients completing and not completing appropriate follow-up was 66 years vs. 69 years (p=0.015). Multivariable analysis for the outcome of appropriate follow-up completion showed that age, race, care setting, nodule size, and Fleischner category were independent predictors (p<0.015), but structured reporting was not. Similarly, competing risks analysis for loss to follow-up showed that age, nodule size, test setting were stronger predictors for loss to follow-up than the use of structured recommendations. A model with age <68 years, nodule >8 mm, outpatient setting, race, and recommendation of 3-6 month follow up, biopsy or PET had area-under-the-curve of 0.71 for appropriate follow-up.*Conclusions Loss to follow-up and appropriate follow-up completion are accounted for by age, nodule size, and care setting more so than use of structured recommendations. Further interventions may be needed to improve care. Widespread standardized reporting would decrease selection bias for larger ILNs and establish clearer benchmarks for rates of appropriate follow-up in larger nodules.*Clinical Relevance/Application After accounting for structured ILN recommendations, patient age, race, nodule size and care setting remain strongly associated with follow-up; competing risks should be accounted for in quality measures and targeted interventions.

RESULTS

1,301 patients met final inclusion criteria, including 255 before and 1,046 after structured recommendations/tracking. In univariate analysis, structured reporting was associated with higher rates of appropriate follow-up completion among those who followed up, 75.0% vs. 56.6% (p<0.001), and less frequent loss to follow-up, 29.5 % vs 40% (p=0.002). The largest differences in follow-up were in ILNs =8 mm in the outpatient setting (both variables p<0.001). All non-white races had significantly lower rates of appropriate follow-up than white patients (p=0.009) and mean age of patients completing and not completing appropriate follow-up was 66 years vs. 69 years (p=0.015). Multivariable analysis for the outcome of appropriate follow-up completion showed that age, race, care setting, nodule size, and Fleischner category were independent predictors (p<0.015), but structured reporting was not. Similarly, competing risks analysis for loss to follow-up showed that age, nodule size, test setting were stronger predictors for loss to follow-up than the use of structured recommendations. A model with age <68 years, nodule >8 mm, outpatient setting, race, and recommendation of 3-6 month follow up, biopsy or PET had area-under-the-curve of 0.71 for appropriate follow-up.

CLINICAL RELEVANCE/APPLICATION

After accounting for structured ILN recommendations, patient age, race, nodule size and care setting remain strongly associated with follow-up; competing risks should be accounted for in quality measures and targeted interventions.

SPR-NPM-6   Association Of Diagnostic Accuracy Estimates, Conclusion Positivity, And Completeness Of Abstract Reporting With Acceptance By Radiology Conferences And Journals: A Meta-Research Study.

Participants
Robert Frank, MD, Ottawa, Ontario (*Presenter*) Nothing to Disclose

PURPOSE

Preferential dissemination of 'positive' studies (i.e., publication bias) is documented in imaging diagnostic test accuracy (DTA) literature. We evaluated the contribution of the editorial process to publication bias by determining whether accuracy estimates, conclusion positivity, and completeness of abstract reporting are associated with acceptance of submitted research by radiology conferences and journals.*Methods and Materials We evaluated abstracts and manuscripts submitted to radiology conferences and journals. Primary studies evaluating sensitivity and specificity of an imaging test were included. We extracted Youden's index, abstract conclusion positivity, STARD for Abstracts adherence, and potential confounding variables (prospective/retrospective, sample size, study duration, assessment of inter-observer agreement, subspecialty, modality). Multivariable logistic regression provided adjusted associations (odds ratio [OR]) of Youden's index, conclusion positivity and completeness of abstract reporting, with study acceptance.*Results We included 1000 abstracts (500 ESGAR, 500 ISMRM) and 1000 manuscripts (505 Radiology, 495 JMRI). Abstract acceptance by radiology conferences was not associated with Youden's index (OR=0.97 for YI>0.8; CI=0.70-1.35), conclusion positivity (OR=1.21 for positive conclusions; CI 0.75-1.90) or STARD for Abstracts adherence (OR=0.96 per unit increase in reported items; CI=0.82-1.18). Abstracts with positive conclusions were less likely to be accepted by radiology journals (OR=0.45; CI=0.24-0.86), while YI (OR=0.85; CI=0.56-1.29) and STARD for Abstracts adherence (OR=1.06; CI=0.87-1.30) showed no association. Positive conclusions were present in 87% of submitted conference abstracts and 90% of submitted journal manuscripts.*Conclusions Imaging DTA studies with positive findings are not preferentially accepted by radiology conferences or journals, and most submitted studies have positive conclusions. Therefore, publication bias may be attributable to factors occurring prior to submission, rather than at the editorial level.*Clinical Relevance/Application Preferential publication of 'positive' studies can lead to overestimation of test accuracy and negative clinical outcomes. Interventions should promote submission of all research, regardless of findings, in order to balance the evidence guiding clinical decisions.

RESULTS

We included 1000 abstracts (500 ESGAR, 500 ISMRM) and 1000 manuscripts (505 Radiology, 495 JMRI). Abstract acceptance by radiology conferences was not associated with Youden's index (OR=0.97 for YI>0.8; CI=0.70-1.35), conclusion positivity (OR=1.21 for positive conclusions; CI 0.75-1.90) or STARD for Abstracts adherence (OR=0.96 per unit increase in reported items; CI=0.82-1.18). Abstracts with positive conclusions were less likely to be accepted by radiology journals (OR=0.45; CI=0.24-0.86), while YI (OR=0.85; CI=0.56-1.29) and STARD for Abstracts adherence (OR=1.06; CI=0.87-1.30) showed no association. Positive conclusions were present in 87% of submitted conference abstracts and 90% of submitted journal manuscripts.

CLINICAL RELEVANCE/APPLICATION

Preferential publication of 'positive' studies can lead to overestimation of test accuracy and negative clinical outcomes. Interventions should promote submission of all research, regardless of findings, in order to balance the evidence guiding clinical

decisions.

SPR-NPM-7 Cost-Effectiveness Of Endovascular Thrombectomy In Childhood Stroke: An Analysis From The Save Childs Study

Participants
Wolfgang Kunz, MD, Munich, Germany (*Presenter*) Nothing to Disclose

PURPOSE

The Save ChildS Study demonstrated that endovascular thrombectomy (EVT) is a safe treatment option for pediatric stroke patients with large vessel occlusions with high recanalization rates. Our aim was to determine the long-term cost, health consequences and cost-effectiveness of EVT in this patient population.*Methods and Materials A decision-analytic Markov model estimated lifetime costs and quality-adjusted life years (QALY, Figure 1). Early outcome parameters were based on subgroups of successful and unsuccessful recanalization within the Save ChildS Study, as no randomized data exist (Figure 2). For modeling of lifetime estimates, pediatric and adult input parameters were obtained from the current literature (Table 1). The analysis was conducted in a United States setting applying healthcare and societal perspectives. Probabilistic sensitivity analyses were performed. The willingness-to-pay (WTP) threshold was set to $100,000 per QALY.*Results The model results yielded EVT as the dominant (cost-effective as well as cost-saving) strategy for pediatric stroke patients. The incremental effectiveness for the average age of 11.3 years at first stroke in the Save ChildS Study was determined as an additional 4.76 lifetime QALYs, with lifetime cost-savings that amounted to $205,506 from a healthcare perspective and $304,531 when applying a societal perspective (Figure 3). Acceptability rates for EVT were 98.1% and 98.5% for the healthcare and societal perspectives.*Conclusions EVT for pediatric stroke patients with large vessel occlusions resulted in added quality-adjusted life years and reduced lifetime costs. Based on the available data in the Save ChildS Study, EVT is very likely to be a cost-effective treatment strategy for childhood stroke.*Clinical Relevance/Application The EVT infrastructure is available as established for adult stroke. Based on the health and economic potential, investments to develop EVT technique and devices for pediatric stroke are justified.

RESULTS

The model results yielded EVT as the dominant (cost-effective as well as cost-saving) strategy for pediatric stroke patients. The incremental effectiveness for the average age of 11.3 years at first stroke in the Save ChildS Study was determined as an additional 4.76 lifetime QALYs, with lifetime cost-savings that amounted to $205,506 from a healthcare perspective and $304,531 when applying a societal perspective (Figure 3). Acceptability rates for EVT were 98.1% and 98.5% for the healthcare and societal perspectives.

CLINICAL RELEVANCE/APPLICATION

The EVT infrastructure is available as established for adult stroke. Based on the health and economic potential, investments to develop EVT technique and devices for pediatric stroke are justified.

SSRO02-3 Radiosurgery Dose Reduction For Brain Metastases On Immunotherapy (RADREMI): Gamma Knife Versus Linear Accelerator Outcomes From A Multicenter Phase I Trial

Participants
Shearwood McClelland III, MD, Indianapolis, Indiana (*Presenter*) Nothing to Disclose

PURPOSE

Symptomatic radiation necrosis occurs in up to 20% of patients treated with immune checkpoint inhibitor (ICI) therapy and concomitant single-fraction stereotactic radiosurgery (SRS) (Martin et al., JAMA Oncology 2018). We present the first prospective comparison of outcomes by SRS modality, derived from the Radiosurgery Dose Reduction for Brain Metastases on Immunotherapy (RADREMI) trial.*Methods and Materials RADREMI is a prospective multicenter single arm Phase I pilot study. Patients of age 18+ receiving ICI with SRS for 1-10 brain metastases on MRI from biopsy-confirmed primary malignancy with disease-specific graded prognostic assessment estimated median survival of at least 6 months and no history of whole brain radiation therapy were eligible. The primary endpoint was six-month symptomatic radiation necrosis (rate of clinical symptomatology requiring steroid administration and/or operative intervention concomitant with imaging findings consistent with radiation necrosis), with secondary endpoints including six-month local control (LC) and six-month radiographic radiation necrosis. LC was defined according to Response Assessment in Neuro-Oncology criteria, and was compared to historical controls of 87-91% six-month LC with RTOG 90-05 SRS dosing. The Fisher's exact test was used for statistical analysis. This trial is registered at clinicaltrials.gov, NCT04047602.*Results Between December 18, 2019 and April 11, 2021, 61 lesions were treated in 20 patients receiving ICI delivered within 30 days before SRS. All patients received RADREMI dosing (18 Gy for lesions 0-2 cm, 14 Gy for lesions 2.1-3 cm, and 12 Gy for lesions 3.1-4 cm). Of the 61 lesions treated, 15 lesions (all on trial protocol) were treated with LINAC SRS, and 46 lesions (35 on protocol, 11 per protocol) were treated with Gamma Knife SRS. Median follow-up was 162 days. There were no significant differences by SRS modality in symptomatic radiation necrosis, radiographic radiation necrosis, or LC rates (p > 0.05).*Conclusions Early analysis from the first prospective trial to investigate dose-reduced SRS with concomitant ICI in treating metastatic brain disease reveals no significant difference in morbidity or efficacy between LINAC or Gamma Knife SRS in this patient population. These findings indicate that despite the inherent dosimetric differences between the two SRS modalities (i.e. isodose lines, hotspots), treating this patient population with reduced-dose SRS via LINAC provides comparable outcomes with lesions treated with Gamma Knife SRS.*Clinical Relevance/Application The SRS treatment modality (LINAC versus Gamma Knife) does not impact the efficacy or morbidity in the treatment of brain metastases for patients receiving concomitant immunotherapy.

RESULTS

Between December 18, 2019 and April 11, 2021, 61 lesions were treated in 20 patients receiving ICI delivered within 30 days before SRS. All patients received RADREMI dosing (18 Gy for lesions 0-2 cm, 14 Gy for lesions 2.1-3 cm, and 12 Gy for lesions 3.1-4 cm). Of the 61 lesions treated, 15 lesions (all on trial protocol) were treated with LINAC SRS, and 46 lesions (35 on protocol, 11 per protocol) were treated with Gamma Knife SRS. Median follow-up was 162 days. There were no significant differences by SRS modality in symptomatic radiation necrosis, radiographic radiation necrosis, or LC rates (p > 0.05).

CLINICAL RELEVANCE/APPLICATION

The SRS treatment modality (LINAC versus Gamma Knife) does not impact the efficacy or morbidity in the treatment of brain metastases for patients receiving concomitant immunotherapy.

SSRO02-4 The Role Of Radiotherapy To The Primary Site In Oropharyngeal Cancer With Limited Metastases - A National Cancer Database (NCDB) Analysis

Participants
Michael Kharouta, MD, Cleveland, Ohio (*Presenter*) Nothing to Disclose

PURPOSE

Oligometastatic oropharyngeal cancer (OPC) at presentation is rare. Literature to guide management is limited. Aggressive treatment to the primary site is controversial but may be warranted especially in patients with favorable prognostic features such as HPV-mediated disease. We sought to determine clinicopathologic variables associated with improved survival in these patients.*Methods and Materials We queried the NCDB for patients age 18-90 years with OPC categorized as cM1 with limited metastatic disease defined as metastatic disease to only one distant site, known HPV status, and first-course radiotherapy (RT) to the primary site or no RT. Full-optimal propensity score matching was used for receipt of RT based on clinicopathologic covariates. Overall survival (OS) was estimated using the Kaplan-Meier method and compared using log-rank testing. Multivariate Cox-proportional hazards (CPH) regression was used to identify covariates associated with overall survival, using Schoenfeld residuals to

assess the proportional hazards assumption.*Results 512 patients met study criteria. After matching, CPH regression violated the proportional hazards assumption which was mitigated by stratifying patients by HPV status. After stratification, multivariable CPH regression showed that RT was associated with a benefit to overall survival regardless of HPV status. For HPV+ patients, receipt of RT (HR 0.69, p = 0.02), and younger age were associated with improved OS. For HPV- patients, receipt of RT (HR = 0.67, p =0.018), less than cT4 disease, tumor size, no metastases to bone, no LVSI, and receipt of chemotherapy were associated with improved OS.*Conclusions In patients with OPC with metastatic disease at presentation limited to a single site, radiation to the primary site is associated with improved OS in both HPV+ and HPV- disease. Further study of factors predicting long-term benefit of radiotherapy for OPC in patients with limited metastatic disease at presentation is warranted.*Clinical Relevance/Application This study provides evidence of an association of radiotherapy to the primary site with improved overall survival in patients with oropharynx cancer with limited metastatic disease regardless of HPV status, which remains a strong prognostic factor in this cohort.

RESULTS

512 patients met study criteria. After matching, CPH regression violated the proportional hazards assumption which was mitigated by stratifying patients by HPV status. After stratification, multivariable CPH regression showed that RT was associated with a benefit to overall survival regardless of HPV status. For HPV+ patients, receipt of RT (HR 0.69, p = 0.02), and younger age were associated with improved OS. For HPV- patients, receipt of RT (HR = 0.67, p =0.018), less than cT4 disease, tumor size, no metastases to bone, no LVSI, and receipt of chemotherapy were associated with improved OS.

CLINICAL RELEVANCE/APPLICATION

This study provides evidence of an association of radiotherapy to the primary site with improved overall survival in patients with oropharynx cancer with limited metastatic disease regardless of HPV status, which remains a strong prognostic factor in this cohort.

SSRO02-5   Multiparametric MRI As A Potential Predictor Of Tumor Infiltrating Lymphocytes And Tissue Hypoxia In Head-and-neck Cancer Patients - Post-hoc Analysis Of A Prospective Imaging Trial

Participants
Alexander Ruhle, MD, Freiburg, Germany (*Presenter*) Research Grant, NovoCure Ltd

PURPOSE

Tumor-infiltrating lymphocytes (TILs) and tumor-associated hypoxia influence outcome of head-and-neck squamous cell carcinoma (HNSCC) patients undergoing chemoradiation and are commonly quantified from tumor biopsies. As biopsies do not allow spatial and longitudinal analyses of tumor biology, we aimed to assess if multiparametric MRI (mpMRI) can be used as a non-invasive surrogate for TIL levels and tissue hypoxia.*Methods and Materials T1- and T2-weighted, dynamic contrast-enhanced perfusion and diffusion-weighted MRI was performed prior to chemoradiation, and hypoxic subvolumes (HSVs) within the primary tumor or metastatic lymph nodes were defined using co-registered [18F]FMISO PET/CT imaging. Hematoxylin-eosin stainings and immunohistochemical analyses for CD3, CD34, CAIX and HIF1a were performed to assess TIL levels, microvessel density and tissue hypoxia in pre-therapeutic tumor samples, respectively. Expression of the tissue hypoxia markers was quantified based on staining intensity and percentage of positive cells using the H score. MpMRI parameters within the HSV and the complementary non-HSV were then correlated with the histology data.*Results Twenty-one HNSCC patients receiving definitive chemoradiation for locally advanced HNSCC were enrolled in this prospective imaging trial and received pre-treatment mpMRI and FMISO PET/CT. The extravascular volume parameter (ve) within the HSV of the primary tumor was significantly lower in patients with increased levels of TILs (0.34 versus 0.23, p<0.01, unpaired t-test). Similarly, ADC values within metastatic lymph nodes as a marker for tumor cell density were significantly higher in patients with increased TIL levels (1175 x 10-3 mm2/s versus 976 x 10-3 mm2/s, p<0.05). The prognostic tissue hypoxia marker CAIX was inversely correlated with ve within metastatic lymph nodes (Pearson's r=-0.622, p<0.01), and high ve within the primary tumor was also linked with a reduced density of CD34-positive tumor microvessels (p<0.05). The volume transfer constant ktrans within the primary tumor, both within the HSV and the non-HSV, corresponded with an increased HIF1a expression (r=0.588, p<0.05 for the primary tumor, r=0.661, p<0.05 for the primary tumor's HSV, r=0.574, p<0.05 for the primary tumor's non-HSV).*Conclusions We could show in this post-hoc analysis of a prospective trial that mpMRI signatures may provide information regarding TIL levels and tissue hypoxia.*Clinical Relevance/Application Although these correlations require further validation, mpMRI may provide surrogate information for prognostic biological tumor characteristics in HNSCC patients undergoing chemoradiation and may allow for non-invasive and longitudinal biological monitoring of these patients.

RESULTS

Twenty-one HNSCC patients receiving definitive chemoradiation for locally advanced HNSCC were enrolled in this prospective imaging trial and received pre-treatment mpMRI and FMISO PET/CT. The extravascular volume parameter (ve) within the HSV of the primary tumor was significantly lower in patients with increased levels of TILs (0.34 versus 0.23, p<0.01, unpaired t-test). Similarly, ADC values within metastatic lymph nodes as a marker for tumor cell density were significantly higher in patients with increased TIL levels (1175 x 10-3 mm2/s versus 976 x 10-3 mm2/s, p<0.05). The prognostic tissue hypoxia marker CAIX was inversely correlated with ve within metastatic lymph nodes (Pearson's r=-0.622, p<0.01), and high ve within the primary tumor was also linked with a reduced density of CD34-positive tumor microvessels (p<0.05). The volume transfer constant ktrans within the primary tumor, both within the HSV and the non-HSV, corresponded with an increased HIF1a expression (r=0.588, p<0.05 for the primary tumor, r=0.661, p<0.05 for the primary tumor's HSV, r=0.574, p<0.05 for the primary tumor's non-HSV).

CLINICAL RELEVANCE/APPLICATION

Although these correlations require further validation, mpMRI may provide surrogate information for prognostic biological tumor characteristics in HNSCC patients undergoing chemoradiation and may allow for non-invasive and longitudinal biological monitoring of these patients.

SSPD04-1 Early Effects Of Prenatal Alcohol Exposure On Regional Brain Volumes - An Atlas-Based Fetal MRI Study

Participants
Marlene Stuempflen, MD, Vienna, Austria (*Presenter*) Nothing to Disclose

PURPOSE

Postnatal imaging studies have shown structural brain anomalies in patients suffering from Fetal Alcohol Spectrum Disorders, including enlarged and malformed hippocampi.[1,2] This atlas-based fetal MRI study aimed to identify early regional effects of prenatal alcohol exposure (PAE) on human fetal brain development.*Methods and Materials This IRB approved prospective single-center study identified pregnant women referred for fetal MRI with variable amounts of alcohol intake during pregnancy using two standardized questionnaires (PRAMS and TACE).[3,4] Postprocessing was conducted generating superresolution imaging and semiautomated atlas-based segmentations. After visual inspection, assessment of data quality and manual correction, an atlas-based analysis of various fetal brain structures was performed. Linear models were applied with an additional factor to account for varying gestational ages and multiple comparisons were corrected using Benjamini-Yekutieli.[5]*Results After excluding subjects with structural brain anomalies and/or poor superresolution image quality, a total of 27 patients with PAE and 36 controls (gestational age 20-37 weeks, mean 27.2 GW) were included and analyzed. In fetuses exposed to alcohol both hippocampi (left p = 0.035, right p = 0.024) and the corpus callosum (p = 0.035) showed significantly larger volumes (mean volumes ± SD), whereas the periventricular/germinal zone (p = 0.003) showed smaller volumes (mean volumes ± SD) compared to controls.*Conclusions While it is well known that PAE may cause neurodevelopmental deficits, this study systematically documented selective effects on regional brain volumes at prenatal stages. Besides the reduction in size of the germinal matrix, an increased regional growth of the hippocampus and the corpus callosum was found.References(1) Norman AL et al. Dev Disabil Res Rev. 2009;15(3):209-217.(2) Roediger DJ et al. Neurotoxicol Teratol. 2021 Jan-Feb;83:106944.(3) Shulman HB et al. Am J Public Health. 2018 Oct;108(10):1305-1313.(4) Sokol RJ et al. Am J Obstet Gynecol. 1989 Apr;160(4):863-870.(5) Benjamini Y et al. Ann. Statist. 2001 Aug;29(4):1165-1188.*Clinical Relevance/Application Prenatal imaging detection of germinal matrix, hippocampal and callosal abnormalities after embryonal/fetal alcohol exposure emphasizes the socioeconomic importance of prevention, detection and support of affected families.

RESULTS

After excluding subjects with structural brain anomalies and/or poor superresolution image quality, a total of 27 patients with PAE and 36 controls (gestational age 20-37 weeks, mean 27.2 GW) were included and analyzed. In fetuses exposed to alcohol both hippocampi (left p = 0.035, right p = 0.024) and the corpus callosum (p = 0.035) showed significantly larger volumes (mean volumes ± SD), whereas the periventricular/germinal zone (p = 0.003) showed smaller volumes (mean volumes ± SD) compared to controls.

CLINICAL RELEVANCE/APPLICATION

Prenatal imaging detection of germinal matrix, hippocampal and callosal abnormalities after embryonal/fetal alcohol exposure emphasizes the socioeconomic importance of prevention, detection and support of affected families.

SSPD04-2 Three-dimensional Visualization Of Large Vessel Anomalies In Fetal MRI Using Super-resolution MultiVane Technique

Participants
Florian Prayer, MD, Vienna, Austria (*Presenter*) Nothing to Disclose

PURPOSE

To assess the feasibility of super-resolution-aided three-dimensional reconstruction of the heart and large vessels in fetal MRI of normal fetuses and fetuses with large vessel anomalies using MultiVane technique.*Methods and Materials The study cohort (n=30) consisted of 15 cases (nine male) with echocardiographically confirmed anomalies of the large vessels, and 15 normal cases (eight male). The pathology group included the following entities: tetralogy of Fallot (n=4), aortic coarctation (3), right descending aorta (2), common arterial trunk (2), persistant left superior vena cava (1), unilateral pulmonary agenesis (1), hypoplastic left heart (1), and heterotaxia syndrome (1). Fetal MRI scans were performed at a mean gestational age of 28+1 gestation weeks (GW) (pathology group) and 29+5 GW (normal group). T2-weighted sequences in three orthogonal planes acquired using MultiVane technique on one 1.5 T scanner (Philips Ingenia) were used to calculate super-resolution datasets. Manual segmentation using free ITK-Snap software was performed to obtain three-dimensional models of the fetal heart and large vessels (aorta, pulmonary arteries, superior and inferior vena cava, umbilical vein, and fetal shunts). T2-weighted images in three orthogonal planes, axial super-resolution images, and three-dimensional models were reviewed for anomalies of the large vessels by two expert fetal radiologists.*Results Super-resolution post-processing based on T2-weighted MultiVane sequences and three-dimensional

reconstruction of the fetal heart and large vessels were feasible in all (30 of 30) cases. Review of T2-weighted MultiVane sequences in three orthogonal planes identified large vessel anomalies in 13 of 15 cases. If super-resolution images and three-dimensional models were available, all (15 of 15) pathologic cases were correctly classified. Vessel anomalies were found in none of the fetuses in the normal group.*Conclusions Fetal MRI-based visualization of large vessel structures using Multivane technique and super-resolution reconstruction is feasible and helpful in the identification of large vessel anomalies during intra-uterine development.*Clinical Relevance/Application Novel MultiVane fetal MRI technique in combination with super-resolution post-processing yields morphologic characterisation of fetal large vessels.

RESULTS

Super-resolution post-processing based on T2-weighted MultiVane sequences and three-dimensional reconstruction of the fetal heart and large vessels were feasible in all (30 of 30) cases. Review of T2-weighted MultiVane sequences in three orthogonal planes identified large vessel anomalies in 13 of 15 cases. If super-resolution images and three-dimensional models were available, all (15 of 15) pathologic cases were correctly classified. Vessel anomalies were found in none of the fetuses in the normal group.

CLINICAL RELEVANCE/APPLICATION

Novel MultiVane fetal MRI technique in combination with super-resolution post-processing yields morphologic characterisation of fetal large vessels.

SSPD04-3 Magnetic Resonance (MR) Imaging Features Of Prenatal Neck Lymphatic Malformations (LM)-correlation With Perinatal Outcomes

Participants
Hasan Habib, BA, Stratford, New Jersey (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate imaging findings on fetal MR that can predict the perinatal course of neck lymphatic malformations (LM), including predictors of complicated delivery and immediate postnatal treatment*Methods and Materials Retrospective study of fetal MR dated 1/1/2000-12/31/2020. Inclusion criteria: neck LM diagnosis with complete postnatal clinical follow up. Features extracted from fetal MR: extension of mass into tongue, mediastinum, airway involvement, lesion margin, midline crossing, hemorrhage, and calcification. Neonatal medical records were reviewed for mode of delivery and immediate perinatal care. A total of 36 fetal MR for 35 fetuses were included. Descriptive statistics and Fisher's exact test were done.*Results Mean gestational age (GA) at fetal MR: 29 ± 5 weeks. Fetal neck lesions extended into the tongue (63 %, 22/35), mediastinum (23 %, 8/35) and other anatomic locations such as face, axilla, upper extremity (29 %, 10/35). Airway deviation: seen in 66 % (23/35); midline crossing in 34 % (12/35). Neck LM had infiltrative margins in 66% (23/35) of cases. Other features included calcification (11%, 4/35) and hemorrhage (31%, 11/35). Neonates were delivered at mean GA of 37 ±1 week, mean weight 3.43 ±0.6 kg via C-section (71%, 25/35), EXIT (11%, 4/35), vaginal delivery (14%, 5/35) and 1 vacuum-assisted delivery. Neonatal resuscitation such as tracheal intubation/nasal intubation, bag-mask positive pressure ventilation, continuous positive airway pressure, or O2 through nasal cannula occurred in 34 % (12/35) of neonates. Treatments/procedures in neonatal period included sirolimus, doxycycline sclerotherapy, airway management, microlaryngoscopy and bronchoscopy with excision or sclerosis, surgical debulking, feeding support (nasogastric tube, G-tube, or total parenteral nutrition) or combination were provided in 68 % (24/35) of patients. Apnea monitoring was done for 71% (25/35) of patients. Mean hospital stay was 64 days (2-362). Mean age at postnatal MR was 4 days (0-58). Lesions that extended into the tongue or mediastinum, had infiltrative margins, crossed the midline or caused airway deviation on fetal MR were statistically significant risk factors for airway intervention during delivery and active neonatal management of the LM (p <0.05 for both outcomes).*Conclusions Fetal MR features of neck LM such as infiltrative margins, extension to tongue or mediastinum, midline crossing, or airway deviation, may serve as important predictors of complex modes of neonatal resuscitation and necessity of perinatal interventions/treatments*Clinical Relevance/Application Detection of these prenatal findings may aid parent counseling and prepare appropriate perinatal care, including delivery and postnatal treatment.

RESULTS

Mean gestational age (GA) at fetal MR: 29 ± 5 weeks. Fetal neck lesions extended into the tongue (63 %, 22/35), mediastinum (23 %, 8/35) and other anatomic locations such as face, axilla, upper extremity (29 %, 10/35). Airway deviation: seen in 66 % (23/35); midline crossing in 34 % (12/35). Neck LM had infiltrative margins in 66% (23/35) of cases. Other features included calcification (11%, 4/35) and hemorrhage (31%, 11/35). Neonates were delivered at mean GA of 37 ±1 week, mean weight 3.43 ±0.6 kg via C-section (71%, 25/35), EXIT (11%, 4/35), vaginal delivery (14%, 5/35) and 1 vacuum-assisted delivery. Neonatal resuscitation such as tracheal intubation/nasal intubation, bag-mask positive pressure ventilation, continuous positive airway pressure, or O2 through nasal cannula occurred in 34 % (12/35) of neonates. Treatments/procedures in neonatal period included sirolimus, doxycycline sclerotherapy, airway management, microlaryngoscopy and bronchoscopy with excision or sclerosis, surgical debulking, feeding support (nasogastric tube, G-tube, or total parenteral nutrition) or combination were provided in 68 % (24/35) of patients. Apnea monitoring was done for 71% (25/35) of patients. Mean hospital stay was 64 days (2-362). Mean age at postnatal MR was 4 days (0-58). Lesions that extended into the tongue or mediastinum, had infiltrative margins, crossed the midline or caused airway deviation on fetal MR were statistically significant risk factors for airway intervention during delivery and active neonatal management of the LM (p <0.05 for both outcomes).

CLINICAL RELEVANCE/APPLICATION

Detection of these prenatal findings may aid parent counseling and prepare appropriate perinatal care, including delivery and postnatal treatment.

SSPD04-5 Prevalence Of Intrarenal Reflux In Pediatric Patients On Contrast Enhanced Voiding Urosonography

Participants
Erica Klein, MD, Chicago, Illinois (*Presenter*) Nothing to Disclose

PURPOSE

Vesicoureteral reflux (VUR) is a common finding on voiding cystourethrogram (VCUG) and contrast enhanced voiding urosonography (CEVUS) studies. Occasionally, VUR can extend into the renal parenchyma, a phenomenon known as intrarenal reflux (IRR) which is thought to be associated with the development of renal scarring. IRR found during fluoroscopic VCUG has been previously studied. The purpose of our study was to determine the prevalence of IRR on the newer, radiation-free modality of CEVUS.*Methods and Materials CEVUS studies performed at our institution between August 2019 and August 2020 with reported VUR (106 studies) were retrospectively reviewed by two pediatric radiologists. The radiologists independently graded the VUR and assessed for the

presence of IRR, noting its location in the kidney and phase of the urinary cycle during which it occurred. Additionally, the presence and location of renal scarring was recorded. Discrepancies were resolved by consensus interpretation.*Results 211 kidneys were evaluated on 106 CEVUS exams. Grade 2 to 5 VUR was detected in 165 kidneys with associated IRR detected in 42 (25.4%). IRR was present in 1 of 40 kidneys (2.5%) with grade 2, 10 of 67 (14.9%) with grade 3, 25 of 47 (53.2%) with grade 4 and 6 of 11 (54.5%) with grade 5 VUR. IRR occurred during the voiding phase of the urinary cycle in 31 of 42 kidneys (73.8%) and was seen most often in the lower pole of the kidney (71.4%) with a significant association between IRR and mid pole renal scarring [OR 3.92; 95% CI (1.49, 10.32); p-value 0.006].*Conclusions Intrarenal reflux was frequently seen on CEVUS, with the highest rate in kidneys with grades 4 and 5 VUR and during voiding phase. Radiologists should have a high index of suspicion for IRR on CEVUS, especially in patients with high grade VUR.*Clinical Relevance/Application Detection of VUR with IRR, which is frequently identified on CEVUS examinations, could influence management with potential early surgical intervention to prevent loss of renal parenchyma.

RESULTS

211 kidneys were evaluated on 106 CEVUS exams. Grade 2 to 5 VUR was detected in 165 kidneys with associated IRR detected in 42 (25.4%). IRR was present in 1 of 40 kidneys (2.5%) with grade 2, 10 of 67 (14.9%) with grade 3, 25 of 47 (53.2%) with grade 4 and 6 of 11 (54.5%) with grade 5 VUR. IRR occurred during the voiding phase of the urinary cycle in 31 of 42 kidneys (73.8%) and was seen most often in the lower pole of the kidney (71.4%) with a significant association between IRR and mid pole renal scarring [OR 3.92; 95% CI (1.49, 10.32); p-value 0.006].

CLINICAL RELEVANCE/APPLICATION

Detection of VUR with IRR, which is frequently identified on CEVUS examinations, could influence management with potential early surgical intervention to prevent loss of renal parenchyma.

SSPD04-6   New Pediatric ADPKD Risk Severity Model Based On 3DUS Volumetry

Participants
Luc Breysem, Leuven, Belgium (*Presenter*) Nothing to Disclose

PURPOSE

A height-adjusted total kidney volume (htTKV) based ADPKD severity model stratifying adult ADPKD (>15 years of age) in five severity groups has been developed in the MAYO clinic. We aimed to evaluate if a similar stratification model to estimate ADPKD progression can be used in a pediatric ADPKD population (<18 years of age) with htTKV based on 3DUS and, if needed, propose a more appropriate model.*Methods and Materials We assessed htTKV based on manual 3DUS contouring in genetically-confirmed PKD1 ADPKD patients between 2015-2020 in a tertiary hospital. Severity group stratification was performed with the MAYO classification model ($y=A*(1+B)^x$, with A=htTKV at age 0 and B=yearly htTKV % increase). First the original model was applied (A=150ml/m and B=1.5, 3, 4.5 and 6%/year), after which the parameters were optimized to our pediatric data.*Results 67 genotyped patients (32 female, 35 male) underwent in total 232 3DUS assessments. Age (mean+/-stdev) at first evaluation was 10.5+/-4.8years (range: 0.2-19.2) and htTKV of 187+/-101mL/m (74-630). Direct extrapolation of the MAYO curves below the age of 15 years strongly underestimated ADPKD severity in children, even with correction for patient height. After optimizing the model's parameters (A=70, 80, 90, 100; B=6, 7.5, 9, 10.5%), the 232 scans were split into five subgroups with 47, 94, 42, 27 and 22 patients respectively, with preferential clustering of the htTKV values in groups with low growth rate below 10 years of age and an accelerated growth after 10 years of age comparing to the expected kidney growth in children. To better match this accelerated growth in the second decade, we proposed a new pediatric ADPKD severity model (formula $y=A*B^{(x^1.6)}$ with A=80, 90, 100, 110 and B=1.01, 1.012, 1.015, 1.018) leading to a more homogeneous distribution of the 232 scans into the five severity categories with 45, 67, 38, 36 and 46 patients (Figure).*Conclusions We provide a new two-parameter model using patients' age and 3DUS-based htTKV for ADPKD risk stratification that better fits the accelerated growth after 10 years of age, which could be useful in future pediatric ADPKD progression assessments.*Clinical Relevance/Application This newly developed risk stratification model in pediatric ADPKD, based on 3DUS volumetry, highlights the potential use of height adjusted TKV as a parameter to predict ADPKD severity from young age.

RESULTS

67 genotyped patients (32 female, 35 male) underwent in total 232 3DUS assessments. Age (mean+/-stdev) at first evaluation was 10.5+/-4.8years (range: 0.2-19.2) and htTKV of 187+/-101mL/m (74-630). Direct extrapolation of the MAYO curves below the age of 15 years strongly underestimated ADPKD severity in children, even with correction for patient height. After optimizing the model's parameters (A=70, 80, 90, 100; B=6, 7.5, 9, 10.5%), the 232 scans were split into five subgroups with 47, 94, 42, 27 and 22 patients respectively, with preferential clustering of the htTKV values in groups with low growth rate below 10 years of age and an accelerated growth after 10 years of age comparing to the expected kidney growth in children. To better match this accelerated growth in the second decade, we proposed a new pediatric ADPKD severity model (formula $y=A*B^{(x^1.6)}$ with A=80, 90, 100, 110 and B=1.01, 1.012, 1.015, 1.018) leading to a more homogeneous distribution of the 232 scans into the five severity categories with 45, 67, 38, 36 and 46 patients (Figure).

CLINICAL RELEVANCE/APPLICATION

This newly developed risk stratification model in pediatric ADPKD, based on 3DUS volumetry, highlights the potential use of height adjusted TKV as a parameter to predict ADPKD severity from young age.

SSCA01-1　Non-contrast Free-breathing Flow-independent Magnetic Resonance Angiography: Assessment Of Thoracic Vasculature In Congenital Heart Disease

Participants

Alexander Isaak, MD, Bonn, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate a non-contrast respiratory- and electrocardiogram-gated 3D relaxation-enhanced angiography without contrast and triggering (REACT) magnetic resonance angiography (MRA) based on magnetization-prepared Dixon method for the assessment of the thoracic vasculature in congenital heart disease (CHD) patients.*Methods and Materials 70 CHD patients (mean: 28 years, range: 10-65 years) who underwent MRI including REACT and standard MRAs were retrospectively included in this study. Image quality (IQ) of REACT-MRA was compared to non-gated multi-phase first-pass-MRA and respiratory- and electrocardiogram-gated steady-state-MRA. Overall IQ of different vessels of interest was independently assessed by two radiologists on a five-point Likert scale. Measurements of vessel diameters were performed in predefined anatomic landmarks. Friedman test, chi-squared test, and Bland-Altman method were used for statistical analysis.*Results Overall IQ score of REACT-MRA was higher compared to first-pass-MRA (3.5±0.4 vs. 2.7±0.4, P<0.001) and did not differ from steady-state-MRA (3.5±0.4 vs. 3.5±0.6, P=0.99). Non-diagnostic IQ of the defined vessels of interest was observed less frequently on REACT-MRA (1.7%) compared to steady-state- (4.3%; P=0.046) or first-pass-MRA (20.9%; P<0.001). Close agreements in vessel diameter measurements were observed between REACT- and steady-state-MRA (e.g. ascending aorta, bias: 0.38±1.0mm, 95% limits of agreement (LOA): -1.62-2.38mm). REACT-MRA showed high intra- (bias: 0.04±1.0mm, 95% LOA: -1.9-2.0mm) and interobserver (bias: 0.20±1.1mm, 95% LOA: -2.0-2.4mm) agreements regarding vessel diameter measurements. Fat-water separation artifacts were observed in 5/70 (7%) cases on REACT-MRA but did not limit diagnostic utility. Seven vascular abnormalities were detected on REACT-MRA that were not seen on standard contrast-enhanced MRA.*Conclusions Non-contrast-enhanced cardiac-gated REACT-MRA offers a high diagnostic quality for assessment of the thoracic vasculature in CHD patients.*Clinical Relevance/Application REACT-MRA allows for a contrast-free visualization of the thoracic vasculature in CHD patients.

RESULTS

Overall IQ score of REACT-MRA was higher compared to first-pass-MRA (3.5±0.4 vs. 2.7±0.4, P<0.001) and did not differ from steady-state-MRA (3.5±0.4 vs. 3.5±0.6, P=0.99). Non-diagnostic IQ of the defined vessels of interest was observed less frequently on REACT-MRA (1.7%) compared to steady-state- (4.3%; P=0.046) or first-pass-MRA (20.9%; P<0.001). Close agreements in vessel diameter measurements were observed between REACT- and steady-state-MRA (e.g. ascending aorta, bias: 0.38±1.0mm, 95% limits of agreement (LOA): -1.62-2.38mm). REACT-MRA showed high intra- (bias: 0.04±1.0mm, 95% LOA: -1.9-2.0mm) and interobserver (bias: 0.20±1.1mm, 95% LOA: -2.0-2.4mm) agreements regarding vessel diameter measurements. Fat-water separation artifacts were observed in 5/70 (7%) cases on REACT-MRA but did not limit diagnostic utility. Seven vascular abnormalities were detected on REACT-MRA that were not seen on standard contrast-enhanced MRA.

CLINICAL RELEVANCE/APPLICATION

REACT-MRA allows for a contrast-free visualization of the thoracic vasculature in CHD patients.

SSCA01-2　Right-left Ventricular Bloodpool T2 Ratio As An Innovative Screening Tool For The Identification Of Left-to-right Shunts In Patients With Dilated Right Ventricle

Participants

Tilman Emrich, MD, Charleston, South Carolina (*Presenter*) Speaker, Siemens AG;Travel support, Siemens AG

PURPOSE

Left-to-right shunts (L-R-Shunt) lead to volume overload of the right ventricular (RV) system, pulmonary hypertension, as well as alterations of the RV myocardium, resulting in adverse cardiac events. CMR is able to detect L-R-Shunts by comparison of phase-contrast measurements of pulmonary and aortic flow (Qp/Qs-ratio), which is not routinely done in clinical CMR examinations. Since T2 is sensitive to the oxygenation of blood, we hypothesized that T2 mapping is able to detect blood oxygenation differences between the ventricles caused by L-R-Shunts. Therefore, the aim of this study was to evaluate T2 mapping for L-R-Shunt detection in patients with dilated RV compared to healthy volunteers.*Methods and Materials We retrospectively analyzed the T2 ratio of the RV/LV blood pool and Qp/Qs-ratio by phase-contrast-imaging from 18 patients with established relevant L-R-shunts. Healthy volunteers (n=41) and patients with dilated right ventricles without L-R-Shunts (ARVC, pulmonary regurgitation, n=10) were used as control groups. Qp/Qs-ratio was calculated by dedicated measurements of pulmonary and aortic flow. T2 ratio of the LV/RV blood pool was calculated from routinely acquired, mid-ventricular T2-Maps.*Results The Qp/Qs ratios in the L-R-Shunt vs the control groups were 1.9 ± 1.0 and 1.0 ± 0.04, respectively (p<0.001). End-diastolic RV volume was significant higher compared to healthy volunteers (120.6 ± 51.1 and 93.0 ± 15.0, p=0.007), but not in comparison to patients with RV disease (120.6 ± 51.1

and 118.2 ± 34.0, p=1.00). T2 RV/LV-Ratio was significantly increased in patients with L-R-Shunts (0.90 ± 0.09) compared to healthy volunteers (0.74 ± 0.11, p<0.001) and patients with dilated RV (0.73 ± 0.16, p=0.004). A ratio over 0.74 showed a 100% sensitivity and 56% specificity for detection of L-R-Shunts, resulting in a negative predictive value of 100%. T2 differences in the LV vs RV could also be depicted by visual assessment.*Conclusions RV-LV-Bloodpool T2 relaxation time ratio has the potential to become a fast and highly reliable method for screening L-R-Shunts. A ratio below 0.74 excluded the presence of a L-R-Shunt, independent of end-diastolic RV volume.*Clinical Relevance/Application The use of RV/LV bloodpool T2 ratio may indicate when more sophisticated Qp/Qs evaluation is needed in the suspicion of L/R-Shunts.

RESULTS

The Qp/Qs ratios in the L-R-Shunt vs the control groups were 1.9 ± 1.0 and 1.0 ± 0.04, respectively (p<0.001). End-diastolic RV volume was significant higher compared to healthy volunteers (120.6 ± 51.1 and 93.0 ± 15.0, p=0.007), but not in comparison to patients with RV disease (120.6 ± 51.1 and 118.2 ± 34.0, p=1.00). T2 RV/LV-Ratio was significantly increased in patients with L-R-Shunts (0.90 ± 0.09) compared to healthy volunteers (0.74 ± 0.11, p<0.001) and patients with dilated RV (0.73 ± 0.16, p=0.004). A ratio over 0.74 showed a 100% sensitivity and 56% specificity for detection of L-R-Shunts, resulting in a negative predictive value of 100%. T2 differences in the LV vs RV could also be depicted by visual assessment.

CLINICAL RELEVANCE/APPLICATION

The use of RV/LV bloodpool T2 ratio may indicate when more sophisticated Qp/Qs evaluation is needed in the suspicion of L/R-Shunts.

SSCA01-3   Aortic Stenosis And Aortic Regurgitation Mediate Systolic And Diastolic Reverse Flow In BIcuspid Aortic Valve Patients With Aortic Dilation

Participants
Elizabeth Weiss, BS, Chicago, Illinois (*Presenter*) Nothing to Disclose

PURPOSE

Bicuspid aortic valve (BAV) disease increases the risk of aortopathies such as aortic dilation, aneurysm, and dissection. Aortic Regurgitation (AR) and Aortic Stenosis (AS) exacerbate BAV related deranged flow and accelerate the need for surgical intervention. Vorticity has been shown to be associated with the degree of aortic dilation but this is a non-standardized measure that requires dedicated analysis tools and is noise-prone. We instead propose using 4D flow MRI to measure voxel-wise reverse flow, an expected but simpler characteristic of vortex flow. We aimed to evaluate reverse flow as a diagnostic metric to quantify deranged flow in BAV patients with AR and AS and to assess its association with aortic dilation.*Methods and Materials 513 patients with BAV (age = 51±13yrs, 24% female), mid-ascending aorta diameter (MAAD) > 35mm and valid 4D flow scans were analyzed. An age and sex-matched healthy control cohort (n=25, age = 49±12yrs, 24% female) was selected. Each 4D flow scan was preprocessed and segmented. 2D analysis planes were equidistantly placed along an automatically calculated centerline to define the direction of reverse flow to quantify voxel-wise reverse flow along the entire aorta (Fig1c-d). The mean reverse flow in the ascending aorta was measured over the first 300ms (systole) and second 300ms (diastole).*Results There were no differences in age, gender, or BMI between the cohorts. There was no difference in MAAD across the AR groups: none, mild, moderate, severe. BAV resulted in significantly increased reverse flow compared to healthy controls even in the absence of AS or AR. Diastolic reverse flow increased significantly with AR severity but had no difference in systole. Reverse flow increased with AS severity in systole but had little change in diastole. Systolic reverse flow across all AR groups had a correlation coefficient of 0.21 with MAAD (p<0.001).*Conclusions Reverse flow maps, measured from 4D flow, captured BAV mediated deranged flow in patients with AR and AS. As expected, reverse flow increased with AR severity, but this increase was isolated to diastole. This suggests that the elevated systolic reverse flow captured BAV related changes in aortic outflow while excluding the effect of deranged flow due to AR. Contrary to AR, AS severity played a significant role in systolic reverse flow. Additionally, systolic reverse flow was found to increase with aortic dilation severity. Overall, we found that reverse flow captured BAV and valve disease related deranged flow and that reverse flow may be a valuable metric for evaluating disease severity.*Clinical Relevance/Application Voxel-wise reverse flow maps, measured from 4D flow MRI, characterizes deranged flow in patients with BAV, aortic dilation, and mixed AS and AR status.

RESULTS

There were no differences in age, gender, or BMI between the cohorts. There was no difference in MAAD across the AR groups: none, mild, moderate, severe. BAV resulted in significantly increased reverse flow compared to healthy controls even in the absence of AS or AR. Diastolic reverse flow increased significantly with AR severity but had no difference in systole. Reverse flow increased with AS severity in systole but had little change in diastole. Systolic reverse flow across all AR groups had a correlation coefficient of 0.21 with MAAD (p<0.001).

CLINICAL RELEVANCE/APPLICATION

Voxel-wise reverse flow maps, measured from 4D flow MRI, characterizes deranged flow in patients with BAV, aortic dilation, and mixed AS and AR status.

SSCA01-5   Diffuse Myocardial Fibrotic Remodeling In Hereditary Thoracic Aortic Disorders

Participants
Gauri Karur, MBBS, Toronto, Ontario (*Presenter*) Nothing to Disclose

PURPOSE

A primary cardiomyopathy has been described in some hereditary thoracic aortic disorders (HTAD). Angiotensin-II receptor blockers (ARB) and beta-blockers (BB) are a mainstay of medical treatment of many HTAD patients. The purpose is to evaluate myocardial remodeling using cardiac MRI in adults with HTAD and investigate the potential anti-fibrotic effect of ARB and BB on the myocardium.*Methods and Materials Gene-positive HTAD patients undergoing clinical cardiac MRI were prospectively recruited for assessment of myocardial fibrosis using native T1 mapping (MOLLI) and were compared with a cohort of healthy controls. Exclusion criteria included prior cardiovascular surgery and valvular disease. To allow comparison across 1.5T and 3T scanners, Z-scores were calculated for T1 using scanner-specific local reference values.*Results A total of 32 patients with HTAD were included, 18 Marfan, 7 Loeys Dietz, 6 Ehler Danlos, and 1 arterial tortuosity syndromes (mean age 34±12 years, 39% female, 22% treated with ARB and 34% with BB). There was no significant difference in age or sex between HTAD patients and controls (n=45, 40.4±14 years, p=0.051; 61% female, p=0.81). HTAD patients had normal left and right ventricular (LV, RV) volumes and LV mass. HTAD patients had lower LV and RV ejection fractions (EF) compared to controls (57.8±5.8 vs. 60.9±3.7, p=0.006; 53.8±7.5 vs. 57.5±4.2,

p=0.03). Native T1 was significantly higher in patients with HTAD compared to controls, suggestive of diffuse myocardial fibrosis (Z-score 0.7±1.5 vs. 0.007±1.0, p=0.02). Native T1 did not correlate significantly with biventricular volumes, mass, EF or aortic root diameter. Patients treated with ARB or BB therapy had slightly lower native T1 compared to untreated patients (Z-score 0.2±1.4 vs. 1.2±1.5, p=0.042).*Conclusions Cardiac MRI biomarkers of diffuse myocardial fibrosis are elevated and biventricular function is lower in HTAD. While the prognostic significance of this finding will need to be investigated in larger longitudinal studies, our data suggest that HTAD patients undergo adverse biventricular remodeling. ARB and BB therapy may have an anti-fibrotic effect on the myocardium.*Clinical Relevance/Application Cardiac MRI provides valuable information about myocardial remodeling in HTAD. Further research is required to investigate the myocardial protective potential of ARB and BB therapy.

RESULTS

A total of 32 patients with HTAD were included, 18 Marfan, 7 Loeys Dietz, 6 Ehler Danlos, and 1 arterial tortuosity syndromes (mean age 34±12 years, 39% female, 22% treated with ARB and 34% with BB). There was no significant difference in age or sex between HTAD patients and controls (n=45, 40.4±14 years, p=0.051; 61% female, p=0.81). HTAD patients had normal left and right ventricular (LV, RV) volumes and LV mass. HTAD patients had lower LV and RV ejection fractions (EF) compared to controls (57.8±5.8 vs. 60.9±3.7, p=0.006; 53.8±7.5 vs. 57.5±4.2, p=0.03). Native T1 was significantly higher in patients with HTAD compared to controls, suggestive of diffuse myocardial fibrosis (Z-score 0.7±1.5 vs. 0.007±1.0, p=0.02). Native T1 did not correlate significantly with biventricular volumes, mass, EF or aortic root diameter. Patients treated with ARB or BB therapy had slightly lower native T1 compared to untreated patients (Z-score 0.2±1.4 vs. 1.2±1.5, p=0.042).

CLINICAL RELEVANCE/APPLICATION

Cardiac MRI provides valuable information about myocardial remodeling in HTAD. Further research is required to investigate the myocardial protective potential of ARB and BB therapy.

SSCA01-6   Prevalence Of Veno-venous Shunting And High-output State In Fontan - Quantification With 4D Flow MRI

Participants
Albert Hsiao, MD,PhD, La Jolla, California (*Presenter*) Co-founder, Arterys Inc;Shareholder, Arterys Inc;Research Grant, Bayer AG;Research Grant, General Electric Company

PURPOSE

Patients with Fontan palliation comprise a growing and complex population, consisting of a variety of underlying cardiac morphologies with multiple potential modes of failure. In this population, veno-venous collaterals are a known cause of cyanosis, but generally considered a minor source of shunting. We sought to assess the potential value of 4D Flow MRI to quantify flow volume throughout the Fontan circuit, including the frequency and hemodynamic contribution of systemic-to-pulmonary veno-venous collaterals.*Methods and Materials We retrospectively reviewed our experience with 4D Flow to evaluate the Fontan circulation in 75 patients over 4 years at three institutions. Flow volume measurements were performed at multiple locations along the Fontan circuit. To assess the inter-observer consistency, duplicate measurements were performed in a subset of 20 patients. Statistical analysis included Pearson correlation, Bland-Altman analysis, t-test and F-test. The frequency of veno-venous collaterals and structural defects were tabulated from concurrent MRA and related to Fontan clinical status.*Results Flow volume measurements of aortic output, right pulmonary artery, pulmonary veins and SVC/Glenn showed highest inter-observer agreement (?=0.901-0.959), slightly lower in the left pulmonary artery and IVC/Fontan (?=0.792, 0.798), Calculated shunt volume also showed strong agreement, based on the difference between aortic and pulmonary flow (?=0.882). 38/75 (51%) of patients exhibited shunts exceeding 1.00 L/min, 31/38 (82%) of whom had pulmonary venous or atrial flow volume step-ups and corresponding veno-venous collaterals. 9/75 (12%) exhibited a high output state (>4 L/min/m2), most of whom had veno-venous shunts exceeding 30% of cardiac output.*Conclusions Veno-venous collaterals are common in Fontan patients and can contribute a substantial proportion of cardiac output, especially those in a high-output state, suggesting a role in high-output failure. 4D Flow MRI can reliably quantify Fontan flow, including shunts and concomitant structural defects, providing hemodynamic information valuable for management of Fontan palliation.*Clinical Relevance/Application 4D Flow MRI provides visualization and quantitative flow volume measurements for management of Fontan patients that complements traditional sequences used in cardiac MRI and enables quantification of veno-venous shunts.

RESULTS

Flow volume measurements of aortic output, right pulmonary artery, pulmonary veins and SVC/Glenn showed highest inter-observer agreement (?=0.901-0.959), slightly lower in the left pulmonary artery and IVC/Fontan (?=0.792, 0.798), Calculated shunt volume also showed strong agreement, based on the difference between aortic and pulmonary flow (?=0.882). 38/75 (51%) of patients exhibited shunts exceeding 1.00 L/min, 31/38 (82%) of whom had pulmonary venous or atrial flow volume step-ups and corresponding veno-venous collaterals. 9/75 (12%) exhibited a high output state (>4 L/min/m2), most of whom had veno-venous shunts exceeding 30% of cardiac output.

CLINICAL RELEVANCE/APPLICATION

4D Flow MRI provides visualization and quantitative flow volume measurements for management of Fontan patients that complements traditional sequences used in cardiac MRI and enables quantification of veno-venous shunts.

SPR-PH-1   Automatic RECIST Measurement In Longitudinal CT Imaging Studies

Participants
Youbao Tang, PhD, Bethesda, Maryland (*Presenter*) Nothing to Disclose

PURPOSE

Monitoring treatment response in longitudinal CT imaging studies by identifying and measuring the corresponding lesions is critical in radiology and oncology workflows. Conducting this procedure manually is labor-intensive, as clinicians must review multiple 3D images, going back and forth among different images for visual comparison. This is usually subject to considerable inter-observer variability. To lower costs, increase turnaround speeds, and improve reliability, we propose a deep learning system to track and measure the lesions in longitudinal studies automatically and accurately.*Methods and Materials Our system consists of two deep convolutional neural networks. The first network is used for key slice selection and RECIST (Response Evaluation Criteria in Solid Tumors) diameter prediction by taking inputs of a CT sequence and a click in the lesion region. The second network is used for lesion tracking to locate the lesion in the follow-up CT sequence. It takes inputs of a baseline CT, the lesion center on the baseline CT, and a follow-up CT. Our system can obtain the RECIST measurement in longitudinal studies automatically by requiring only one click from radiologists. The models were trained on the large-scale NIH DeepLesion dataset consisting of 32,735 lesions labeled with RECIST diameters from 10,594 studies of 4,459 patients. 1,000 lesions were randomly selected from 500 patients and manually delineated as the validation set of the RECIST model, the remaining patient data were used for training. 3,008, 403, and 900 lesion pairs were constructed from the DeepLesion dataset as the training, validation, and testing set of the lesion tracking model.*Results For each lesion pair, we can compute its tumor response class, as complete response (CR), partial response (PR), progressive disease (PD), or stable disease (SD), of the manual RECIST and our automated RECIST assessments, based on RECIST version 1.1. On the 900 test lesion pairs, our system achieved an accuracy of 0.91, a macro-F1 score of 0.81, and a micro-F1 score of 0.91 for the tumor response classification.*Conclusions A deep learning system to automate RECIST measurements in longitudinal CT studies via a simple click achieves comparable accuracies to expert clinicians, but with markedly reduced time and labor efforts.*Clinical Relevance/Application Our system can serve as a reliable tool for clinicians to annotate sequential RECIST measurements with only minimal human effort required to attain efficiency, objectiveness and reproducibility, and may have high positive clinical impacts.

RESULTS

For each lesion pair, we can compute its tumor response class, as complete response (CR), partial response (PR), progressive disease (PD), or stable disease (SD), of the manual RECIST and our automated RECIST assessments, based on RECIST version 1.1. On the 900 test lesion pairs, our system achieved an accuracy of 0.91, a macro-F1 score of 0.81, and a micro-F1 score of 0.91 for the tumor response classification.

CLINICAL RELEVANCE/APPLICATION

Our system can serve as a reliable tool for clinicians to annotate sequential RECIST measurements with only minimal human effort required to attain efficiency, objectiveness and reproducibility, and may have high positive clinical impacts.

SPR-PH-10   Quantification Of Regional Cerebral Blood Flow Using Diffusion Imaging With Phase-contrast (dpc)

Participants
Fumiki Sugita, Kanazawa, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Although the perfusion-related diffusion coefficient in triexponential analysis is closely correlated with regional cerebral blood flow (rCBF) assessed by arterial spin labeling (ASL), it is only a semiquantitative relative value of rCBF, which makes absolute rCBF quantification challenging. To resolve this problem, we developed a novel diffusion imaging method with phase contrast (DPC), in which the total CBF from phase-contrast (PC)-magnetic resonance imaging (MRI) was used to convert perfusion-related diffusion coefficients in the brain to absolute rCBF.*Methods and Materials Eleven healthy volunteers (nine men and two women; mean age, 23.9 years) participated in this study. 3.0 T, single-shot diffusion echo-planar imaging with multiple b-values in combination with PC-MRI was performed to obtain tCBF from the volumetric flow rate at the main feeding arteries into the cranium. Using tCBF obtained from PC-MRI, we converted the perfusion-related diffusion coefficients in the brain into absolute rCBF. We measured rCBF and its correlations in gray and white matter (GM and WM, respectively) in healthy volunteers using DPC and ASL and assessed the relationship between the two methods.*Results A highly significant positive correlation between DPC and ASL in terms of rCBF was observed in GM (R = 0.9; P < 0.05), whereas the correlation between the methods was poor in WM (R = 0.09; P = 0.8). The rCBF in GM (54.4 ± 11.8 mL/100 g/min) and WM (19.6 ± 4.5 mL/100 g/min) and the GM/WM ratio (2.9 ± 0.7) obtained using DPC were consistent with the literature values assessed using [15O]-water positron emission tomography. The rCBF obtained using DPC was significantly higher in GM and WM than that using ASL (P < 0.05 for both; GM [ASL], 31.9 ± 8.1 mL/100 g/min; WM [ASL], 10.0 ± 3.8 mL/100 g/min).*Conclusions DPC makes it possible to quantitatively evaluate rCBF as well as standard diffusion parameters.*Clinical Relevance/Application Diffusion imaging with phase-contrast (DPC) makes it possible to quantitatively evaluate regional cerebral blood flow as well as standard diffusion parameters.

A highly significant positive correlation between DPC and ASL in terms of rCBF was observed in GM (R = 0.9; P < 0.05), whereas the correlation between the methods was poor in WM (R = 0.09; P = 0.8). The rCBF in GM (54.4 ± 11.8 mL/100 g/min) and WM (19.6 ± 4.5 mL/100 g/min) and the GM/WM ratio (2.9 ± 0.7) obtained using DPC were consistent with the literature values assessed using [15O]-water positron emission tomography. The rCBF obtained using DPC was significantly higher in GM and WM than that using ASL (P < 0.05 for both; GM [ASL], 31.9 ± 8.1 mL/100 g/min; WM [ASL], 10.0 ± 3.8 mL/100 g/min).

CLINICAL RELEVANCE/APPLICATION

Diffusion imaging with phase-contrast (DPC) makes it possible to quantitatively evaluate regional cerebral blood flow as well as standard diffusion parameters.

SPR-PH-11   Of Mice And Men - Spatial Resolution Of A Novel Photon Counting Dual-Source CT Scanner In Routine Clinical Acquisition Modes

Participants
Florian Schwarz, MD, Augsburg, Germany (*Presenter*) Nothing to Disclose

PURPOSE

The potential benefits of Photon-Counting Detector CT (PCD-CT) include substantially improved spatial resolution, elimination of electronic noise and intrinsic spectral sensitivity. The aim of our study was to examine the spatial resolution of a novel photon counting Dual-Source CT (NAEOTOM Alpha, Siemens Healthineers, Erlangen, Germany) in biological tissue and determine its dose dependency.*Methods and Materials A euthanized mouse was purchased from a pet food store and used as a specimen. It was scanned at two different CT scanners currently in use at our institution with protocols optimized for bone imaging and identical CTDI settings (A: 20-slice MDCT with energy-integrating detector (EID), B: PCD-CT with ultra-high-resolution mode (UHR)). Scans were performed at different CTDI's with a range from 2.2 to 20 mGy*cm. For image noise measurements, all datasets were reconstructed at 1 mm slice thickness using reconstruction algorithms with closest similarity in Modulation Transfer Function (B75h and Hr68). Image noise was quantified as standard deviation of HU-values in a large Volume of Air next to the mouse. For the evaluation of spatial resolution, reconstructions were performed at 0.2 mm slice thickness with 0.1 mm increment (PCD-CT); and with 0.6 mm slice thickness with 0.1 mm increment (EID-CT). The latter were reformatted to 0.2 mm series with 0.1 mm increment by a commercially available postprocessing software. To guarantee a "fair comparison", spatial resolution was also compared using the aforementioned Kernels (B75h and Hr68). Two readers semiquantitatively evaluated two defined regions of the spine (cervical spine and lumbar spine) for the delineation of intervertebral disks on a three point Likert scale. Additional Hr98 reconstructions are provided to visualize the much higher spatial resolution routinely available by UHR PCD-CT acquisitions.*Results For all CTDI values, noise was significantly lower in PCD-CT reconstructions than in EID-CT reconstructions using comparable reconstruction algorithms (p's< 0.01). At EID, delineation of the cervical spine structures required a CTDI = 20 mGy, whereas at PCD-CT this delineation was possible at CTDI values = 4 mGy. Delineation of lumbar vertebrae started at CTDI values = 3 mGy for PCD-CT, whereas clear delineation at EID-CT was only possible with CTDI's = 15 mGy.*Conclusions In this direct comparisons of the subtle bone structures of a young mouse, PCD-CT showed clearly superior delineation of small bone details at much lower CTDI's.*Clinical Relevance/Application This study highlights the increased spatial resolution of PCD-CT systems in comparison to EID-CT systems at routine acquisition protocols. This is particularly relevant for high-contrast structures inside the human body.

RESULTS

For all CTDI values, noise was significantly lower in PCD-CT reconstructions than in EID-CT reconstructions using comparable reconstruction algorithms (p's< 0.01). At EID, delineation of the cervical spine structures required a CTDI = 20 mGy, whereas at PCD-CT this delineation was possible at CTDI values = 4 mGy. Delineation of lumbar vertebrae started at CTDI values = 3 mGy for PCD-CT, whereas clear delineation at EID-CT was only possible with CTDI's = 15 mGy.

CLINICAL RELEVANCE/APPLICATION

This study highlights the increased spatial resolution of PCD-CT systems in comparison to EID-CT systems at routine acquisition protocols. This is particularly relevant for high-contrast structures inside the human body.

SPR-PH-12   Physical Characteristics Of A New Photon-counting Detector CT: Comparison Of The Spatial Resolution With That On Conventional Energy-integrated Detector CT Scans

Participants
Toru Higaki, PhD, Minami-ku, Hiroshima, Japan (*Presenter*) Nothing to Disclose

PURPOSE

FUJIFILM Healthcare Corporation developed a photon-counting detector CT (PCD-CT) scanner whose photon sensor was made of CdZnTe. It features two scan modes, multi-energy discrimination (MED) mode where 3x3 detector pixels are bundled [detector pixel pitch (DPP) 0.58x0.63 mm, the same as the conventional energy-integrated detector CT [EID-CT scanner]. It can obtain projection data of four energy bins. The other is the ultra-high resolution (UHR) mode where each detector pixel is used separately; it can yield high spatial resolution images (DPP: 0.19x0.21 mm) with projection data of one energy bin. We compared the spatial resolution obtained with the UHR mode of the PCD-CT with EID-CT results.*Methods and Materials The prototype PCD-CT instrument was built on the platform of a conventional EID-CT scanner (SCENARIA View, FUJIFILM Healthcare Corporation). We created a phantom consisting of a cylindrical water background (diameter 20 cm, 0 Hounsfield units) and a 0.18-mm diameter stainless wire placed 30 mm off-center. The scanning parameters for both scanners were scan field-of-view 42.6 cm, tube voltage 120 kV, tube current time product, 300 mAs, tube focal spot 0.7x0.8 mm, view rate 2880 view/sec, slice thickness,1.25 mm, matrix size 512x512, reconstruction with filtered back projection (kernel: abdominal sharp). The number of energy bin of the PCD-CT was 1. We calculated the modulation transfer function (MTF) using the radial frequency method.*Results With PCD-CT in UHR mode, the 50%, 10%, and 2% MTF was 8.5, 13.6, and 16.5 lp/cm, respectively. For conventional EID-CT these values were 4.9, 8.4, and 10.1 lp/cm, respectively. The MTF in the UHR mode of the PCD-CT scanner was higher than that of the EID-CT scanner in the entire frequency range.*Conclusions The spatial resolution of the new PCD-CT scanner was better than of the conventional EID-CT instrument.*Clinical Relevance/Application As the spatial resolution is higher on scans acquired in the UHR mode of the PCD-CT- than the EID-CT scanner, it may be useful for analyzing the microstructures of the lungs and middle ear.

RESULTS

With PCD-CT in UHR mode, the 50%, 10%, and 2% MTF was 8.5, 13.6, and 16.5 lp/cm, respectively. For conventional EID-CT these

values were 4.9, 8.4, and 10.1 lp/cm, respectively. The MTF in the UHR mode of the PCD-CT scanner was higher than that of the EID-CT scanner in the entire frequency range.

CLINICAL RELEVANCE/APPLICATION

As the spatial resolution is higher on scans acquired in the UHR mode of the PCD-CT- than the EID-CT scanner, it may be useful for analyzing the microstructures of the lungs and middle ear.

SPR-PH-13   Accuracy Of CT Number On Virtual Non-contrast Enhanced Images Generated From Stochastic Material Decomposition

Participants
Toru Higaki, PhD, Minami-ku, Hiroshima, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Virtual non-contrast enhanced (VNC) CT image is an application derived from dual-energy CT (DECT). Since VNC images can be generated from contrast-enhanced CT (CECT) scans, the radiation exposure may be reduced by eliminating the need for non-contrast CT imaging. VNC images are generally generated by 3-material decomposition (3MD). However, the CT value of VNC scans may be incorrect for tissues that do not meet the material definition. To solve this problem, we developed a novel VNC image-generation method that does not assume a specific tissue and named it "stochastic material decomposition (SMD)". We investigated the accuracy of the CT number on VNC images generated by SMD.*Methods and Materials We used a 320-detector row CT scanner that featured a deep-learning-based rapid kV switching dual-energy mode (Aquilion One, Canon Medical Systems). For image processing, we used NIH ImageJ. To generate VNC images, we reconstructed 50- and 70 keV virtual monochromatic X-ray images (VMI) of patients who had undergone liver dynamic CT studies. Figure 1 shows the algorithm for conventional 3MD. The proposed SMD method uses a tissue probability distribution map (TPDM) (Fig. 2) that was a 2-D histogram of two VMIs generated from previously acquired true non-contrast (TNC) images. Starting at the measurement point on each voxel, we extended a straight line along with the slope coefficient and looked for the point with the highest value on the TPDM. Its CT number was taken as that of the VNC image. We then evaluated the accuracy of the CT number on VNC images generated with 3MD and SMD and recorded the difference in the CT number between VNC- and TNC images of the liver, spleen, and aorta.*Results Figure 3 shows a TNC image of liver dynamic CT scans and VNC images generated from early- and delayed phase images. Compared to the SMD-generated VNC image, 3MD-generated VNC images exhibited a rough texture, and attenuation of the stomach- and spleen density was low. Figure 4 shows the difference (error) in the CT number between VNC- and TNC images. Errors in the liver were similar on 3MD and SMD images; in the spleen and aorta, they were significantly smaller on SMD images.*Conclusions As the proposed SMD method did not require tissue definition for the generation of VNC scans, it facilitates the generation of highly accurate VNC scans of multiple tissues.*Clinical Relevance/Application The proposed SMD method yields accurate VNC images and helps to lower the radiation dose at DECT studies.

RESULTS

Figure 3 shows a TNC image of liver dynamic CT scans and VNC images generated from early- and delayed phase images. Compared to the SMD-generated VNC image, 3MD-generated VNC images exhibited a rough texture, and attenuation of the stomach- and spleen density was low. Figure 4 shows the difference (error) in the CT number between VNC- and TNC images. Errors in the liver were similar on 3MD and SMD images; in the spleen and aorta, they were significantly smaller on SMD images.

CLINICAL RELEVANCE/APPLICATION

The proposed SMD method yields accurate VNC images and helps to lower the radiation dose at DECT studies.

SPR-PH-14   A Comparative Study Of Image Quality And Radiation Dose Of Coronary CT Under Free Breathing And Breath-holding Scanning

Participants
Jingyao Zheng, Shizuishan, China (*Presenter*) Nothing to Disclose

PURPOSE

To explore the radiation dose of coronary CT angiography (CCTA) under different conditions of free breathing and breath-holding.*Methods and Materials Thirty patients with suspected coronary atherosclerotic heart disease to undergo CCTA examination were collected. 15 cases of group A were scanned by traditional breath-holding method,15 cases in group B were scanned by free breathing. All patients underwent CCTA examination with 256-slice wide-body detector CT (Revolution CT, GE Healthcare). And patients signed an informed consent form before the examination. The 4 groups of images are respectively 20% ASiR-V (group A), 40% ASiR-V (group B), 60% ASiR-V (group C), 80% ASiR-V (group D) for standard image reconstruction. The reconstructed image is transferred to GE AW 4.7 workstation to analyze. Two radiologists with cardiovascular CT diagnosis experience scored the images of coronary artery imaging subjectively and objectively by blind method, and compared the radiation measurement between the two groups.*Results There was no statistically significant difference in the subjective scores of image quality between the two groups (p=0.286,p=0.521,p=205). In the state of free breathing, the excellent blood vessel rates of the right coronary artery (RCA), the left ascending artery (LAD), and the left circumflex artery (LCX) are 37.5% (45/120) ,35.8% (43/120) and 31.6% (38/120). The excellent blood vessel rates of RCA, LAD, and LCx in breath-holding state are 36.6% (44/120), 35.8% (43/120) and 20.8% (25/120). There was no statistically significant difference between the two groups (p>0.05). The SD values of the aortic roots examined by CCTA under free breathing and breath-holding state were 31.62±5.70, 29.62±3.76 HU. There was no statistically significant difference between the two groups (p=0.268). The difference in CT value, SNR and CNR was also not statistically significance (p=0.715, p=308, p=0.327), the ED values of groups A and B were (8.25±1.18) mSv and (8.15±1.15) mSv, respectively, and the difference was not statistically significant (p=0.809).*Conclusions With the same 16cm wide detector CT, the scanning dose of the free breathing method and the traditional breath-hold method CCTA examination are equivalent, and there is no statistical difference in the excellent blood vessel rate between the two methods, so the free-breath method can replace the traditional breath-hold method CCTA examination.*Clinical Relevance/Application Using 16 cm wide detector CT,there is no statistical difference in scanning dose and excellent blood vessel rate between free breathing CCTA and traditional breath-holding CCTA., Therefore, the free breathing method CCTA provides the possibility for a wider range of clinical applications.

RESULTS

There was no statistically significant difference in the subjective scores of image quality between the two groups (p=0.286,p=0.521,p=205). In the state of free breathing, the excellent blood vessel rates of the right coronary artery (RCA), the left ascending artery (LAD), and the left circumflex artery (LCX) are 37.5% (45/120) ,35.8% (43/120) and 31.6% (38/120). The

excellent blood vessel rates of RCA, LAD, and LCx in breath-holding state are 36.6% (44/120), 35.8% (43/120) and 20.8% (25/120). There was no statistically significant difference between the two groups (p>0.05). The SD values of the aortic roots examined by CCTA under free breathing and breath-holding state were 31.62±5.70, 29.62±3.76 HU. There was no statistically significant difference between the two groups (p=0.268). The difference in CT value, SNR and CNR was also not statistically significance (p=0.715, p=308, p=0.327), the ED values of groups A and B were (8.25±1.18) mSv and (8.15±1.15) mSv, respectively, and the difference was not statistically significant (p=0.809).

CLINICAL RELEVANCE/APPLICATION

Using 16 cm wide detector CT,there is no statistical difference in scanning dose and excellent blood vessel rate between free breathing CCTA and traditional breath-holding CCTA., Therefore, the free breathing method CCTA provides the possibility for a wider range of clinical applications.

SPR-PH-15 Performance Evaluation Of A Deep Learning Based Reconstruction Method For Low Dose PET Imaging

Participants
Yan Xing, Shanghai, China (*Presenter*) Nothing to Disclose

PURPOSE

This study aimed to evaluate the performance of a deep progressive learning (DPL) method, (HYPER AiR, United Imaging Healthcare) for PET image reconstructions with simulated low dose PET acquisitions in comparison to the standard ordered-subsets expectation maximization (OSEM) method.*Methods and Materials Nineteen oncological patients undergoing 18F-FDG PET/CT imaging with an acquisition of 120s per bed position were retrospectively included. Images reconstructed with OSEM were used as the standard of reference. Subsequently, 37.5%, 50%, 75% and 100% of the full counts were extracted from the list-mode data to simulate low dose PET imaging and reconstructed by the DPL method. A volume of interest (VOI) with a diameter of 30±3mm was manually drawn in the liver to measure the standard uptake values (SUVs) and standard deviations (SDs). For each patient, a VOI was drawn on the lesion with the highest uptake or a diameter of = 15 mm (with an overall maximum of five lesions per patient) to measure the SUVpeak and SUVmax value. Liver signal-to-noise ratio (SNR) and lesion target-to-background ratio (TBR) were obtained. Paired-samples t-test was performed to compare the parameters between the methods.*Results Compared with the reference, there was no significant difference regarding liver SUVs. DPL images with 50% counts and above revealed significantly larger SNR values than the reference (all p<0.001). DPL images with 37.5% counts showed a slightly higher SNR compared to the reference (p=0.438). Compared with the reference lesion SUVmax, SUVpeak and TBR, DPL images showed significantly larger values for lesions with the highest uptake or a diameter of = 15 mm (all p<0.01).*Conclusions The proposed deep progressive learning method provided a non-inferior image quality even with reduced counts by 62.5%. Moreover, the DPL method yielded significantly higher lesion TBR values compared to the reference method, indicating a better lesion contrast. DPL would play a potentially important role in low-dose PET imaging.*Clinical Relevance/Application The proposed deep progressive learning (DPL) method can provide a non-inferior image quality with reduced counts, indicating its application in low dose PET imaging.

RESULTS

Compared with the reference, there was no significant difference regarding liver SUVs. DPL images with 50% counts and above revealed significantly larger SNR values than the reference (all p<0.001). DPL images with 37.5% counts showed a slightly higher SNR compared to the reference (p=0.438). Compared with the reference lesion SUVmax, SUVpeak and TBR, DPL images showed significantly larger values for lesions with the highest uptake or a diameter of = 15 mm (all p<0.01).

CLINICAL RELEVANCE/APPLICATION

The proposed deep progressive learning (DPL) method can provide a non-inferior image quality with reduced counts, indicating its application in low dose PET imaging.

SPR-PH-16 Characterization Of Spectral CT Image Quality Using Covariance Weighted Contrast-to-noise Ratio

Participants
Jayasai Rajagopal, BA, Durham, North Carolina (*Presenter*) Nothing to Disclose

PURPOSE

To develop a metric for spectral CT image data that is able to account for the signal and noise interrelationship between images in an energy selective dataset and as an analogue to the contrast-to-noise ratio in conventional CT image quality*Methods and Materials A metric was developed to incorporate the covariance between images in spectral CT datasets into the calculation, the covariance-weighted contrast-to-noise ratio (Covar-CNR). This metric relates the contrast in a specific image to the shared noise component between that image and others within the spectral dataset. An investigational photon-counting CT system (Siemens CounT) was used to image an open bore water phantom containing vials of iodine (2, 4, 8 mg/mL). Images were acquired with three different tube voltages (100, 120 and 140 kV) at 150 mAs. The macro mode of the scanner was used with optimally selected threshold values of 25 and 52 keV. Regions of interest were drawn within each vial and used to calculate the conventional and covariance weighted CNRs of both spectral images.*Results Both conventional and covariance weighted CNRs increased as a function of iodine concentration across all three tube voltages. Across tube voltages, both conventional and covariance weighted CNRs decreased for the two highest concentrations of iodine, while they increased slightly for the lowest concentration of iodine. The lower energy image had a 42% higher conventional CNR and 142% lower covariance weighted CNR than the high energy image across all conditions. Covariance weighted CNRs were higher than conventional CNR by 124% and 73% in the low and high energy images respectively, providing a fuller representative picture of the interactions within the spectral dataset.*Conclusions While conventional CNR reflects the noise and contrast within an image, the covariance weighted CNR measures how much that noise and contrast are shared across images within the spectral dataset. Together, they provide a more complete characterization of spectral CT datasets.*Clinical Relevance/Application Modifying image quality metrics to reflect differences in spectral detectors and post-processing tasks in material separation can increase confidence in and promote clinical use of these techniques

RESULTS

Both conventional and covariance weighted CNRs increased as a function of iodine concentration across all three tube voltages. Across tube voltages, both conventional and covariance weighted CNRs decreased for the two highest concentrations of iodine, while they increased slightly for the lowest concentration of iodine. The lower energy image had a 42% higher conventional CNR and 142% lower covariance weighted CNR than the high energy image across all conditions. Covariance weighted CNRs were higher than conventional CNR by 124% and 73% in the low and high energy images respectively, providing a fuller representative picture

of the interactions within the spectral dataset.

CLINICAL RELEVANCE/APPLICATION

Modifying image quality metrics to reflect differences in spectral detectors and post-processing tasks in material separation can increase confidence in and promote clinical use of these techniques

SPR-PH-17   Automatic Liver Lesion Localization Using Large-scale Unlabeled And Sequence-incomplete MR Imaging Data

Participants
Bolin Lai, MENG, Shanghai, China (*Presenter*) Nothing to Disclose

PURPOSE

Early detection of liver lesions can significantly boost patient prognosis. But even with multi-phasic MRI, reported sensitivities are still low, e.g., 47% for < 2cm hepatocellular carcinoma. Computer-aided detection (CADe) solutions may help address this challenge, but current algorithms cannot easily exploit existing sources of large-scale data: they expect fully annotated data and a pre-defined set of MRI sequences. Yet, hospital archives house unlabeled MRI studies whose acquired sequences can vary. We investigate how to leverage unlabeled and sequence-incomplete MRI data to train a highly effective deep learning CADe algorithm.*Methods and Materials We collected 1099 multi-sequence MRI studies (T1, T1 contrast-enhanced arterial and venous phases, T2, and DWI) of patients who had undergone a liver resection or transplantation. Three sub-types are included in the dataset: HCC, ICC and metastasized tumors. For 430 studies with all five sequences, we labelled each present lesion with 3D bounding boxes via visual observation and cross-referencing the histopathological reports. We developed a CADe algorithm with two technical innovations. First, we incorporate hetero-modal learning to exploit studies with missing sequences. Second, we propose a semi-supervised mean teacher workflow tailored for detection. Unlike prior art, it enforces consistency on both detection confidences and bounding box sizes. As well, it uses hetero-modal learning to exert consistency across varying sequence inputs.*Results For evaluation, we utilized five-fold cross validation on the labelled studies. We tested a range of training setups under differing ratios of labeled-to-unlabeled data (5%-30%). Under the 10% setting and using free-response ROC analysis, our CADe system achieves an average sensitivity of 55.2%, which is 13.3% higher than its fully supervised counterpart (41.9%) since more (unlabeled) data is used for training, and 3.5% better than the next best state-of-the-art semi-supervised detection method. Commensurate improvements are also observed under other labeled ratios.*Conclusions We proposed a semi-supervised CADe method and hetero-modal learning strategy that can exploit large-scale unlabeled and sequence-incomplete clinical data. Experiments validated its superiority over fully supervised detectors and other semi-supervised methods.*Clinical Relevance/Application Automatic lesion detection could serve as an end goal to help radiologists discover lesions quickly and precisely, or as a critical step for computer-aided diagnosis and prognosis.

RESULTS

For evaluation, we utilized five-fold cross validation on the labelled studies. We tested a range of training setups under differing ratios of labeled-to-unlabeled data (5%-30%). Under the 10% setting and using free-response ROC analysis, our CADe system achieves an average sensitivity of 55.2%, which is 13.3% higher than its fully supervised counterpart (41.9%) since more (unlabeled) data is used for training, and 3.5% better than the next best state-of-the-art semi-supervised detection method. Commensurate improvements are also observed under other labeled ratios.

CLINICAL RELEVANCE/APPLICATION

Automatic lesion detection could serve as an end goal to help radiologists discover lesions quickly and precisely, or as a critical step for computer-aided diagnosis and prognosis.

SPR-PH-18   A Novel Interpretable Deep Learning Prostate Cancer Detector For Bi-parametric MRI

Participants
Nathan Lay, PhD, Bethesda, Maryland (*Presenter*) Inventor, Abris Capital Partners

PURPOSE

Magnetic resonance imaging (MRI) is useful for targeting prostate lesions for biopsy. Reader experience requirements and complexity of MRI sequences have motivated the development of numerous automated prostate cancer detectors. Some recent cancer detectors employ deep learning which achieves state-of-the-art performance for challenging computer vision tasks. However, deep learning still suffers from lack of model interpretability and prediction explainability.We propose a differentiable decision forest, Hinge Forest, that can efficiently operate in concert with deep learning machinery. We use it for prostate cancer detection and show good preliminary test performance (0.91 AUC) on a large prostate cancer cohort along with an example of model interpretability.*Methods and Materials Our Hinge Forest defines an alternative consistent logic on the real numbers with MIN, MAX being logical AND, OR and TRUE, FALSE being positive, negative real numbers. We further define the comparison operation $X > Y$ to be $ReLU(X-Y)$ to guarantee that a unique decision tree leaf is visited for each example. Using this system of logic, the logical conjunctions represented by decision trees become differentiable and identically preserve their original logical meaning.Our deep neural network is comprised of a single VGG block (3 Conv+ReLU followed by max pool) followed by a linear aggregated Hinge Forest classifier comprised of 100 depth 7 trees. The neural network uses T2 weighted (T2w) and apparent diffusion coefficient (ADC) images and was trained end-to-end on 616 prostate MRI scans (517 in-house, 99 ProstateX), validated on 306 scans (250 in-house, 56 ProstateX), and tested on 309 scans (260 in-house, 49 ProstateX) with no patient overlap. The training objective was the weighted cross entropy loss. We trained for 16 epochs and chose the model state with the best validation area under the curve (AUC).*Results Our method achieved an AUC of 0.91 on the test set. The method can achieve 88% lesion detection rate at 20% false positive rate. As a test of interpretability, we visualized a leaf map of one tree and extracted a rule for cancer from a leaf that describes the cancerous lesion.*Conclusions Our Hinge Forest can operate with deep learning, maintain good performance and provide the interpretability and explainability of decision forests.*Clinical Relevance/Application Hinge Forest shows good preliminary performance for prostate cancer detection while providing some model interpretability and prediction explainability which are important for clinical applications.

RESULTS

Our method achieved an AUC of 0.91 on the test set. The method can achieve 88% lesion detection rate at 20% false positive rate. As a test of interpretability, we visualized a leaf map of one tree and extracted a rule for cancer from a leaf that describes the cancerous lesion.

SPR-PH-19   Transposition Of The European Basic Safety Standards Directive At National Level: Impact On A Pan European Healthcare Provider

Participants
Federica Zanca, PhD, Leuven, Belgium (*Presenter*) Nothing to Disclose

PURPOSE

The European Union (EU) issued the 2013/59/Euratom Basic Safety Standards Directive (BSSD) and set 02/06/2018 as a deadline for Member States to bring into force the laws required to comply with its requirements. The aim of this study was two-fold: 1) to evaluate the status of implementation of the BSSD by the EU member states; 2) to assess medical center level compliance with selected elements, independently of the implementation of the same by member states.*Methods and Materials A questionnaire was distributed between January-March 2021 involving 59 CT diagnostic centers in 11 Member States, where a Dose Management Program (DMP) is implemented. Categories of BSSD legal requirements: procedures and population dose evaluation, responsibilities, and asymptomatic patients. Sanctions for non-compliance were investigated.*Results Out of the 11 members states, in 10 the BSSD was fully implemented. Only 55% of the investigated member states have defined National DRLs or require dose from a CT procedure to be reported. CT optimization projects are required in 64% of the countries. In terms of responsibilities, all countries have a framework specifying the role of a Radiation Protection Expert, a Medical Physics Expert, and a Radiation Protection Officer. In terms of justification of exposure of asymptomatic individuals, 91% of the countries have a framework for mammography. Only 1 country (10%) has a regulation in place for lung cancer screening; 37% is preparing the legislation or running a clinical trial. Sanctions for non-compliance were fines from 2k euro to the withdrawal of license to operate. When looking at compliance at center for procedures and population dose evaluation, all centers had established local DRLs and continuous data collection allowed detection of non-optimized exposures; structured dose reporting and high dose level alerts were also in place. *Conclusions Despite of a lower compliance of the transposed BSSD for CT modality in several Member States, the centers participating in this study showed higher compliance with the key BSSD elements investigated thanks to the implementation of a DMP.*Clinical Relevance/Application This survey revealed a lack of compliance at country level with BSSD RP requirements. The level of compliance is higher at local level, especially for centers where a DMP is in place.

RESULTS

Out of the 11 members states, in 10 the BSSD was fully implemented. Only 55% of the investigated member states have defined National DRLs or require dose from a CT procedure to be reported. CT optimization projects are required in 64% of the countries. In terms of responsibilities, all countries have a framework specifying the role of a Radiation Protection Expert, a Medical Physics Expert, and a Radiation Protection Officer. In terms of justification of exposure of asymptomatic individuals, 91% of the countries have a framework for mammography. Only 1 country (10%) has a regulation in place for lung cancer screening; 37% is preparing the legislation or running a clinical trial. Sanctions for non-compliance were fines from 2k euro to the withdrawal of license to operate. When looking at compliance at center for procedures and population dose evaluation, all centers had established local DRLs and continuous data collection allowed detection of non-optimized exposures; structured dose reporting and high dose level alerts were also in place.

CLINICAL RELEVANCE/APPLICATION

This survey revealed a lack of compliance at country level with BSSD RP requirements. The level of compliance is higher at local level, especially for centers where a DMP is in place.

SPR-PH-2   Diagnostic Reference Levels And Achievable Doses For The 11 Most Commonly Performed Pediatric CT Examinations In The United States As A Function Of Patient Age And Size In The American College Of Radiology CT Dose Index Registry.

Participants
Kalpana M. Kanal, PhD, Seattle, Washington (*Presenter*) Nothing to Disclose

PURPOSE

To develop diagnostic reference levels (DRLs) and achievable doses (ADs) for the 11 most commonly performed pediatric CT examinations in the United States (USA) as a function of patient age and size using the American College of Radiology (ACR) CT Dose Index Registry.*Methods and Materials Data on the 11 most commonly performed pediatric CT examinations acquired between 2016 - 2020 from 1637 facilities were analyzed. For head, neck and extremity examinations, doses were analyzed based on patient age; for body examinations, doses were analyzed based on both patient age and effective diameter. Data from 1,562,016 examinations provided medians (AD) as well as 75th percentiles (DRL) for CTDIvol, DLP and SSDE. Applicable results were compared with DRLs from other countries.*Results Of all facilities analyzed, 65.2% of the facilities were community hospitals, 16.8% were freestanding centers, 9.5% were academic facilities and only 3.5% were dedicated children's hospitals. Head CT was the most frequently performed examination in the study (56.1%) followed by the abdomen/pelvis CT (28.1%). ADs and DRLs (for both CTDIvol and DLP) for all examinations generally increased as a function of age and patient effective diameter. For head without contrast examinations, the CTDIvol AD and DRL ranged from 19-46 mGy and 23-55 mGy, respectively increasing with age. For abdomen/pelvis without contrast examinations, the CTDIvol ADs and DRLs ranged from 2.1-24 mGy and 2.6-28 mGy, respectively with increasing effective diameter. Although international pediatric DRL methodology and results vary, our results fall within the ranges reported across other countries.*Conclusions DRLs and ADs as a function of patient age and effective diameter were developed from a wide range of USA practice environments for the 11 most common CT pediatric examinations using data from over 1.5 million pediatric examinations. These determinations can serve as practical benchmarks for accountability and for improvement in pediatric CT practice.*Clinical Relevance/Application The results of this study will enable US as well as international facilities to compare their patient dose indices to these benchmarks. Because smaller and younger patients require less radiation to obtain adequate image quality, the new DRLs and ADs will enable facilities to adjust their CT protocols more effectively for the wide range of patient habitus and age commonly seen in the pediatric population.

RESULTS

Of all facilities analyzed, 65.2% of the facilities were community hospitals, 16.8% were freestanding centers, 9.5% were academic facilities and only 3.5% were dedicated children's hospitals. Head CT was the most frequently performed examination in the study

(56.1%) followed by the abdomen/pelvis CT (28.1%). ADs and DRLs (for both CTDIvol and DLP) for all examinations generally increased as a function of age and patient effective diameter. For head without contrast examinations, the CTDIvol AD and DRL ranged from 19-46 mGy and 23-55 mGy, respectively increasing with age. For abdomen/pelvis without contrast examinations, the CTDIvol ADs and DRLs ranged from 2.1-24 mGy and 2.6-28 mGy, respectively with increasing effective diameter. Although international pediatric DRL methodology and results vary, our results fall within the ranges reported across other countries.

CLINICAL RELEVANCE/APPLICATION

The results of this study will enable US as well as international facilities to compare their patient dose indices to these benchmarks. Because smaller and younger patients require less radiation to obtain adequate image quality, the new DRLs and ADs will enable facilities to adjust their CT protocols more effectively for the wide range of patient habitus and age commonly seen in the pediatric population.

SPR-PH-21 Machine Learning-based Optimal Radiation Treatment Technique Suggestion Using Dosimetric Parameters

Participants
Dongmin Ryu, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To develop a model which can suggest the optimal radiation treatment (RT) technique using dosimetric parameters of breast cancer patients.*Methods and Materials Whole dataset was obtained from 400 breast cancer patients who underwent RT after breast-conserving surgery. Each dataset consists of a CT image, a contour map of four organs (breast, left lung, right lung, and heart) from RT-structure file (RS), and dose maps for four RT techniques, 2D tangential beams (2D), forward IMRT (f-IMRT), inverse IMRT (i-IMRT), and VMAT, from each RT-dose file (RD). Whole dataset includes 140, 192, 35, and 33 patients for 2D, f-IMRT, i-IMRT, and VMAT, respectively. Every plan's prescription dose was 4240 cGy (16 fractions with 265 cGy). The dataset was randomly divided into a training set of 350 patients and a test set of 50 patients (20 2D, 20 f-IMRT, 5 i-IMRT, and 5 VMAT) considering a ratio of each plan. To develop a RT technique suggestion model, a total of 36 parameters (9 types of dosimetric parameters for each plan) were calculated. In the training stage, XGBoost, a novel machine-learning algorithm, was implemented and parameter optimization was done using a simple grid search algorithm with 7-fold cross-validation to prevent overfitting. Multi log loss was applied, and model's outputs were probabilities of four RT techniques for each case. To evaluate the optimal RT technique prediction performance of the trained model, a confusion matrix was drawn for four plans. Precision, recall, F1-score for four plans were calculated respectively. To determine the accuracy considering the cases suitable for two or more plans, top-2 accuracy was also calculated along with top-1 accuracy.*Results The trained XGBoost model showed suitable RT technique suggestion results for each plan. Top-1 and top-2 accuracies for the test set were 76.0% and 94.0%, respectively. All three RT techniques except VMAT achieved 100% top-2 accuracy. Model performance could be improved by adding more i-IMRT and VMAT patient cases in the dataset. These results could help radiologist's plan selection in the real clinic by showing two most probable techniques with each technique's probability. Furthermore, by applying deep learning-based multi-organ segmentation and dose map estimation techniques that our group already has, an end-to-end CT to RT technique prediction model could be developed.*Conclusions The proposed machine learning-based framework showed suitable performance and successfully suggested which RT technique is the most appropriate for each patient with probability information.*Clinical Relevance/Application For whole breast RT, the optimal RT technique for each patient can be automatically chosen by using the proposed model, without manual treatment plannings for comparison.

RESULTS

The trained XGBoost model showed suitable RT technique suggestion results for each plan. Top-1 and top-2 accuracies for the test set were 76.0% and 94.0%, respectively. All three RT techniques except VMAT achieved 100% top-2 accuracy. Model performance could be improved by adding more i-IMRT and VMAT patient cases in the dataset. These results could help radiologist's plan selection in the real clinic by showing two most probable techniques with each technique's probability. Furthermore, by applying deep learning-based multi-organ segmentation and dose map estimation techniques that our group already has, an end-to-end CT to RT technique prediction model could be developed.

CLINICAL RELEVANCE/APPLICATION

For whole breast RT, the optimal RT technique for each patient can be automatically chosen by using the proposed model, without manual treatment plannings for comparison.

SPR-PH-22 Noise Properties And Low Contrast False Positive And False Negative Assessment Of A Super Resolution Deep Learning Reconstruction Algorithm Trained With Data From A Commercial High Resolution CT System

Participants
Kirsten Lee Boedeker, PHD, Los Angeles, California (*Presenter*) Employee, Canon Medical Systems Corporation

PURPOSE

To evaluate the noise properties and low contrast false positive and false negative performance of a Super Resolution Deep Learning Reconstruction (SR-DLR) trained to enhance spatial resolution.*Methods and Materials A 20cm Catphan and 32cm water phantom were scanned on a wide volume CT scanner (Canon Aquilion ONE Prism) with a standard cardiac protocol and reconstructed with a prototype SR-DLR which outputs a 1024 matrix and slice width less than the 0.5mm acquisition slice thickness. The raw data was also reconstructed with hybrid iterative reconstruction (AIDR Enhanced) and Filtered Backprojection (FBP). A 160mm FOV was used. The SR-DLR uses high-dose CT data acquired on a commercial high resolution CT system (Aquilion Precision). The Precision CT system used for training acquires data with a 0.25 mm detector element size at isocenter, both in-plane and longitudinal. Simulated low-dose normal resolution data was used as the training input. Both the Noise Power Spectra (NPS) and the statistical distribution properties of the noise were determined, including outlier analysis. The Receiver Operator Characteristic (ROC) curve, plotting true positive fraction vs false positive fraction was determined for low contrast objects using a model observer.*Results SR-DLR yielded equivalent or improved LCD compared to the conventional reconstruction algorithms for the cardiac CT protocol examined. NPS was similar to the current clinical standard of hybrid iterative reconstruction. Some noise outliers were present in the low frequency band, but due to overall reduced noise magnitude SR-DLR resulted in a lower false positive/negative fraction than conventional reconstruction algorithms. The false positive fraction was lower for SR-DLR along the entire length of the ROC curve.*Conclusions SR-DLR has equivalent or improved noise and LCD properties to conventional reconstruction, including false positive and false negative fractions.*Clinical Relevance/Application The work addresses the

robustness of noise properties of a new SR-DLR Cardiac CT reconstruction algorithm, a common clinical concern for adoption of machine learning based technology

RESULTS

SR-DLR yielded equivalent or improved LCD compared to the conventional reconstruction algorithms for the cardiac CT protocol examined. NPS was similar to the current clinical standard of hybrid iterative reconstruction. Some noise outliers were present in the low frequency band, but due to overall reduced noise magnitude SR-DLR resulted in a lower false positive/negative fraction than conventional reconstruction algorithms. The false positive fraction was lower for SR-DLR along the entire length of the ROC curve.

CLINICAL RELEVANCE/APPLICATION

The work addresses the robustness of noise properties of a new SR-DLR Cardiac CT reconstruction algorithm, a common clinical concern for adoption of machine learning based technology

SPR-PH-23 Preliminary Application Value Of T1 Mapping Of Cardiac Magnetic Resonance Imaging And Tissue Tracking Technique In Cardiac Amyloidosis And Hypertrophic Cardiomyopathy.

Participants
Xiaohu Li, MD, Hefei, China (*Presenter*) Nothing to Disclose

PURPOSE

To explore the value of magnetic resonance native T1 value and tissue tracking technique(CMR-TT) in differentiating myocardial amyloidosis (CA) from hypertrophic cardiomyopathy (HCM).*Methods and Materials A retrospective analysis of 14 CA patients and 16 HCM patients diagnosed in our hospital, retrieved medical records, cardiac magnetic resonance images, ultrasound reports and other clinical data, and selected the same period 16 healthy subjects whose gender and age matched the CA group and HCM group without organic and functional heart disease underwent 3.0T cardiac magnetic resonance examination. The native T1 value and strain indexes in the differential diagnosis of CA and HCM was evaluated by curve of receiver operating characteristic (ROC).For single factors with high discriminating value, the dual-parameter joint logistic regression model is used to combine the predicted probability, and the backword method combined with ROC is used to obtain the discriminating value.*Results The native T1 value of global, basal, papillary muscle and apical myocardium in CA group (1455.68 ±153.23ms, 1446.97 ±170.53 ms, 1442.31 ±151.92 ms, 1468.31 ±141.83 ms respectively) were higher than those in HCM group (1323.18 ±42.51ms, 1329.45 ±46.14 ms, 1330.04 ±41.49 ms, 1327.41 ±46.55 ms respectively) (P < 0.001),but there was no statistical difference between the HCM group and the healthy control group (1305.97±49.83 ms, 1284.57±57.82 ms, 1303.67±56.45 ms, 1323.99±60.79 ms, respectively). The results of CMR-TT strain analysis showed that 2D GRS(15.75±4.41 vs. 24.75±10.21), 2D GCS(-11.11±2.40vs. -14.85±4.50), 3D GRS(14.08±4.22 vs. 26.87±13.45) and 3D GCS(-13.69±2.50 vs.-17.23±4.76) in CA group were lower than those in HCM group (P < 0.05).The combination of 3D GRS&3D GCS, the predicted probability AUC=0.786, the sensitivity rate and specificity rate are 100%, 68.75%, P=0.0028 The CA patients presented as " slowly up -slowly down-rapidly down" form, the HCM presented as "slowly up-rapidly down" form, and healthy control presented as " rapidly up-rapidly down " form.*Conclusions Evaluating the differences in native T1 value and 3D GRS and 3D GCS is helpful to differentiate CA from HCM patients.*Clinical Relevance/Application Myocardial strain technology and T1mapping technology based on movie sequence imaging have good clinical application value in left ventricular hypertrophic cardiomyopathy

RESULTS

The native T1 value of global, basal, papillary muscle and apical myocardium in CA group (1455.68 ±153.23ms, 1446.97 ±170.53 ms, 1442.31 ±151.92 ms, 1468.31 ±141.83 ms respectively) were higher than those in HCM group (1323.18 ±42.51ms, 1329.45 ±46.14 ms, 1330.04 ±41.49 ms, 1327.41 ±46.55 ms respectively) (P < 0.001),but there was no statistical difference between the HCM group and the healthy control group (1305.97±49.83 ms, 1284.57±57.82 ms, 1303.67±56.45 ms, 1323.99±60.79 ms, respectively). The results of CMR-TT strain analysis showed that 2D GRS(15.75±4.41 vs. 24.75±10.21), 2D GCS(-11.11±2.40vs. -14.85±4.50), 3D GRS(14.08±4.22 vs. 26.87±13.45) and 3D GCS(-13.69±2.50 vs.-17.23±4.76) in CA group were lower than those in HCM group (P < 0.05).The combination of 3D GRS&3D GCS, the predicted probability AUC=0.786, the sensitivity rate and specificity rate are 100%, 68.75%, P=0.0028 The CA patients presented as " slowly up -slowly down-rapidly down" form, the HCM presented as "slowly up-rapidly down" form, and healthy control presented as " rapidly up-rapidly down " form.

CLINICAL RELEVANCE/APPLICATION

Myocardial strain technology and T1mapping technology based on movie sequence imaging have good clinical application value in left ventricular hypertrophic cardiomyopathy

SPR-PH-24 Tube Current Modulation Reconstruction From Chest CT Images Using Deep-learning Regression Algorithms

Participants
Marios Myronakis, PhD, Irakleio, Greece (*Presenter*) Nothing to Disclose

PURPOSE

Accurate estimates of patient organ-doses require knowledge of the actual tube-current modulation values applied during CT acquisition. The tube-current information included in CT metadata represents an average of z-axis and angular modulation per CT slice rather than a full description of the actual current modulation values. The actual modulation values were determined either during the localizer scan or in real-time and cannot be retrospectively reproduced using analytical methods. The aim of this work was to reconstruct patient-specific tube-current modulation patterns along the anterior-posterior (AP) and lateral directions using deep-learning algorithms.*Methods and Materials Current modulation tables and CT images from 50 patients undergoing chest CT examinations on a scanner that predetermines angular and z-axis modulation during the localizer scan (GE Revolution GSI) were collected. Patient-specific water-equivalent diameter (WED) was estimated and z-position extracted from each CT slice. WED values were correlated with z-positions and normalized. Normalized WED values from 30 patients were used as features and the corresponding set of tube-current modulation tables as dependent parameters. A long short-term memory (LSTM) deep learning network was trained to predict tube-current modulation pattern for each patient WED values. The remaining 20 patient sets were used to test the model.*Results The validation loss of LSTM algorithm was 0.1 and the root mean squared error was 0.0647. The generated modulation patterns demonstrated a median and average deviation of 0.008% and -0.04% respectively from actual current modulation patterns obtained during localizer scan.*Conclusions Preliminary results with 50 patients demonstrated that the method can accurately reconstruct tube current modulation patterns for patients undergoing chest CT examinations using the

acquired CT images. Additional data are currently collected to extend the training and test sets.*Clinical Relevance/Application The technique can be employed for accurate retrospective estimation of patient organ dose after chest CT examination and chest CT exposure settings optimization for CT scanners from various vendors.This project has received funding from the Euratom research and training programme 2014-2018 under grant agreement No 755523

RESULTS

The validation loss of LSTM algorithm was 0.1 and the root mean squared error was 0.0647. The generated modulation patterns demonstrated a median and average deviation of 0.008% and -0.04% respectively from actual current modulation patterns obtained during localizer scan.

CLINICAL RELEVANCE/APPLICATION

The technique can be employed for accurate retrospective estimation of patient organ dose after chest CT examination and chest CT exposure settings optimization for CT scanners from various vendors.This project has received funding from the Euratom research and training programme 2014-2018 under grant agreement No 755523

SPR-PH-25   3d Dose Distribution Estimation For Various Treatment Techniques Using Deep Learning Framework For Radiation Therapy

Participants
Jimin Lee, Ulsan, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To develop a deep learning model that generates 3D dose distributions of four different radiation treatment (RT) techniques, conventional 2D tangential beams (2D), forward IMRT (f-IMRT), inverse IMRT (i-IMRT), and VMAT, from 3D patient CT images and contour maps of four organs (breast, left lung, right lung, and heart).*Methods and Materials A whole dataset consists of 400 patients' CT images, contour maps, and 3D dose distributions of four RT techniques obtained from RT-dose file. The dataset was randomly divided into 281, 69, and 50 patients for training, validation, and test sets, respectively. To develop a multi-channel 3D dose distribution generation model, a convolutional neural network-based 3D SCNAS-Net which was optimized structure by an auto-ML technique SCNAS (Scalable Neural Architecture Search) was implemented. The model was trained to generate four 3D dose distributions: 2D, f-IMRT, i-IMRT, and VMAT from the two channel input of 3D CT image and its corresponding contour map. During the training, L2 loss was implemented with total variation regularization. To evaluate the trained model quantitatively, Pearson correlation coefficient (PCC), peak signal-to-noise ratio (PSNR), and structural similarity (SSIM) between output and target dose distributions were calculated for each RT technique. Target V90% (percentage of breast volume receiving more than 90% of the prescribed dose, 4240 cGy), target mean dose, and ipsilateral lung V1800cGy (percentage of ipsilateral lung volume receiving more than 1800 cGy) were also calculated for the quantitative analysis.*Results The trained model showed superior dose distribution estimation performance as shown in the figure. Average PCC, PSNR, and SSIM scored 0.947, 28.6, 0.893 for the test set. Metrics for each RT technique are described in the figure. For dosimetric parameters, target V90% of the output dose distributions was 2.9% smaller than that of the target. The target mean dose was 0.3% larger and ipsilateral lung V1800cGy was 1.9% larger.*Conclusions A novel deep learning-based multi-channel 3D dose distribution estimation model was successfully developed, and 3D dose distributions for four types of RT techniques were generated with a small error.*Clinical Relevance/Application The proposed model could help treatment planning and dose prescription by presenting dose distribution and dose-volume histogram in advance without manual treatment plannings to compare each RT technique.

RESULTS

The trained model showed superior dose distribution estimation performance as shown in the figure. Average PCC, PSNR, and SSIM scored 0.947, 28.6, 0.893 for the test set. Metrics for each RT technique are described in the figure. For dosimetric parameters, target V90% of the output dose distributions was 2.9% smaller than that of the target. The target mean dose was 0.3% larger and ipsilateral lung V1800cGy was 1.9% larger.

CLINICAL RELEVANCE/APPLICATION

The proposed model could help treatment planning and dose prescription by presenting dose distribution and dose-volume histogram in advance without manual treatment plannings to compare each RT technique.

SPR-PH-3   Practical Evaluation Of The Dose Per Image Slice In Body CT

Participants
Xinhua Li, PhD, Boston, Massachusetts (*Presenter*) Employee, Constellation Pharmaceuticals

PURPOSE

Size-specific dose estimate (SSDE) was introduced for the average dose to the patient midslice from fixed-mA scans of 15-30 cm (scan length). This study proposes practical evaluation of the dose per image slice (Dslice) for all slices of body CT exams and test the method with Monte Carlo simulation.*Methods and Materials Each image slice was considered a scan range just covering the slice, whose kVp and mA-adjusted CTDIvol (from the DICOM headers) were used to directly calculate a z-axis dose profile for the average dose over the cross section of a water phantom, whose diameter was equal to the patient WED (water equivalent diameter), using the approach to equilibrium function. WED calculation followed AAPM Report No. 220, excluding the patient table. The above was repeated at all slices of a single or multiple scan series. At a z-axis location, Dslice was accumulated from all profiles. As proof of concept, full body CT images and mA values (from the DICOM headers) of a 70-kg male were imported into a previously validated CT simulation program (Geant4) to assess Dslice, alternatively, and the results of two approaches were compared.*Results Dslice largely changed with anatomic location but it was consistent between direct evaluation and simulation, with the 95th percentile difference in magnitude 9.2% for chest exam and 10.5% for abdominopelvic exam. Direct Dslice evaluation was further illustrated with CT-guided interventions, including liver biopsy (male, 60 kg) with 7 series, and aspiration of the right sacroiliac joint (male, 108 kg) with 19 series, including CT fluoroscopy.*Conclusions Direct Dslice evaluation is suited for all image slices of any scan length, specific tube current modulation algorithm and number of scan series, permitting exam-level patient dose monitoring in multiphase studies and CT interventions. Our proposal may assist CT manufacturers and dose index monitoring software in assessing Dslice (IEC publication no. 62985) and the overall energy absorbed in the patient, irrespective of CTDI phantom diameter (16 or 32 cm).*Clinical Relevance/Application Direct evaluation of the dose per image slice is suited for body CT scans from sub-cm to >1 m, any mA profile shapes and multiple scan series, potentially benefits to various parties in patient care.

RESULTS

Dslice largely changed with anatomic location but it was consistent between direct evaluation and simulation, with the 95th percentile difference in magnitude 9.2% for chest exam and 10.5% for abdominopelvic exam. Direct Dslice evaluation was further illustrated with CT-guided interventions, including liver biopsy (male, 60 kg) with 7 series, and aspiration of the right sacroiliac joint (male, 108 kg) with 19 series, including CT fluoroscopy.

CLINICAL RELEVANCE/APPLICATION

Direct evaluation of the dose per image slice is suited for body CT scans from sub-cm to >1 m, any mA profile shapes and multiple scan series, potentially benefits to various parties in patient care.

SPR-PH-5   Radiofrequency-Induced Tissue Heating Adjacent To Metallic Orthopedic Screws For 7 Tesla MRI: A Simulation Study Comparison With Lower Field Strengths

Participants
Andrew Fagan, Rochester, Minnesota (*Presenter*) Nothing to Disclose

PURPOSE

MRI at 7 Tesla has significant benefits over imaging at lower field strengths including increased SNR, increased spatial and spectral resolution, and improved susceptibility-related image contrast. However, uncertainties exist relating to the safety of imaging patients with implanted metallic devices, primarily due to fears of tissue heating adjacent to the implants arising from radiofrequency energy coupling into the implant. Moreover, only a handful of devices have been tested for MR Conditionality status at 7T. The aim of this study was to investigate the potential for radiofrequency-induced tissue heating adjacent to metallic orthopedic screws as a function of MRI magnetic field strength from 3 to 7 Tesla. The hypothesis under test was whether tissue heating invariably increases with field strength.*Methods and Materials Electromagnetic simulations were performed using a finite-difference time-domain solver (Sim4Life, ZMT) from 3 to 7 Tesla using a GPU (Tesla V100, NVIDIA). Orthopedic titanium bone screws of variable length (18 - 183 mm) were placed within a volume of 40x40x20cm3 with assigned dielectric properties of bone tissue at each field strength. The electromagnetic fields were generated using a dipole antenna, chosen to ensure a uniform background electric field at the implant location. The screws were placed 40 mm from the antenna center. Simulations were performed over160x160x160cm3 to avoid boundary effects, resulting in approx. 277 million cells and taking 4 hrs to run. The RF power delivered by the antenna was adjusted such that a B1+ field of 0.45 µT was achieved at the center of the implant in each scenario. The maximum 1g-averaged local SAR (SARmax) for each screw length and field strength was determined from each simulation. The effects of varying the tissue type in which the screw was embedded (bone, brain and muscle) were also investigated.*Results SARmax showed a peak around 4T with a 36% reduction at 7T. The implant length at which the SARmax was measured for all field strengths occurred at approximately one-third of the wavelength. The tissue's electric permittivity and conductivity had a large effect on the simulated SAR values, the peak of which was approximately 60% lower for muscle than bone.*Conclusions The data presented herein demonstrate that RF-induced tissue heating near metallic implants can, in certain circumstances, be lower at higher fields. SAR tissue values at 7T are higher adjacent to screws implanted in bone compared to either brain or muscle.*Clinical Relevance/Application This study dispels conventional wisdom that tissue heating adjacent to metallic implants must increase at 7 Tesla MRI, and will facilitate the wider clinical use of this technology in patients with such implants.

RESULTS

SARmax showed a peak around 4T with a 36% reduction at 7T. The implant length at which the SARmax was measured for all field strengths occurred at approximately one-third of the wavelength. The tissue's electric permittivity and conductivity had a large effect on the simulated SAR values, the peak of which was approximately 60% lower for muscle than bone.

CLINICAL RELEVANCE/APPLICATION

This study dispels conventional wisdom that tissue heating adjacent to metallic implants must increase at 7 Tesla MRI, and will facilitate the wider clinical use of this technology in patients with such implants.

SPR-PH-6   Applications And Benefits Of Using Traceable Phantoms From The NIST/NIBIB Medical Phantom Lending Library To Monitor MRI Scanner Performance

Participants
Stephen Russek, PhD, Boulder, Colorado (*Presenter*) Nothing to Disclose

PURPOSE

NIST has instituted a medical phantom lending library (https://www.nist.gov/programs-projects/nistnibib-medical-imaging-phantom-lending-library) to provide easy access to traceable medical phantoms and analysis software. These phantoms allow a wide variety of quality control (QC) checks and assessment of accuracy of many image-based measurements. Currently MRI system, diffusion, and breast phantoms are available, with more phantoms being added. Here, we show the utility of these phantoms for QC, scanner evaluation, and MRI technician training.*Methods and Materials The MRI system phantom contains a fiducial array for geometric distortion and image uniformity measurement, slice profile and resolution insets, a proton density inset for SNR, and 2 relaxation time arrays to measure accuracy of T1, T2 mapping. The diffusion phantom has 13 cells with 6 different isotropic diffusion coefficients that have well defined mono-exponential signal decay. Both phantoms include MRI readable thermometers to correct for variable bore temperatures. The phantom components were calibrated at NIST with traceability to the international system of units.*Results The fiducial sphere centers are located in a 3D GRE scan to within ±0.1 mm and are used to measure geometric distortion, which for the MRI scanners tested, varied from ±2 mm down to ±0.2 mm over a 200 mm field of view when postprocessing distortion corrections were included. Image uniformity measurements were mapped showing large coil/ scanner specific variations. Measurements of the resolution are made with an ACR-like resolution inset and can identify both protocol dependent resolution due to finite k-space sampling and intrinsic scanner resolution. The slice profile inset has been used to characterize the accuracy of the slice thickness as well as the shape of the slice profile. Large scanner to scanner variation in the slice profile has been observed. Finally, the MR-parameter arrays have been used to assess the accuracy of a variety of T1, T2 mapping protocols. The diffusion phantom has been used to assess the accuracy of ADC-mapping and error due to gradient nonuniformity. Typical measurements at 20C can determine the accuracy of ADC measurements to ±2% over the range of tissue ADC values.*Conclusions The phantoms from the public lending library allow for scanner QC measurements and assessment of the accuracy of MR parameter mapping. The phantoms have the advantage of being freely available and curated by a national metrology institute.*Clinical Relevance/Application Easily accessible curated phantoms will allow medical physicists and MR technicians to better understand and monitor scanner performance and allow radiologists to more precisely evaluate the accuracy of quantitative MR measurements.

RESULTS

The fiducial sphere centers are located in a 3D GRE scan to within ±0.1 mm and are used to measure geometric distortion, which for the MRI scanners tested, varied from ±2 mm down to ±0.2 mm over a 200 mm field of view when postprocessing distortion corrections were included. Image uniformity measurements were mapped showing large coil/ scanner specific variations. Measurements of the resolution are made with an ACR-like resolution inset and can identify both protocol dependent resolution due to finite k-space sampling and intrinsic scanner resolution. The slice profile inset has been used to characterize the accuracy of the slice thickness as well as the shape of the slice profile. Large scanner to scanner variation in the slice profile has been observed. Finally, the MR-parameter arrays have been used to assess the accuracy of a variety of T1, T2 mapping protocols. The diffusion phantom has been used to assess the accuracy of ADC-mapping and error due to gradient nonuniformity. Typical measurements at 20C can determine the accuracy of ADC measurements to ±2% over the range of tissue ADC values.

CLINICAL RELEVANCE/APPLICATION

Easily accessible curated phantoms will allow medical physicists and MR technicians to better understand and monitor scanner performance and allow radiologists to more precisely evaluate the accuracy of quantitative MR measurements.

SPR-PH-7   A Prototype Ultra-high-resolution CT For Extremities With 89-µm Detector Pitch: Design And Performance

Participants
Soei Shimokawa, Kanazawa, Japan (*Presenter*) Nothing to Disclose

PURPOSE

We developed a prototype ultra-high-resolution (UHR) CT for extremities using a complementary metal-oxide-semiconductor (CMOS) detector and a dedicated system design for achieving uncompromising UHR with 89-µm detector pitch and clinical availability. Unlike the bench top system with phantom rotation previously reported, the developed system has real gantry capable of scanning of human extremities. This study aims to evaluate the performance of this UHR CT.*Methods and Materials The CMOS detector (1536 channels, 440 rows) equipped with a fiber grid (grid ratio, 12:1; grid density, 64 lines/cm) was located opposite to the compact X-ray tube (focal spot size, 0.8 mm) on a metallic ring rail. The rotation speed of the ring rail was controlled by a high-speed stepping motor. 500 projections of 36 mm z-directional coverage were obtained with a rotation for 5 s. CT images with both pixel pitch and increment of 100 µm were reconstructed by the Feldkamp algorithm. Spatial resolution (modulation transfer function: MTF), and noise (noise power spectrum: NPS) were measured, and these values were compared with those measured using a clinical UHR CT system with 0.25 mm detector (Precision, Canon Medical). Additionally, an anthropomorphic foot phantom including dry bones was imaged to assess the visibilities of three-dimensional (3D) microstructures of trabecular bones.*Results The measured CTDIw was 8.4 mGy. The 5%MTF were 4.0 mm-1, which was notably higher than that of the clinical UHR CT (2.6 mm-1). However, NPS was ~15% higher at low frequencies due to the less sensitivity of the CMOS detector. Even with non-edge-enhanced reconstruction kernels, the trabecular bones of the foot phantom were clearly visualized in 3D voxel data with the 100-µm pitch.*Conclusions The developed CT system provided notably clear UHR images of trabecular bones without the help of edge-enhanced reconstruction kernels. The images were significantly clearer than those of clinical UHR CT. Unlike the bench top system, this system first demonstrated a clinical availability of UHR CT system that can analyze microstructures in extremities.*Clinical Relevance/Application The non-edge-enhanced images of developed CT could provide quantitative analysis of 3D trabecular bone structure in extremities and detect of occult fracture and microhemorrhage in extremities.

RESULTS

The measured CTDIw was 8.4 mGy. The 5%MTF were 4.0 mm-1, which was notably higher than that of the clinical UHR CT (2.6 mm-1). However, NPS was ~15% higher at low frequencies due to the less sensitivity of the CMOS detector. Even with non-edge-enhanced reconstruction kernels, the trabecular bones of the foot phantom were clearly visualized in 3D voxel data with the 100-µm pitch.

CLINICAL RELEVANCE/APPLICATION

The non-edge-enhanced images of developed CT could provide quantitative analysis of 3D trabecular bone structure in extremities and detect of occult fracture and microhemorrhage in extremities.

SPR-PH-8   Multi-organ Universal Lesion Detection In CT Scans: An Independent External Validation

Participants
Lianyan Xu, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

Multi-organ universal lesion detection in CT scans has been actively developed since NIH DeepLesion dataset was released in 2018. We aim to evaluate the performance and assess the clinical indications of a latest development via an external user study in a real-world clinical setting.*Methods and Materials Our universal lesion detection system consists of a convolutional neural network (CNN) trained on 80K lesion annotations from 12K CT studies in the DeepLesion dataset and five other public organ-specific datasets. Our external test sets include 164 non-contrasted chest/upper-abdomen CT scans collected from a private external hospital, and 187 low-dose helical CT scans from the National Lung Screening Trial (NLST). The private test set is a successive selection of CT scans stored in this hospital's PACS from Feb to March in 2021. NLST test set consists of randomly selected patients with reported cancer or metastasis. We run our algorithm on these two test sets to output lesion detection. Then, two board-certified radiologists read the CT scans and verify the detection results. Tumor-like lesions at all extrapulmonary organs including the liver, kidney, pancreas, thyroid, lymph nodes, body wall, thoracic spine, etc. at visualized CT images are recorded and measured. One of our goals is detecting and assessing the incidental findings from NLST.*Results In the private dataset, the lesion-level precision and sensitivity of our algorithm are 58% and 66%, respectively. On average, our algorithm detects 2.1 findings per scan, and among them, 0.9 are FPs. We find that our algorithm works well at liver lesions with 79% precision and 93% sensitivity, followed by kidney with 70% precision and 58 % sensitivity. It is also sensitive to contour and density change in pancreas with 50.00% sensitivity and 50.00% precision. Note that our algorithm discovers the only one body wall's lesion in 164 scans. There are still some normal structures misclassified as lesions. In the NLST test set, we obtain 75 % precision and 52% sensitivity despite the relatively high noise level in the soft tissue. The accuracy is relatively higher on liver lesions and thoracic lymph nodes.*Conclusions The performance of multi-organ universal lesion detection on external real-world data has shown good promise on a multiple-purposed CAD system. It is trained on public datasets such as DeepLesion but can generalize well to external validation data, annotated by external clinical sites.*Clinical Relevance/Application Our algorithm is helpful for large-scale CT screening and triage to prioritize patients with

significant lesions for clinicians to read first. It may also reduce their missing rate and workload by pre-selecting suspicious lesions.

RESULTS

In the private dataset, the lesion-level precision and sensitivity of our algorithm are 58% and 66%, respectively. On average, our algorithm detects 2.1 findings per scan, and among them, 0.9 are FPs. We find that our algorithm works well at liver lesions with 79% precision and 93% sensitivity, followed by kidney with 70% precision and 58 % sensitivity. It is also sensitive to contour and density change in pancreas with 50.00% sensitivity and 50.00% precision. Note that our algorithm discovers the only one body wall's lesion in 164 scans. There are still some normal structures misclassified as lesions. In the NLST test set, we obtain 75 % precision and 52% sensitivity despite the relatively high noise level in the soft tissue. The accuracy is relatively higher on liver lesions and thoracic lymph nodes.

CLINICAL RELEVANCE/APPLICATION

Our algorithm is helpful for large-scale CT screening and triage to prioritize patients with significant lesions for clinicians to read first. It may also reduce their missing rate and workload by pre-selecting suspicious lesions.

SPR-PH-9   **Image Characteristics Of Virtual Monochromatic Images With Deep Learning-based Image Reconstruction In Fast-kilovoltage Switching Dual-energy CT In Patients With Pancreatic Ductal Adenocarcinoma**

Participants
Akiyo Fukutomi, MS, RT, Kobe, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Contrast-enhanced CT with high image quality is essential for the diagnosis of pancreatic ductal adenocarcinoma (PDAC). Although virtual monochromatic images (VMI) obtained from dual-energy CT (DECT) can improve tissue contrast, increased image noise at low kiloelectron-volt (keV) may have a concern. To improve image quality, deep learning-based image reconstruction (DLIR) has been recently implemented into fast-kilovoltage (kV) switching DECT. The purpose of this study was to evaluate image characteristics of VMI with DLIR in fast-kV switching DECT in patients with PDAC.*Methods and Materials This retrospective study included 30 patients (21 males; mean age, 70.3 years) with PDAC who underwent contrast-enhanced fast-kV switching DECT (Revolution CT; GE Healthcare). Image data on arterial and portal venous phase were reconstructed with 1.25-mm section thickness using iterative reconstruction (ASiR-V 30% and 50%) and DLIR (True Fidelity medium). Image noise of the paraspinal muscle (PsM) and contrast-to-noise ratio (CNR) of the pancreas, artery, portal vein, and liver were calculated on 70 keV VMI as follows: $CNR_{Object} = (HU_{Object} - HU_{PsM}) / image\ noise$. Pancreas-to-lesion CNR was calculated on VMI at 40-100 keV in 10 keV intervals as follows: $Pancreas\text{-}tumor\ CNR = (HU_{Pancreas} - HU_{Tumor}) / image\ noise$. The calculated values were compared among the three reconstruction algorithms by using one-way repeated measures ANOVA test with Bonferroni correction. In addition to the patient examinations, a phantom experiment using noise power spectra (NPS) generated from a water phantom was performed to examine the variance and spatial frequency characteristics of image noise.*Results The image noise was significantly lower on 70 keV VMI using True Fidelity than that using ASiR-V 30% and 50% (P<.001 for all). The CNRsobject were significantly higher on 70 keV VMI using True Fidelity (P<.001 for all), while CT values were consistent among the three reconstruction algorithms (P=.891-.999). True Fidelity yielded significantly higher pancreas-tumor CNR at each keV VMI compared with ASiR-V 30% (P<.0001) and ASiR-V 50% (P=.015-.046), and these differences were greater as the lower keV VMIs. In the NPS curves, the True Fidelity yielded quantifiable noise reduction across the entire spectrum of spatial frequencies, which was more prominent at lower spatial frequencies.*Conclusions DLIR can improve image quality in fast-kV switching DECT, in which noise reduction characteristics are beneficial for the abdomen. VMI using DLIR can provide higher contrast with less image noise in the diagnosis of PDAC.*Clinical Relevance/Application DLIR contributes to improved image quality in VMI of the abdomen, and lower keV images may yield higher diagnostic performance of PDAC.

RESULTS

The image noise was significantly lower on 70 keV VMI using True Fidelity than that using ASiR-V 30% and 50% (P<.001 for all). The CNRsobject were significantly higher on 70 keV VMI using True Fidelity (P<.001 for all), while CT values were consistent among the three reconstruction algorithms (P=.891-.999). True Fidelity yielded significantly higher pancreas-tumor CNR at each keV VMI compared with ASiR-V 30% (P<.0001) and ASiR-V 50% (P=.015-.046), and these differences were greater as the lower keV VMIs. In the NPS curves, the True Fidelity yielded quantifiable noise reduction across the entire spectrum of spatial frequencies, which was more prominent at lower spatial frequencies.

CLINICAL RELEVANCE/APPLICATION

DLIR contributes to improved image quality in VMI of the abdomen, and lower keV images may yield higher diagnostic performance of PDAC.

SSPH04-1 Evaluation Of Image Quality And Artifact In Deep Learning Reconstruction Method Using An ACR Phantom

Participants
Mo Kadbi, PhD, Irvine, California (*Presenter*) Employee, Canon Medical Systems Corporation;

PURPOSE

In MR imaging using conventional reconstruction (CR), it is required to repeat and average the acquisitions to increase the image Signal-to-Noise Ratio (SNR). Deep Learning Reconstruction (DLR) is an emerging technique that can be utilized to improve the MR image quality by increasing SNR and reducing potential image artifacts without increasing the scan time. In addition, increased SNR can be used to improve spatial resolution without sacrificing image quality. In this study, an ACR phantom was used to evaluate DLR's performance in improving spatial resolution and SNR, preserving image contrast, and reducing imaging artifacts while maintaining image structures and details.*Methods and Materials An ACR phantom was scanned on a 3T scanner using the standard ACR protocol, including axial T1 and T2 sequences. The images were reconstructed using CR with no post-processing filter as well as DLR. The axial T1 scan was repeated with higher resolution and reconstructed using CR and DLR. The resolution was increased from 1x1 mm2 in standard ACR protocol to 0.3x0.3 mm2 in the high-resolution (HR) scan to investigate the impact of DLR on SNR in HR images. Based on ACR guidelines, High-Contrast spatial Resolution (HCR) and Low-Contrast Detectability (LCD) tests were performed on both CR and DLR images. Additionally, SNR and artifacts were investigated for both reconstruction methods.*Results The HCR test of both standard and HR T1 images reconstructed using CR and DLR passed the ACR test, but the ringing artifact was significantly reduced in images with DLR compared to CR. Similarly, both CR and DLR images with standard and HR T1 images passed the LCD test of ACR phantom with similar detectability of low contrast spokes. Reducing noise and ringing artifact in DLR helped to better visualize very small spokes compared to CR. In both standard and high-resolution T1 images, the SNR was measured on the uniform section of the phantom using both CR and DLR. In the standard T1, SNR using the DLR was 12% higher than the CR. In the high-resolution image, the SNR was increased by 173% using DLR. The SNR improvement is more noticeable in high-resolution images as the original images are inherently noisier. This SNR improvement can help to better detect the small details.*Conclusions This study affirms that with the DLR method, the image quality can be improved by increasing the spatial resolution and SNR. Additionally, the DLR can reduce the ringing artifact assisting to detect the small details in the images.*Clinical Relevance/Application Deep learning reconstruction improves SNR and reduces ringing artifact, while preserving image detail and passing the ACR test. It can be also used to increase the spatial resolution without compromising SNR.

RESULTS

The HCR test of both standard and HR T1 images reconstructed using CR and DLR passed the ACR test, but the ringing artifact was significantly reduced in images with DLR compared to CR. Similarly, both CR and DLR images with standard and HR T1 images passed the LCD test of ACR phantom with similar detectability of low contrast spokes. Reducing noise and ringing artifact in DLR helped to better visualize very small spokes compared to CR. In both standard and high-resolution T1 images, the SNR was measured on the uniform section of the phantom using both CR and DLR. In the standard T1, SNR using the DLR was 12% higher than the CR. In the high-resolution image, the SNR was increased by 173% using DLR. The SNR improvement is more noticeable in high-resolution images as the original images are inherently noisier. This SNR improvement can help to better detect the small details.

CLINICAL RELEVANCE/APPLICATION

Deep learning reconstruction improves SNR and reduces ringing artifact, while preserving image detail and passing the ACR test. It can be also used to increase the spatial resolution without compromising SNR.

SSPH04-2 Projection-domain Material Decomposition In A Dual-layer Flat-panel Detector Using Perceptron Neural Networks

Participants
Wenying Wang, Baltimore, Maryland (*Presenter*) Nothing to Disclose

PURPOSE

Geometric misalignment between layers and layer-dependent spatial resolution can degrade material decomposition estimates using dual-layer flat-panel detectors (FPDs). We investigate data-driven methods for projection-domain decomposition (PDD) that can compensate for these effects.*Methods and Materials Using a dual-layer FPD simulator with spectral, geometric, and scintillator blur models to emulate a prototype (Varex) detector, we trained two perceptron neural networks for PDD using pixel-wise and 3x3 patch inputs, respectively. Both models employed two hidden layers of 48 neurons each with ELU activation and training with ground-truth iodine line-integrals. The training and testing data were simulated from 1000 procedurally generated water-iodine phantoms - including both ideal projection datasets without the misalignment and blur and a realistic dataset with a complete physical model.

Decomposition accuracy was evaluated by mean absolute errors on a test dataset and in quantitative studies using specialized cylindrical iodine inserts of varying sizes.*Results Compared with traditional polynomial PDD, the perception networks showed significant improvements in quantitative accuracy. Using patch inputs yields significant improvements over pixel-wise input, yielding reconstruction accuracy improvements of 60%. The patch-wise model trained on a realistic dataset outperforms the others in contrast quantification test by 10%. The contrast recovery rate increase with increasing size and is above 88% for cylinders of diameter greater 0.5 mm.*Conclusions Two perceptron neural networks were trained for PDD in a dual-layer FPD. The proposed methods achieve better quantification over traditional methods. Patch inputs allow for better reduction of the bias induced by the geometric mismatch and layer-dependent blur.*Clinical Relevance/Application Dual-layer FPDs permit material decomposition enabling, e.g., high-resolution angiography. The proposed methods maintain accuracy and improve small vessel visualization in the presence of realistic degradations.

RESULTS

Compared with traditional polynomial PDD, the perception networks showed significant improvements in quantitative accuracy. Using patch inputs yields significant improvements over pixel-wise input, yielding reconstruction accuracy improvements of 60%. The patch-wise model trained on a realistic dataset outperforms the others in contrast quantification test by 10%. The contrast recovery rate increase with increasing size and is above 88% for cylinders of diameter greater 0.5 mm.

CLINICAL RELEVANCE/APPLICATION

Dual-layer FPDs permit material decomposition enabling, e.g., high-resolution angiography. The proposed methods maintain accuracy and improve small vessel visualization in the presence of realistic degradations.

SSPH04-3 Estimation Of Local Vascular Velocity Using Contrast Dilution Gradients (CGD) From 1000 Fps High Speed Angiography

Participants
Kyle Williams, BS, Buffalo, New York (*Presenter*) Nothing to Disclose

PURPOSE

Estimation of blood flow velocity from 2D angiography using contrast dilution gradients (CDG), has been limited due to detector temporal resolution restrictions. Recent imaging technology breakthrough allows unprecedented 1000 fps temporal resolution. This work applies a CDG method to recover hemodynamic information from high speed angiography (HSA) in the neurovascular domain using precise in-vitro simulations.*Methods and Materials According to CDG theory, the spatial contrast gradient and the contrast derivative are covariates related by velocity (diffusion negligible). The CDG algorithm used here maps contrast changes in arterial centerline profiles as a function of frame number to obtain a "contrastagram", which allows velocity estimation along the artery as a function of time using temporal and spatial derivatives. We validated the method using noiseless simulations, then tested it with HSA in patient-specific 3D printed phantoms at 1000 fps under constant flow conditions using the Direct Conversion Inc. Actaeon photon-counting detector. Ground truth velocities along the centerline were obtained using Computational Fluid Dynamics (CFD) with boundary conditions obtained from the experiment. CDG velocities were compared with CFD calculations. To assess the dependence of the method on temporal resolution, angiographic sequences at frame rates of 500, 250, 100, 50, 25, and 10 fps were simulated via retrospective temporal binning of 1000 fps acquisitions.*Results For computer-simulated angiograms, the CDG method showed strong agreement with expected velocity values (MSE = 0.00, p = 0.001). For HSA, the best results were obtained at 1000 fps with a percent difference of 1.2% between CDG and CFD. With decreasing frame rate, the percent difference between CDG and CFD increases with a substantial increase to 78% difference when using 100 fps.*Conclusions The results indicate that high speed angiography could be used for accurate estimation of velocity in neurovascular applications at temporal resolutions at or above 250 fps.*Clinical Relevance/Application CDG with HSA can be used to estimate local 2D flow velocities in complex vascular geometries. This data may be used for image guided surgery or to assess vascular lesion severity.

RESULTS

For computer-simulated angiograms, the CDG method showed strong agreement with expected velocity values (MSE = 0.00, p = 0.001). For HSA, the best results were obtained at 1000 fps with a percent difference of 1.2% between CDG and CFD. With decreasing frame rate, the percent difference between CDG and CFD increases with a substantial increase to 78% difference when using 100 fps.

CLINICAL RELEVANCE/APPLICATION

CDG with HSA can be used to estimate local 2D flow velocities in complex vascular geometries. This data may be used for image guided surgery or to assess vascular lesion severity.

SSPH04-4 Automatic Windowing Parameter Estimation For Chest Radiographs: A Deep Learning Approach

Participants
HyunJoon An, PhD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

The windowing process is an important preliminary step for handling chest X-ray (CXR) images. However, in rare cases, inappropriate window level (WL) and window width (WW) could be set by CXR devices and/or stored by the readers in PACS. Since these images could lead to critical problems when fed into various downstream processes such as CADe and CADx, we propose and evaluate a deep learning-based regression model to automatically estimate the windowing parameters.*Methods and Materials The dataset consists of 31,466 CXR images with corresponding windowing parameters, WW and WL, stored in DICOM format. The images were collected from several hospitals, scanned with equipment from various manufacturers. If not handled properly, raw pixel data of CXR images would have visually inappropriate contrast by markers attached to the X-ray device or various medical devices implanted in the patient. We trained a model using these raw pixel data as an input variable and the windowing parameters as target variables to adjust the appropriate contrast. Each input and target variables with a scale of 12/16 bits were normalized to a value of 0 to 1 to prevent numerical problems. The EfficientNet-B0 was used as the regression model and was optimized using stochastic gradient descent with mean squared error on two target variables, WL and WW. The model was evaluated on both mean absolute error (MAE) and mean absolute percentage error (MAPE). MAE was calculated at a scale of 8 bits to give more intuitive results, because most medical displays used in industry support 8-bit resolution.*Results The regression model showed MAE of 6.63 and MAPE, a measure irrelevant to the value scale, of 5.78% on 7,866 validation images. Additionally, qualitative evaluation was performed on samples with high MAEs, and these samples were confirmed that the windowing parameters were actually stored inappropriately.*Conclusions We have developed a deep learning-based regression model for windowing parameter estimation and

shown to accurately predict these parameters with only pixel data as input. However, from a practical point of view, estimating windowing parameters using a 2D image-based deep learning model could be a heavy process. Therefore, further studies are required such as converting to 1D signal or using a lighter model.*Clinical Relevance/Application This method of estimating windowing parameters could reduce the process of adjusting WL and WW, which is a process that consumes the reader's time and energy, and provide more appropriate input images to downstream tasks such as CADe or CADx.

RESULTS

The regression model showed MAE of 6.63 and MAPE, a measure irrelevant to the value scale, of 5.78% on 7,866 validation images. Additionally, qualitative evaluation was performed on samples with high MAEs, and these samples were confirmed that the windowing parameters were actually stored inappropriately.

CLINICAL RELEVANCE/APPLICATION

This method of estimating windowing parameters could reduce the process of adjusting WL and WW, which is a process that consumes the reader's time and energy, and provide more appropriate input images to downstream tasks such as CADe or CADx.

SSPH04-5   A Low-dose Multi-contrast Chest X-ray Radiography Prototype System With Single-shot Acquisition In A Single Breath Hold

Participants
Ran Zhang, PhD, Madison, Wisconsin (*Presenter*) Nothing to Disclose

PURPOSE

In conventional chest x-ray radiography (CXR), pulmonary lesions are often blocked by overlapping ribs such that they are difficult to detect due to their relatively low contrast compared to the surrounding lung tissues. In this work, we report a low-dose and multi-contrast CXR imaging system that can provide three mutually complementary images from a single acquisition: the conventional absorption contrast, the differential phase contrast, and the dark field contrast images to jointly enhance the imaging functionality of CXR.*Methods and Materials The constructed multi-contrast CXR system consists of a motorized patient table and a gantry to hold the x-ray tube, the flat-panel detector, and the gratings. During data acquisitions, the patient is scanned in a scanning mode while the table moves along the superior-inferior (SI) direction. The system employs several technical innovations to achieve data acquisition of the entire chest with a coverage of 28 cm along the SI direction within 4 seconds. The initial imaging performance tests were performed using an anthropomorphic chest phantom. To simulate potential lung nodules, a container containing microbubble powder and calcium hydroxyapatite was attached onto the chest phantom. The phantom was scanned at a speed of 7 cm/s. The tube was operated in a pulse-fluoro mode with 70 kVp, 60 mA, and a duty cycle of 40%. The exposure was measured using a 10X6-6 RadCal 6 cc chamber and was converted to air kerma and effective dose.*Results The estimated air kerma and effective dose were 53 uGy and 9.2 uSv, respectively, which is well below the effective dose for a typical CXR (~20 uSv). The quality of the absorption contrast image matches that of conventional CXR. In addition, the dark field image revealed the microbubble and the calcium hydroxyapatite, which was invisible in the absorption image due to anatomical noise. No table translation-induced artifacts were observed in the multi-contrast CXR images.*Conclusions A new prototype multi-contrast CXR system was developed to enable low radiation dose and fast scans of human chest-sized objects within 4 seconds.*Clinical Relevance/Application The new multi-contrast CXR system offers the potential to improve the clinical diagnosis and screening of lung diseases such as screening for lung cancer.

RESULTS

The estimated air kerma and effective dose were 53 uGy and 9.2 uSv, respectively, which is well below the effective dose for a typical CXR (~20 uSv). The quality of the absorption contrast image matches that of conventional CXR. In addition, the dark field image revealed the microbubble and the calcium hydroxyapatite, which was invisible in the absorption image due to anatomical noise. No table translation-induced artifacts were observed in the multi-contrast CXR images.

CLINICAL RELEVANCE/APPLICATION

The new multi-contrast CXR system offers the potential to improve the clinical diagnosis and screening of lung diseases such as screening for lung cancer.

SSPH04-6   In Vivo Relative Dosimetry With Xact Imaging: A Feasibility Study

Participants
Kiana Prather, BS, Oklahoma City, Oklahoma (*Presenter*) Nothing to Disclose

PURPOSE

In the thermoacoustic phenomenon, acoustic waves are generated by objects irradiated by short-pulsed ionizing radiation due to transient local temperature change. The thermoacoustic effect has been increasingly investigated as a novel imaging modality. One of the potential applications capitalizing on this phenomenon is X-ray acoustic computed tomography (XACT), which utilizes acoustic waves generated by X-ray beams that are clinically available. The field of XACT has garnered growing interest as a potential tool for in vivo dosimetry during radiotherapy at no extra radiation. This study aims to investigate the feasibility of using XACT as a relative dosimetry tool without the use of additional marker.*Methods and Materials X-ray acoustic (XA) signals generated from an X-ray beam in water were collected by a single element, broadband ultrasound transducer submerged in water (Fig. 1a). The XA signal was amplified by a 60-dB Olympus preamplifier and acquired on an oscilloscope with 1024 averaging at a 5 MHz sampling rate. The beam was delivered by a Varian TrueBeam system at 10 MV flattening filter free (FFF) and 6 MV FFF energy with a 4 μs pulse duration. To capture the change in X-ray dose with increasing water depth, the height of the transducer was varied from 2.60 cm to 11.00 cm from the water surface at multi-millimeter steps. The peak-to-peak amplitude of the beam edge XA signal was plotted against the transducer depth, and the XACT image was reconstructed in MATLAB using back-projection after 10 kHz high-pass filtering.*Results XA signals from the near and far edges of the X-ray beam corresponding to the field size can be observed (Fig. 1b). As the transducer depth is increased, the signal amplitude decreases, while the signal profile remains largely unchanged (Fig. 2a). Fig. 2b demonstrate the near linear relationship between the near-edge XA signal amplitude and the transducer depth, which is comparable to the percentage depth dose curves of 10 and 6 MV beams within this depth range. A reconstruction of the depth plane of the beam is shown in Fig. 3, with the near and far edges of the beam visible at ~4 cm apart.*Conclusions This study demonstrates the feasibility of relative dosimetry using XACT imaging. While a more robust method to quantify the XA signals is warranted, the results of this study contribute to further advancing utilizing XACT to improve the precision of X-ray based radiotherapy.*Clinical Relevance/Application There currently does not exist an in vivo, direct dosimetry method for radiotherapy. This study demonstrates the feasibility of XACT as a non-invasive and affordable dosimetry method that

can be used during patient treatment with no additional radiation to improve the safety and accuracy of photon-based radiotherapy.

RESULTS

XA signals from the near and far edges of the X-ray beam corresponding to the field size can be observed (Fig. 1b). As the transducer depth is increased, the signal amplitude decreases, while the signal profile remains largely unchanged (Fig. 2a). Fig. 2b demonstrate the near linear relationship between the near-edge XA signal amplitude and the transducer depth, which is comparable to the percentage depth dose curves of 10 and 6 MV beams within this depth range. A reconstruction of the depth plane of the beam is shown in Fig. 3, with the near and far edges of the beam visible at ~4 cm apart.

CLINICAL RELEVANCE/APPLICATION

There currently does not exist an in vivo, direct dosimetry method for radiotherapy. This study demonstrates the feasibility of XACT as a non-invasive and affordable dosimetry method that can be used during patient treatment with no additional radiation to improve the safety and accuracy of photon-based radiotherapy.

SPR-PD-1   **Detecting Pediatric Wrist Fractures Using Deep Learning-based Object Detection**

Participants
John Zech, MD,MA, New York, New York (*Presenter*) Nothing to Disclose

PURPOSE

Buckle fractures of the distal radius are unique to pediatric patients, and may be unrecognized due to their subtle presentation on imaging. We investigated the ability of a deep learning framework to detect acute pediatric wrist fractures and specifically evaluated its ability to detect buckle fractures.*Methods and Materials A sample of 1144 radiographs from 397 examinations of 397 patients under the age of 18 who had wrist radiographs performed between 1/9/2015-11/15/2019 containing at least two orthogonal projections were obtained (mean age 10.1 years, min 0.82, max 17.84; 37.5% female; 64.4% positive for fracture; 29.7% positive for buckle fracture). Only examinations that served as an initial evaluation for fracture were considered for inclusion. The available radiographs were divided into train (n=791 radiographs, 272 examinations) and test (n=353 radiographs, 125 examinations) datasets. The report of the attending radiologist served as ground truth.Bounding boxes containing imaging findings indicative of buckle fracture were manually segmented. For each image containing no pathologic findings, a background bounding box was randomly generated. A Faster R-CNN was trained in PyTorch 1.7.0 [1,2] using the Detectron2 library [3] contributed by Facebook AI Research (1000 epochs, batch size 10, learning rate 0.01). A classification probability of 85% was required to consider a region a positive for pathology. The maximum probability over all regions predicted by the model across images corresponding to a single examination served as the model's overall prediction.*Results The model demonstrated AUC of 93.6%, accuracy of 92.9% (n=117/127), sensitivity of 93.9% (n=77/82), and specificity of 88.9% (n=40/45) in identifying any fracture. It accurately identified 97.5% of buckle fractures (n=39/40).*Conclusions An object detection-based deep learning approach was able to detect pediatric wrist fractures with high accuracy. Of note, the model demonstrated strong ability to detect subtle buckle fractures.*Clinical Relevance/Application This approach may be used to assist in detection of these fractures.References:1. PURPOSE

Hepatic veno-occlusive disease (VOD) is one of the complications following hematopoietic stem cell transplantation (HSCT). This study aimed to assess the usefulness of two-dimensional shear wave elastography (2D-SWE) for predicting hepatic VOD in pediatric patients who underwent HSCT.*Methods and Materials Pediatric patients who received HSCT between November 2019 and January 2021 were monitored for the presence or absence of sonographic signs of VOD using grayscale, color doppler, and 2D-SWE ultrasound examination once a week for 4-week. Ultrasound parameters were assessed as follows: the craniocaudal length of the liver at the mid-clavicular level, the presence of ascites, gallbladder wall edema, resistance index of hepatic arteries, peak velocity and flow direction of hepatic and portal veins, and median liver stiffness value on 2D-SWE. The clinical diagnosis and assessment were based on the European Society for Blood and Marrow Transplantation (EBMT) pediatric criteria. Each parameter was compared between VOD and non-VOD group using unpaired t-test and Chi-square test. The risk of VOD in an individual in relation to ultrasound parameters which were repeatedly measured was analyzed using the generalized estimating equation.*Results A total of 34 (27 allogenic and 7 autologous) patients were included in our study. The patients' demographics were as follows: the median age of 8 years (range 2-21 years), and 18 boys (52.9%). The grayscale ultrasound of the VOD group revealed gallbladder wall edema, ascites, and hepatomegaly more frequently (p-value<0.001). However, there was no significant difference in the color doppler parameters. The liver stiffness value of the VOD group was higher than the non-VOD group (12.5±5.2 vs. 5.9±2.6 kPa, p-value<0.001). When the liver stiffness value increased by one unit, the risk of VOD occurrence for an individual was 1.703 times

[95%C.I: 1.263, 2.296] (p-value=0.001).*Conclusions Patients who developed VOD had signi&7;cantly increased liver stiffness as measured by 2D-SWE compared to patients who did not develop VOD. Our study results show that changes in 2D-SWE can provide quantitative information for the risk of VOD than current conventional imaging criteria.*Clinical Relevance/Application The 2D-SWE offers the novel potential tool for VOD monitoring to help make early decision-making for therapeutic intervention that may impact the outcome of HSCT.

RESULTS

A total of 34 (27 allogenic and 7 autologous) patients were included in our study. The patients' demographics were as follows: the median age of 8 years (range 2-21 years), and 18 boys (52.9%). The grayscale ultrasound of the VOD group revealed gallbladder wall edema, ascites, and hepatomegaly more frequently (p-value<0.001). However, there was no significant difference in the color doppler parameters. The liver stiffness value of the VOD group was higher than the non-VOD group (12.5±5.2 vs. 5.9±2.6 kPa, p-value<0.001). When the liver stiffness value increased by one unit, the risk of VOD occurrence for an individual was 1.703 times [95%C.I: 1.263, 2.296] (p-value=0.001).

CLINICAL RELEVANCE/APPLICATION

The 2D-SWE offers the novel potential tool for VOD monitoring to help make early decision-making for therapeutic intervention that may impact the outcome of HSCT.

SPR-PD-12 Non-contrast Pulmonary MRI: Long-term Monitoring Of Structural Lung Disease In Patients With Cystic Fibrosis

Participants
Michael Esser, MD, Tuebingen, Germany (Presenter) Nothing to Disclose

PURPOSE

Phenotypic expression and pulmonary impairment vary substantially across cystic fibrosis (CF) patients. The purpose of this study was to evaluate the change in structural lung disease over 6 years assessed by pulmonary MRI (pMRI) and correlated to pulmonary function testing with forced expiratory volume in 1 s (FEV1).*Methods and Materials In this retrospective study CF patients were included with biennial pMRI continuing over at least 6 years and with pulmonary function testing. All pMRIs consisted of the same protocol and were conducted on a 1.5 T scanner (PDw Flash 3D in breath-hold, coronal T2w TSE with double-triggering and functional sagittal PDw Flash 2D sequence in submaximal in- and expiration). Structural lung disease was assessed per lung lobe using the semi-quantitative MR-CF-S scoring system, which comprises bronchiectasis/peribronchial wall thickening, mucus plugging, centrilobular opacities, consolidation, sacculation, and air trapping. For better comparison, z-scores were calculated for each patient`s examination and pulmonary function testing, which were correlated to time.*Results 41 patients (mean age 10.2±5.2 years, 19 males, 22 females) were included. Over a 6 year period, an overall decrease of FEV1 of -0.77 % per year (SD 2.1) was observed with a baseline FEV1 of 91.1% (SD 14.3). Concurrently, the baseline MR-CF-S with an average of 5.6±5.0 showed an increase of 6.4 points (SD 3,69) over the 6 years. There was a significant difference in the z-scores that were correlated to the examination time points: z-FEV1 (-1) showed a slope of 0.03 (p=0.38) and z-MR-CF-S 0.14 (p<0.001). The most significant categorical differences in z-MR-CF-S were seen for bronchiectasis and air trapping.*Conclusions The increase in MR-CF-S over the 6 years showed a significantly swifter disease progression than FEV1, suggesting that the pMRI is more sensitive than pulmonary function testing.*Clinical Relevance/Application CF patients can benefit from biennial pulmonary MRIs. MR-CF-S scoring system is a reliable marker for long-term disease evaluation.

RESULTS

41 patients (mean age 10.2±5.2 years, 19 males, 22 females) were included. Over a 6 year period, an overall decrease of FEV1 of -0.77 % per year (SD 2.1) was observed with a baseline FEV1 of 91.1% (SD 14.3). Concurrently, the baseline MR-CF-S with an average of 5.6±5.0 showed an increase of 6.4 points (SD 3,69) over the 6 years. There was a significant difference in the z-scores that were correlated to the examination time points: z-FEV1 (-1) showed a slope of 0.03 (p=0.38) and z-MR-CF-S 0.14 (p<0.001). The most significant categorical differences in z-MR-CF-S were seen for bronchiectasis and air trapping.

CLINICAL RELEVANCE/APPLICATION

CF patients can benefit from biennial pulmonary MRIs. MR-CF-S scoring system is a reliable marker for long-term disease evaluation.

SPR-PD-13 Postnatal Urinary Tract Dilation Classification System For Assessing Surgical Outcome In Neonates And Young Infants

Participants
Jisun Hwang, MD, Hwaseong-si, Korea, Republic Of (Presenter) Nothing to Disclose

PURPOSE

To validate postnatal urinary tract dilation (UTD) classification system proposed in 2014 by correlating with the need for surgical intervention*Methods and Materials We retrospectively identified young infants (= 3-months-old) who underwent postnatal US for evaluating prenatal hydronephrosis between 2010 and 2017. The children who underwent US within 48 hours after birth, did not undergo a follow-up US at least 30 days later, or were treated by fetal intervention were excluded. The kidney units (KUs; either right, left, or bilateral) were graded using the UTD classification system (P1 [low risk] to P3 [high risk]) based on seven US findings (anterior-posterior renal pelvic diameter, central and peripheral calyceal dilation, renal parenchymal thickness and appearance, bladder abnormalities, and ureteral abnormalities). The P0 (very low risk) was assigned for KUs which did not met the criteria of P1 but showed measurable pelvic dilatation. Kaplan-Meier analysis and log rank test were conducted to compare the need for surgical intervention among the groups. Multivariate Cox regression analysis was performed to determine predictors of surgical intervention among the US parameters of the UTD system.*Results A total of 517 KUs from 335 patients (mean age, 18.38 ± 15.88 days; range, 1 - 94 day; male, 275) who showed UTD on postnatal US were included with median follow-up of 24.2 months. Fifty-eight KUs (0 % [0 of 101 KUs] in P0, 1.0% [2 of 201 KUs] in P1, 15.9% [24 of 151 KUs] in P2, and 62.7% [32 of 51 KUs] in P3) underwent surgical intervention. Significant differences were observed among the Kaplan-Meier curves of the UTD groups by log-rank test (all P=0.001), except P0 vs. P1 (P=0.5). Anterior-posterior renal pelvic diameter (Hazard ratio [HR], 1.09; 95 CI, 1.61-10.95), peripheral calyceal dilation (HR, 8.10;95 CI, 2.39-27.47), ureteral dilation (HR, 4.90; 95 CI, 2.40-10.02), parenchymal thickness abnormality (HR, 4.09; 95 CI, 2.01-8.32), bladder abnormality (HR, 4.46; 95 CI, 1.72-11.56) were significantly associated with the occurrence of surgery (all P=0.001).*Conclusions Postnatal UTD classification system well stratified the risk of clinical outcome in terms of the need for surgical intervention. Peripheral calyceal dilation is the most predictive US sign.*Clinical Relevance/Application Postnatal UTD classification system well stratified the risk of clinical outcome in terms of the need for surgical intervention and it is a useful

system for diagnosis and management of postnatal UTD.

RESULTS

A total of 517 KUs from 335 patients (mean age, 18.38 ± 15.88 days; range, 1 - 94 day; male, 275) who showed UTD on postnatal US were included with median follow-up of 24.2 months. Fifty-eight KUs (0 % [0 of 101 KUs] in P0, 1.0% [2 of 201 KUs] in P1, 15.9% [24 of 151 KUs] in P2, and 62.7% [32 of 51 KUs] in P3) underwent surgical intervention. Significant differences were observed among the Kaplan-Meier curves of the UTD groups by log-rank test (all P=0.001), except P0 vs. P1 (P=0.5). Anterior-posterior renal pelvic diameter (Hazard ratio [HR], 1.09; 95 CI, 1.61-10.95), peripheral calyceal dilation (HR, 8.10;95 CI, 2.39-27.47), ureteral dilation (HR, 4.90; 95 CI, 2.40-10.02), parenchymal thickness abnormality (HR, 4.09; 95 CI, 2.01-8.32), bladder abnormality (HR, 4.46; 95 CI, 1.72-11.56) were significantly associated with the occurrence of surgery (all P=0.001).

CLINICAL RELEVANCE/APPLICATION

Postnatal UTD classification system well stratified the risk of clinical outcome in terms of the need for surgical intervention and it is a useful system for diagnosis and management of postnatal UTD.

SPR-PD-2   Ferumoxytol MRI Detects Joint Infiltration Of Bone Sarcomas In Pediatric Patients

Participants
Ashok Joseph Theruvath, MD, Stanford, California (*Presenter*) Nothing to Disclose

PURPOSE

The diagnosis of joint infiltration by a malignant bone tumor affects surgical management. The specificity of standard MRI for diagnosing joint infiltration is limited. During our MRI evaluations of pediatric bone sarcomas with ferumoxytol nanoparticles, we observed a surprising marked T1-enhancement of the joint effusion in some patients and not others. The purpose of this study was to evaluate, if nanoparticle extravasation differed between joints with and without tumor infiltration.*Methods and Materials We retrospectively identified 15 pediatric cancer patients and young adults (mean age 16±4 years) with bone sarcomas who underwent 18 MRI scans at 1 hour (n=7) or 24 hours (n=11) after intravenous ferumoxytol infusion. Twelve patients also received a gadolinium(Gd)-enhanced MRI. We determined the presence or absence of tumor invasion into the joint or pleural space, based on imaging findings (n=18) and histology (n=14). We compared the signal-to-noise ratio (SNR) and contrast-to-noise ratio (CNR) of the joint fluid for tumors with and without joint invasion using a Mann-Whitney test.*Results MRI scans at 24 hours after intravenous ferumoxytol infusion demonstrated a positive T1-enhancement of the effusion in all joints with tumor infiltration and no joint without infiltration. Corresponding SNR (P=0.0043) and CNR values (P=0.0043) were significantly higher for joints with than without tumor infiltration. By contrast, unenhanced MRI, Gd-enhanced MRI and 1 hour postcontrast ferumoxytol-MRI did not show any enhancement of the joint effusion, with or without tumor infiltration.*Conclusions This pilot study suggests that 24 hour postcontrast ferumoxytol-MRI scans can non-invasively differentiate between joints with and without tumor infiltration.*Clinical Relevance/Application Ferumoxytol-MRI can be used to determine joint infiltration status of patients with bone sarcoma and therefore can affect surgical management by stratifying patients towards more or less invasive surgeries.

RESULTS

MRI scans at 24 hours after intravenous ferumoxytol infusion demonstrated a positive T1-enhancement of the effusion in all joints with tumor infiltration and no joint without infiltration. Corresponding SNR (P=0.0043) and CNR values (P=0.0043) were significantly higher for joints with than without tumor infiltration. By contrast, unenhanced MRI, Gd-enhanced MRI and 1 hour postcontrast ferumoxytol-MRI did not show any enhancement of the joint effusion, with or without tumor infiltration.

CLINICAL RELEVANCE/APPLICATION

Ferumoxytol-MRI can be used to determine joint infiltration status of patients with bone sarcoma and therefore can affect surgical management by stratifying patients towards more or less invasive surgeries.

SPR-PD-3   Brain Tissue Relaxation Time And Cerebral Blood Flow In Preterm Neonates: Association With Neurodevelopmental Outcome

Participants
Hyun Gi Kim, MD, PhD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Both relaxation time and cerebral blood flow are known to reflect maturation in neonates' brains. Whether relaxation time or cerebral blood flow of early preterm neonates' brains is associated with later neurodevelopmental outcomes remains unknown. The objective of this study was to find out the association between either relaxation time or cerebral blood flow and later neurodevelopmental outcomes.*Methods and Materials this prospective study, preterm neonates in the intensive care unit were recruited and synthetic MRI and multi-delay arterial spin labeling (ASL) was performed before discharge. These neonates underwent the Bayley Scales of Infant Development test at 18 months of age and both cognitive and motor outcome scores were measured. T1 and T2 relaxation times and cerebral blood flow values in different brain regions were measured. Linear regression was done between 'regional relaxation times and neurodevelopmental outcome scores' and between 'cerebral blood flow values and neurodevelopmental outcome scores'.*Results Forty-nine neonates (median [interquartile range] gestational age, 209 [17] days; range, 169 - 245 days; 28 boys, 21 girls) underwent MRI scan at or near term equivalent age (median [interquartile range] corrected gestational age, 258 [15] days; range, 239 - 321 days). Gestational age at birth showed a positive relationship with cognitive score (P = .018) and was included as a confounding factor. After controlling for gestational age at birth, the frontal white matter T1 relaxation times were significantly associated with the cognitive scores (coefficient, 0.034; 95% confidence interval [CI], 0.005 - 0.063; P = .025). No other regional T1 and T2 relaxation times showed association with cognitive or motor scores. Frontal white matter cerebral blood flow values were significantly associated with the cognitive score after controlling for gestational age at birth (coefficient, -0.949; 95% CI, -1.807- -0.091; P = .031). No other regional cerebral blood flow values showed association with cognitive or motor scores.*Conclusions There were significant associations between 'T1 relaxation times and cerebral blood flow values in frontal white matter' acquired in preterm neonates and their later cognitive outcome.*Clinical Relevance/Application 'T1 and T2 relaxation times' and 'cerebral blood flow values' were measured in preterm neonates using synthetic MRI and multi-delay arterial spine labeling, respectively. Preterm neonate's brain tissue properties and developmental degrees were quantified by T1 and T2 relaxation times and cerebral blood flow values. Higher T1 relaxation times and lower cerebral blood flow values in frontal white matter were associated with better cognitive outcomes at age 18 months.

RESULTS

Forty-nine neonates (median [interquartile range] gestational age, 209 [17] days; range, 169 - 245 days; 28 boys, 21 girls) underwent MRI scan at or near term equivalent age (median [interquartile range] corrected gestational age, 258 [15] days; range, 239 - 321 days). Gestational age at birth showed a positive relationship with cognitive score (P = .018) and was included as a confounding factor. After controlling for gestational age at birth, the frontal white matter T1 relaxation times were significantly associated with the cognitive scores (coefficient, 0.034; 95% confidence interval [CI], 0.005 - 0.063; P = .025). No other regional T1 and T2 relaxation times showed association with cognitive or motor scores. Frontal white matter cerebral blood flow values were significantly associated with the cognitive score after controlling for gestational age at birth (coefficient, -0.949; 95% CI, -1.807--0.091; P = .031). No other regional cerebral blood flow values showed association with cognitive or motor scores.

CLINICAL RELEVANCE/APPLICATION

'T1 and T2 relaxation times' and 'cerebral blood flow values' were measured in preterm neonates using synthetic MRI and multi-delay arterial spine labeling, respectively. Preterm neonate's brain tissue properties and developmental degrees were quantified by T1 and T2 relaxation times and cerebral blood flow values. Higher T1 relaxation times and lower cerebral blood flow values in frontal white matter were associated with better cognitive outcomes at age 18 months.

SPR-PD-4   MRI-based Radiomics And Machine Learning For Ependymoma: An International Study

Participants
Edward Wang, London, British Columbia (*Presenter*) Nothing to Disclose

PURPOSE

Patients with posterior fossa ependymoma (PFE) routinely receive magnetic resonance (MR) imaging for diagnosis and surgical planning. PFEs are divided into two molecular subgroups (A versus B), with subgroup A having worse prognoses. Standard treatment of ependymomas is surgery with adjuvant radiation therapy. In this study, we extracted radiomic features from pre-treatment MR images to develop machine learning models for survival prognosis and tumour molecular classification.*Methods and Materials In the largest machine learning study of ependymoma, imaging and clinical data from 157 children (95M/62F, median age of 87 months) from 11 different international centers were evaluated. We manually isolated tumor volumes on T1-post contrast (T1) and T2-weighted (T2) MR images for high-dimensional feature extraction using PyRadiomics. We extracted 900 features on each image comprising first-order statistics, shape, size, and second-order texture features including Gray Level Co-occurrence Matrix (GLCM), Gray Level Run Length Matrix (GLRLM), Gray Level Size Zone Matrix (GLZM), Neighboring Gray Tone Difference Matrix (NGTDM), and Gray Level Dependence Matrix (GDLM). Proportional hazard Cox models were used for survival prediction, and logistic regression models were used for molecular subgroup classification. Least Absolute Shrinkage and Selection Operator (LASSO) was used to select the optimal features to feed into the model. The models were trained on T1 MR features only, T2 MR features only, and both T1 and T2 MR features. 4-fold nested cross validation was used for feature selection and model training.*Results T1 and T2 MR images were collected for 103 and 90 patients respectively. Molecular subtype information was available for 79 patients (64A/15B). T2 features were more predictive of survival status and T1 features were more predictive of molecular classification. A Cox model trained on T2 features that appeared in all 4 outer-loop folds was able to successfully stratify patients into high and low risk groups (p<0.05). A logistic regression model trained on T1 features was able to achieve an AUC of 0.86 [95% CI: 0.73-0.96]. GLZM features were consistently identified by LASSO for both survival analysis and molecular classification.*Conclusions Our pilot study shows the potential role for MR-based radiomics and machine learning for PFE risk stratification and molecular classification. Additional work is needed to validate the findings on an external dataset.*Clinical Relevance/Application These findings from an international cohort suggests that radiomic imaging features may assist clinicians in risk stratifying children at higher risk of progression to better personalize treatment options.

RESULTS

T1 and T2 MR images were collected for 103 and 90 patients respectively. Molecular subtype information was available for 79 patients (64A/15B). T2 features were more predictive of survival status and T1 features were more predictive of molecular classification. A Cox model trained on T2 features that appeared in all 4 outer-loop folds was able to successfully stratify patients into high and low risk groups (p<0.05). A logistic regression model trained on T1 features was able to achieve an AUC of 0.86 [95% CI: 0.73-0.96]. GLZM features were consistently identified by LASSO for both survival analysis and molecular classification.

CLINICAL RELEVANCE/APPLICATION

These findings from an international cohort suggests that radiomic imaging features may assist clinicians in risk stratifying children at higher risk of progression to better personalize treatment options.

SPR-PD-6   Evaluation Of Treatment Response In Children With Perianal Crohn's Disease Using Transperineal Ultrasonography

Participants
Jae-Hyeop Jung, MD, Seongnam, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To assess the accuracy of transperineal ultrasound (TPUS) for evaluating treatment response, compared with pelvis MRI and colonoscopic examination, in children with perianal CD (PACD).*Methods and Materials Twenty-nine children with PACD who underwent baseline and follow-up TPUS and pelvis MRI were included between January 2016 and February 2020. Perianal fistulae with or without abscesses were identified by their presence and location, and thickness of the fistula and size of the abscess were measured on each modality. The fistulae were classified according to Park's and St. James's University Hospital classifications. Two radiologists assessed the treatment response based on the fistula thickness and the abscess size of each baseline and follow-up examinations in consensus, and classified it into two groups; response and no response. Regarding the treatment response, the agreement between TPUS and MRI and between colonoscopy and MRI were assessed using the weighted Cohen kappa test. Interobserver agreement of perianal fistula thickness was evaluated by calculating the intraclass correlation coefficient (ICC). We evaluated intraobserver correlation of the fistula thickness between TPUS and MRI using the Pearson correlation coefficient.*Results Fifty-six fistulae (six superficial, forty-six intersphincteric, and four transsphincteric) with six-teen abscesses were detected using MRI. On MRI, thirty-nine fistulae (70%) showed a response, and the remaining seventeen fistulae did not show response. We evaluated the treatment response of forty-five and thirty-nine lesions using TPUS and colonoscopic examination, respectively. Thirty-three cases of treatment response on TPUS (accuracy 73.3%), and twenty-four cases of that on the colonoscopic exam (accuracy 61.5%) corresponded with MRI. Concerning evaluation for treatment response, the agreement between TPUS and MRI was moderate (kappa value 0.486), while the agreement between colonoscopy and MRI was slight (kappa value 0.180). The interobserver agreement in the measurement of the fistula thickness was excellent (ICC = 0.890-0.953), and the

fistula thickness between TPUS and MRI among intra-observers showed a strong positive correlation (Pearson correlation coefficient, 0.432-0.484, P < 0.001). Of 12 TPUS-MRI discordances, ten lesions (83%) demonstrated the response in MRI but remained unchanged in TPUS.*Conclusions TPUS is an appropriate, simple, and real-time method for evaluating the treatment response of perianal fistula with or without abscess in children with PACD.*Clinical Relevance/Application TPUS can be alternative to the pelvis MRI to evaluate treatment response in children with PACD compared to the colonoscopic exam.

RESULTS

Fifty-six fistulae (six superficial, forty-six intersphincteric, and four transsphincteric) with six-teen abscesses were detected using MRI. On MRI, thirty-nine fistulae (70%) showed a response, and the remaining seventeen fistulae did not show response. We evaluated the treatment response of forty-five and thirty-nine lesions using TPUS and colonoscopic examination, respectively. Thirty-three cases of treatment response on TPUS (accuracy 73.3%), and twenty-four cases of that on the colonoscopic exam (accuracy 61.5%) corresponded with MRI. Concerning evaluation for treatment response, the agreement between TPUS and MRI was moderate (kappa value 0.486), while the agreement between colonoscopy and MRI was slight (kappa value 0.180). The interobserver agreement in the measurement of the fistula thickness was excellent (ICC = 0.890-0.953), and the fistula thickness between TPUS and MRI among intra-observers showed a strong positive correlation (Pearson correlation coefficient, 0.432-0.484, P < 0.001). Of 12 TPUS-MRI discordances, ten lesions (83%) demonstrated the response in MRI but remained unchanged in TPUS.

CLINICAL RELEVANCE/APPLICATION

TPUS can be alternative to the pelvis MRI to evaluate treatment response in children with PACD compared to the colonoscopic exam.

SPR-PD-7   Simulated Dose Reduction And Snapshot In Total-body 18F-FDG PET/CT In Pediatric Patients Using The UEXPLORER Scanner

Participants
Yu-Mo Zhao, Guangzhou, China (*Presenter*) Nothing to Disclose

PURPOSE

Pediatric patients due to less tolerance and long lifetime expectance are susceptive to the ionizing radiation and the acquisition time for PET examinations. The purpose of this study was to explore the promising minimum threshold of the acquisition time and administered dose for 18F-fluorodeoxyglucose (18F-FDG) PET imaging in pediatric patients by using the digital PET/CT scanner with 194-cm long axial field-of-view -- uEXPLORER.*Methods and Materials A total of 28 pediatric patients (age 7.6±4.8 years, weight 28.2±17.8 kg) have been enrolled in this study. By truncating the list-mode PET data to reducing statistic count density, a series of simulated low-dose 18F-FDG PET images have been reconstructed with various durations (20 s, 40 s, 1 min, 2 min, 5 min, and 10 min), representing the PET images of 10 min with simulated administered dose (0.12 MBq/kg - 3.7 MBq/kg). The reconstruction method was time-of-flight ordered-subsets expectation maximization with point-spread function (OSEM-TOF-PSF). Dose or time-related image quality has been subjectively and objectively evaluated. For subjective evaluation, we performed Likert 5-point scales with 3 radiologists to assess overall image quality, image noise, and lesion conspicuity. The measurements of standard uptake value (SUV) are used in the objective evaluations, where the SUVmax, SUVmean, and SD at the liver, the SUVmax at lesions, and lesion-to-background ratio (LBR) was recorded.*Results In this study, the feasibility of dose-reduction and snapshot in total-body 18F-FDG PET imaging for pediatric patients has been proved by using the state-of-the-art PET/CT scanner. As the acquisition time or dose decreases, the SUVmax and SD at liver increases due to low statistic count induced noise effect, there is a significant difference among different reconstructed groups (p < 0.05). Nevertheless, the SUVmean at the liver is relatively stable in different groups. Strikingly, the SUVmax at lesions as well as the LBR is relatively fixed (with or without Bonferroni correction, all p > 0.1).*Conclusions By utilizing a 194-cm-long axial FOV PET/CT scanner, pediatric patients could undergo PET/CT examinations with 0.25 MBq/kg for 10 min or 3.7 MBq/kg during 40 s, while the PET image quality was qualitatively and quantitatively acceptable in the clinical diagnosis. Such examinations could be utilized in pediatric patients who are susceptive to ionizing-radiation-induced DNA damage or sedation.*Clinical Relevance/Application The digital PET/CT scanner with a long axial field-of-view has a great potential to reduce the administered dose and the acquisition time for pediatric oncological patients.

RESULTS

In this study, the feasibility of dose-reduction and snapshot in total-body 18F-FDG PET imaging for pediatric patients has been proved by using the state-of-the-art PET/CT scanner. As the acquisition time or dose decreases, the SUVmax and SD at liver increases due to low statistic count induced noise effect, there is a significant difference among different reconstructed groups (p < 0.05). Nevertheless, the SUVmean at the liver is relatively stable in different groups. Strikingly, the SUVmax at lesions as well as the LBR is relatively fixed (with or without Bonferroni correction, all p > 0.1).

CLINICAL RELEVANCE/APPLICATION

The digital PET/CT scanner with a long axial field-of-view has a great potential to reduce the administered dose and the acquisition time for pediatric oncological patients.

SPR-PD-9   Left Ventricular Systolic Dysfunction In Kawasaki Disease With Coronary Artery Dilation Detected By Cardiovascular Magnetic Resonance Tissue Tracking

Participants
Zhongqin Zhou, Chengdu, China (*Presenter*) Nothing to Disclose

PURPOSE

The association between left ventricular (LV) systolic function and coronary artery dilation (CAD) in Kawasaki disease (KD) patients remains unclear. We sought to quantify global and regional LV strain parameters in KD patients using cardiovascular magnetic resonance (CMR) tissue tracking, and assess the association of CAD with LV systolic function.*Methods and Materials Thirty-one KD patients with CAD (26 male, average age 5.82±3.35 years), 22 patients without CAD (13 male, average age 5.57±1.97 years) and 27 age- and sex-matched normal controls (18 men; average age 6.3±2.45 years) underwent CMR examination on a 3.0T clinical MRI scanner. The internal diameter of coronary artery was recorded by ultrasound to calculate Z score. Z score > 2 was defined as CAD. Global LV strain parameters and regional LV strain parameters in basal, middle, and apical level and 16 AHA segmentation including radial, circumferential and longitudinal peak strain (PS), and LV function were measured and compared among groups.*Results There was no difference in LV ejection fraction among controls, KD patients with CAD and patients without CAD (all p>0.05). Global longitudinal peak strain (GLPS) was lower in groups with CAD compared to groups without CAD (-12.55±4.05% vs -14.94±2.60%, p<0.05). There was on difference in radial,circumferential and longitudinal PS at basal, middle, and apical level (all

p<0.05). However, for regional strain, the segments with CAD (n=301) were lower than those in both normal controls (n=416) and segments without CAD (n=547) for regional radial, circumferential and longitudinal PS (all P<0.05). Severity of CAD was positively correlated to GLPS and regional longitudinal PS (r=0.388 and r=0.222; both p<0.05) in patients with KD.*Conclusions CMR tissue tracking could sensitively identify subclinical LV dysfunction in KD patients with CAD. LV systolic dysfunction is associated with severity of CAD and particularly occurs in myocardium dominated by dilated coronary artery.*Clinical Relevance/Application CMR tissue tracking can sensitively detect subclinical LV dysfunction in KD patients with CAD. Early clinical intervention is necessary to KD patients with CAD.

RESULTS

There was no difference in LV ejection fraction among controls, KD patients with CAD and patients without CAD (all p>0.05). Global longitudinal peak strain (GLPS) was lower in groups with CAD compared to groups without CAD (-12.55±4.05% vs -14.94±2.60%, p<0.05). There was on difference in radial,circumferential and longitudinal PS at basal, middle, and apical level (all p<0.05). However, for regional strain, the segments with CAD (n=301) were lower than those in both normal controls (n=416) and segments without CAD (n=547) for regional radial, circumferential and longitudinal PS (all P<0.05). Severity of CAD was positively correlated to GLPS and regional longitudinal PS (r=0.388 and r=0.222; both p<0.05) in patients with KD.

CLINICAL RELEVANCE/APPLICATION

CMR tissue tracking can sensitively detect subclinical LV dysfunction in KD patients with CAD. Early clinical intervention is necessary to KD patients with CAD.

SSGI14-1   GI Fluoroscopy 2021: What Are We Still Doing? What The Numbers Reveal And Implications For Trainees

Participants
David Disantis, MD, Jacksonville, Florida (*Presenter*) Nothing to Disclose

PURPOSE

By analyzing utilization trends for GI fluoroscopy since 2000, we identified which studies are still performed in significant volume as a guide for matching trainee education with current practice.*Methods and Materials Medicare yearly procedure volumes from 2000 through 2019 were compiled for the most common GI fluoroscopy procedures: esophagram, swallowing study, upper GI, small bowel follow-through, and barium enema.Medicare numbers were then extrapolated to estimate nationwide procedure volumes.*Results In the latest reporting year (2019), more than 2.9 million GI fluoroscopy studies were performed in the U.S. Comparing each procedure's peak volume year with 2019, all procedure volumes dropped. The degree of change, however, was extremely disparate. For example, swallowing studies down 4%; esophagrams fell 11%; single contrast upper GIs dropped 65%; double contrast upper GIs fell 77%; single contrast barium enemas plunged 89%, and double contrast barium enemas plummeted 95%.*Conclusions With 2.9 million studies yearly, GI fluoroscopy -- in particular esophagography and swallowing studies -- will remain a part of standard radiology practice for the foreseeable future.*Clinical Relevance/Application These data allow radiology training programs to match fluoroscopy instruction with the real-world clinical demand that their graduates will face.

RESULTS

In the latest reporting year (2019), more than 2.9 million GI fluoroscopy studies were performed in the U.S. Comparing each procedure's peak volume year with 2019, all procedure volumes dropped. The degree of change, however, was extremely disparate. For example, swallowing studies down 4%; esophagrams fell 11%; single contrast upper GIs dropped 65%; double contrast upper GIs fell 77%; single contrast barium enemas plunged 89%, and double contrast barium enemas plummeted 95%.

CLINICAL RELEVANCE/APPLICATION

These data allow radiology training programs to match fluoroscopy instruction with the real-world clinical demand that their graduates will face.

SSGI14-3   Nationwide Estimates Of CT Colonography Utilization: Cross-sectional Survey Results From The 2019 National Health Interview Survey

Participants
Anand Narayan, MD,PhD, Cambridge, Massachusetts (*Presenter*) Nothing to Disclose

PURPOSE

Colon cancer screening reduces deaths from colorectal cancer. CT colonography is a minimally invasive screening test with high sensitivity for colonic polyps (>1 cm). Prior studies have suggested that CT colonography utilization remains low, however there are few studies evaluating recent CT colonography utilization. Our purpose was to estimate recent nationwide CT colonography utilization using 2019 nationally representative cross-sectional survey data.*Methods and Materials Participants between ages 50 and 75 without colorectal cancer history in the 2019 National Health Interview Survey cross-sectional data were included. Proportion of participants reporting utilization of CT colonography was estimated. Logistic regression analyses evaluated predictors of CT colonography, optical colonoscopy, and sigmoidoscopy utilization. All analyses were conducted accounting for complex survey design elements to obtain statistically valid estimates for the civilian, noninstitutionalized US population. *Results Overall, 14,153 respondents between the ages 50 and 75 years old were included. 1.4% of participants reported ever having CT colonography (95% CI 1.2 to 1.7), of whom 39.7% reported undergoing CT colonography within the last year, 18.7% reported within the last two years, 12.6% within the last three years, 8.8% within the last 5 years, 10.9% within the last 10 years, 9.3% underwent CT colonography 10 years ago or more. 60.1% of participants reported ever undergoing optical colonoscopy or sigmoidoscopy. Multiple variable logistic regression analyses revealed that Hispanic (OR 2.73, 95% CI 1.72 to 4.34, p < 0.001) and Black (OR 2.34, 95% CI 1.50 to 3.64, p < 0.001) participants were more likely to undergo CT colonography. Multiple variable logistic regression analyses revealed that Hispanic (OR 0.61, 95% CI 0.52 to 0.72, p < 0.001) and Black (OR 0.49, 95% CI 0.39 to 0.63, p < 0.001) participants were less likely to report optical colonoscopy or sigmoidoscopy.*Conclusions In comparison with prior published reports, survey results suggest that nationwide utilization of CT colonography remains low. Black and Hispanic participants were more likely to report undergoing CT colonography and were less likely to report undergoing optical colonoscopy or sigmoidoscopy.*Clinical Relevance/Application Continued public awareness and health insurance coverage expansion will promote improved CT colonography

utilization and overall colorectal cancer screening rates. Promotion of CT colonography may reduce racial/ethnic disparities in colorectal cancer screening.

RESULTS

Overall, 14,153 respondents between the ages 50 and 75 years old were included. 1.4% of participants reported ever having CT colonography (95% CI 1.2 to 1.7), of whom 39.7% reported undergoing CT colonography within the last year, 18.7% reported within the last two years, 12.6% within the last three years, 8.8% within the last 5 years, 10.9% within the last 10 years, 9.3% underwent CT colonography 10 years ago or more. 60.1% of participants reported ever undergoing optical colonoscopy or sigmoidoscopy. Multiple variable logistic regression analyses revealed that Hispanic (OR 2.73, 95% CI 1.72 to 4.34, p < 0.001) and Black (OR 2.34, 95% CI 1.50 to 3.64, p < 0.001) participants were more likely to undergo CT colonography. Multiple variable logistic regression analyses revealed that Hispanic (OR 0.61, 95% CI 0.52 to 0.72, p < 0.001) and Black (OR 0.49, 95% CI 0.39 to 0.63, p < 0.001) participants were less likely to report optical colonoscopy or sigmoidoscopy.

CLINICAL RELEVANCE/APPLICATION

Continued public awareness and health insurance coverage expansion will promote improved CT colonography utilization and overall colorectal cancer screening rates. Promotion of CT colonography may reduce racial/ethnic disparities in colorectal cancer screening.

SSGI14-6   Final Diagnosis And Patient Disposition Following Equivocal Results On 2-mSv CT Vs. Conventional-dose CT In Adolescents And Young Adults With Suspected Appendicitis: A Post Hoc Analysis Of Large Pragmatic Randomized Trial Data

Participants
Jungheum Cho, MD, Seongnam, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To compare 2-mSv CT and conventional-dose CT (CDCT, typically 7-8 mSv) regarding final diagnosis and patient disposition following equivocal CT results in adolescents and young adults with suspected appendicitis.*Methods and Materials 3,074 patients of 15-44 years (28 ± 9 years, 1672 women) from 20 hospitals were randomized to undergo contrast-enhanced 2-mSv CT (n = 1535) or CDCT (n = 1539) from December 2013 through August 2016. 161 radiologists prospectively rated the likelihood of appendicitis in a Likert scale (i.e., grades 1-5). Final diagnosis was based on CT image, surgical, pathologic, and clinical findings. Post hoc analysis was performed for final diagnosis, surgical procedure, and delay in patient management following equivocal CT results (i.e., grade 3).*Results The prevalence of confirmed appendicitis among patients with equivocal CT results was 49% (18/37) and 36% (19/53) in the 2-mSv CT and CDCT groups, respectively. The 2-mSv CT and CDCT groups were comparable for final diagnosis following equivocal results, including confirmed appendicitis (1.2% [18 patients] vs. 1.2% [19], P > 0.99), negative appendectomy (0.1% [2] vs. 0.3% [4], P = 0.53), and perforated appendicitis (0.1% [1] vs. 0.2% [3], P = 0.53). More patients were confirmed as not having appendicitis following equivocal results in the CDCT group than in the 2-mSv CT group (2.2% [34] vs. 1.0% [16], P = 0.016). The two groups were comparable for the need of appendectomy (1.4% [22] vs. 1.5% [23], P > 0.99), need of additional imaging tests (0.7% [11] vs. 1.1% [17], P = 0.35), and delay in patient management following equivocal CT results.*Conclusions 2-mSv CT is comparable to CDCT regarding final diagnosis and patient disposition following equivocal CT results.*Clinical Relevance/Application Equivocal CT results cause a challenging situation for practitioners in the management of patients with suspected appendicitis. Our results justified the use of low-dose CT instead of CDCT in patients with suspected appendicitis.

RESULTS

The prevalence of confirmed appendicitis among patients with equivocal CT results was 49% (18/37) and 36% (19/53) in the 2-mSv CT and CDCT groups, respectively. The 2-mSv CT and CDCT groups were comparable for final diagnosis following equivocal results, including confirmed appendicitis (1.2% [18 patients] vs. 1.2% [19], P > 0.99), negative appendectomy (0.1% [2] vs. 0.3% [4], P = 0.53), and perforated appendicitis (0.1% [1] vs. 0.2% [3], P = 0.53). More patients were confirmed as not having appendicitis following equivocal results in the CDCT group than in the 2-mSv CT group (2.2% [34] vs. 1.0% [16], P = 0.016). The two groups were comparable for the need of appendectomy (1.4% [22] vs. 1.5% [23], P > 0.99), need of additional imaging tests (0.7% [11] vs. 1.1% [17], P = 0.35), and delay in patient management following equivocal CT results.

CLINICAL RELEVANCE/APPLICATION

Equivocal CT results cause a challenging situation for practitioners in the management of patients with suspected appendicitis. Our results justified the use of low-dose CT instead of CDCT in patients with suspected appendicitis.

SSCH04-2 Development And Validation Of A Novel Deep Learning-based Survival Prediction Algorithm On COPD Patients Utilizing Chest Radiographs

Participants
Ju Nam, MD, Seoul, Korea, Republic Of (*Presenter*) Research grant from VUNO.

PURPOSE

Although prediction of survival is important for management of chronic obstructive pulmonary disease (COPD) patients, pre-existing COPD-specific indices require complex history taking or exercise tests, making their wide utilization impractical. We aimed to develop and validate a deep learning-based survival prediction model on COPD patients (DLSP) utilizing chest radiograph (CXR) and clinical information.*Methods and Materials For development of DLSP, COPD patients who underwent post-bronchodilator spirometry and CXR within 1 month in 2011-2015 were retrospectively collected, and split into training (n= 3,475), tuning (n= 435), and internal validation (n= 315) datasets. First, deep learning algorithm predicting survival from patients' CXR was trained (DLSPCXR), using DenseNet backbone whose last dense layer modified to adopt a negative log likelihood loss function. Afterwards, integration model of DLSPCXR and clinical information, including age, sex, body-mass index (BMI), and diabetes mellitus history, was generated as the final DLSP. For external validation, three independent cohorts were collected from different institutions (n= 337-416). Discrimination performance of DLSP was evaluated and compared with other clinical factors using time-dependent area under the receiver operating characteristic curve (TD-AUROC) for 5-year survival. Using one external validation cohort, DLSP was compared with four COPD-specific clinical indices: BODE, ADO, CAT, and SGRQ. Goodness-of-fit statistics with Hosmer-Lemeshow test was performed for model calibration.*Results DLSP showed TD-AUROC of 0.710-0.814 in predicting 5-year survival of COPD patients, which were significant higher than that of FEV1 (%predicted), age, and BMI in all three external validation cohorts. DLSP also showed higher TD-AUROC than three out of four evaluated clinical indices including BODE (TD-AUROC, 0.860 vs. 0.801; P= .53), CAT (0.927 vs. 0.549; P< .001), and SGRQ (0.848 vs. 0.702; P= .16). DLSP exhibited good calibration on all cohorts (P> .05). On Cox multivariate proportional hazard analysis, DLSP worked as an independent survival predictor from FEV1 in all three cohorts (Ps< .01).*Conclusions DLSP utilizing both CXR and simple clinical information worked as a significant predictor of the survival of COPD patients, surpassing FEV1 and other COPD-specific clinical indices.*Clinical Relevance/Application Independent from FEV1, DLSP may work as an easily accessible and powerful survival predictor for COPD patients, only utilizing CXR and simple clinical information.

RESULTS

DLSP showed TD-AUROC of 0.710-0.814 in predicting 5-year survival of COPD patients, which were significant higher than that of FEV1 (%predicted), age, and BMI in all three external validation cohorts. DLSP also showed higher TD-AUROC than three out of four evaluated clinical indices including BODE (TD-AUROC, 0.860 vs. 0.801; P= .53), CAT (0.927 vs. 0.549; P< .001), and SGRQ (0.848 vs. 0.702; P= .16). DLSP exhibited good calibration on all cohorts (P> .05). On Cox multivariate proportional hazard analysis, DLSP worked as an independent survival predictor from FEV1 in all three cohorts (Ps< .01).

CLINICAL RELEVANCE/APPLICATION

Independent from FEV1, DLSP may work as an easily accessible and powerful survival predictor for COPD patients, only utilizing CXR and simple clinical information.

SSCH04-3 Parametric Response Mapping Correlation With FEV1/FVC In COPD: Influence Of Registration Accuracy And Direction

Participants
Silvia Almeida, Heidelberg, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Parametric response mapping (PRM), based on in- and expiratory computed tomography (CT) volumes' registration, phenotypes lung parenchyma voxels as normal, emphysema (PRMEmph) and functional small airway disease (PRMfSAD), in chronic obstructive pulmonary disease (COPD). We investigated the impact of two registration methods and direction on %PRM volumes and their association to forced expiratory volume in 1 second / forced vital capacity (FEV1/FVC), to clarify their roles and to exclude their influence as a source of error.*Methods and Materials Paired in- and expiratory volumetric CT scans from 358 consecutive participants of a COPD cohort study (64 ± 9 years old, COSYCONET) were subject to automated lung segmentation using a specialized software (YACTA). Two algorithms (R1; R2), differing on the similarity metric (sum of squared tissue volume differences; advanced normalized correlation with a bending penalty), and the two possible registration directions (inspiratory to expiratory I/E and the reverse E/I) were tested and fine-tuned. The Dice Similarity Coefficient (DSC) was computed between the lung masks as a measure of registration accuracy. %PRM volumes were compared for each registration method and direction and correlated with FEV1/FVC.*Results R2 showed the best overlap (R1: I/E DSC = 0.91±0.08 and E/I DSC = 0.90±0.09 vs R2: I/E DSC = 0.98±0.01; E/I DSC = 0.99±0.01) and the direction seems not to influence the DSC, for both algorithms. However, I/E shows greater median

DSC difference (R2 - R1) and range: 0.05, 0.00-0.49, comparing to E/I: 0.04, 0.00-0.40. This difference in registration accuracy results in %PRM volumes variation from R1 to R2: mean absolute increment of 1.18% in I/E and 1.59% in E/I for %PRMfSAD; and 0.81% in I/E and 0.86% in E/I for %PRMEmph, with limits of agreement: -3.84 to 3.86 for E/I and -3.13 to 3.16 for I/E. This translates into subtle but noticeable Pearson correlation coefficient changes from I/E to E/I, between FEV1/FVC and %PRMfSAD (-0.47 to -0.49 R1; -0.51 to -0.52 R2) and %PRMEmph (-0.69 to -0.70 R1 and constant -0.70 R2).*Conclusions Both registration methods reach high volumetric overlap (in terms of mean DSC > 0.90), but the remaining difference still results %PRM volumes variability, in particular for fSAD, and their correlation with FEV1/FVC. This effect was larger than the registration direction itself. However, if the registration accuracy is compromised, the direction seems to influence the %PRM, especially for fSAD. Further investigation is warranted to improve the registration process, since it seems to be a key factor to derive PRM.*Clinical Relevance/Application Optimizing registration performance improves the accuracy of %PRM volumes and correlation with FEV1/FVC, regardless of the registration direction.

RESULTS

R2 showed the best overlap (R1: I/E DSC = 0.91±0.08 and E/I DSC = 0.90±0.09 vs R2: I/E DSC = 0.98±0.01; E/I DSC = 0.99±0.01) and the direction seems not to influence the DSC, for both algorithms. However, I/E shows greater median DSC difference (R2 - R1) and range: 0.05, 0.00-0.49, comparing to E/I: 0.04, 0.00-0.40. This difference in registration accuracy results in %PRM volumes variation from R1 to R2: mean absolute increment of 1.18% in I/E and 1.59% in E/I for %PRMfSAD; and 0.81% in I/E and 0.86% in E/I for %PRMEmph, with limits of agreement: -3.84 to 3.86 for E/I and -3.13 to 3.16 for I/E. This translates into subtle but noticeable Pearson correlation coefficient changes from I/E to E/I, between FEV1/FVC and %PRMfSAD (-0.47 to -0.49 R1; -0.51 to -0.52 R2) and %PRMEmph (-0.69 to -0.70 R1 and constant -0.70 R2).

CLINICAL RELEVANCE/APPLICATION

Optimizing registration performance improves the accuracy of %PRM volumes and correlation with FEV1/FVC, regardless of the registration direction.

SSCH04-4   CT Findings And Patterns Of Electronic Cigarette Or Vaping Product Use-associated Lung Injury (evali), A Multicenter Cohort Of 160 Cases

Participants
Seth J. Kligerman, MD, La Jolla, California (*Presenter*) Speakers Bureau, Boehringer Ingelheim GmbH;Author, RELX;Consultant, Riverain Technologies, LLC;Consultant, Bayer AG

PURPOSE

Electronic cigarette and vaping-induced lung injury (EVALI) causes a spectrum of CT lung injury patterns. Relative frequencies and associations with vaping behavior are unknown.*Methods and Materials CT scans of 160 subjects with EVALI from 15 institutions were retrospectively reviewed. CT findings and patterns were defined via consensus. The parenchymal organizing pneumonia (OP) pattern was defined as regional or diffuse GGO +/- consolidation without centrilobular nodules (CN). Airway-centered OP was defined as diffuse CN with little or no GGO; Mixed OP was a combination of the two. Other patterns were diffuse alveolar damage (DAD), acute eosinophilic pneumonia-like (AEP-like), and pulmonary hemorrhage (DAH). Cases were classified as atypical if they did not fit into a pattern. Pattern frequencies and injury severity were correlated with vaping history (substance vaped and frequency), geography and state marijuana (THC) legality. One-way ANOVA, Chi square test, and multivariable analyses (MVA) were used for statistical analysis*Results 160 patients (79.4% male) with mean age of 28.2 yrs (range 15-68) with EVALI underwent CT. 77 (48.1%), 15 (9.4%), and 68 (42.5%) admitted to vaping THC, nicotine, or both, respectively. Common findings include diffuse or lower lobe GGO with subpleural (78.1%), lobular (59.4%) or peribronchovascular (PBV) sparing (40%). Septal thickening (50.6%), lymphadenopathy (63.1%), and CN (36.3%) were common. PBV sparing was associated with younger age (p=0.02). 156 of 160 (97.5%) subjects had 1of 6 defined patterns. Parenchymal, airway-centered, and mixed OP patterns were seen in 89 (55.6%), 14 (8.8%), and 32 (20%) respectively. AEP-like (6/160, 3.8%), DAD (9/160, 5.6%), DAH (6/160, 3.8%), and atypical (4/160, 2.5%) patterns were less common. Increased vaping frequency was associated with more severe injury (p=0.008). MVA showed negative association between vaping for >6 months and DAD pattern (p=0.03). Two subjects (1.25%) with DAD pattern died. There was no relation between pattern and injury severity and geographic location and state legality of THC.*Conclusions EVALI typically causes an OP pattern but exists on a spectrum of acute lung injury (ALI). Vaping habits do not correlate with CT patterns except for negative correlation between vaping >6 months and DAD pattern. PBV sparing, not previously described in ALI, is a common finding.*Clinical Relevance/Application Vaping should be included in the history of all patients with ALI particularly if they are young and otherwise healthy. Some patients demonstrated CT findings less commonly reported in other causes of ALI, including superimposed upper lobe predominant CN and PBV sparing. .

RESULTS

160 patients (79.4% male) with mean age of 28.2 yrs (range 15-68) with EVALI underwent CT. 77 (48.1%), 15 (9.4%), and 68 (42.5%) admitted to vaping THC, nicotine, or both, respectively. Common findings include diffuse or lower lobe GGO with subpleural (78.1%), lobular (59.4%) or peribronchovascular (PBV) sparing (40%). Septal thickening (50.6%), lymphadenopathy (63.1%), and CN (36.3%) were common. PBV sparing was associated with younger age (p=0.02). 156 of 160 (97.5%) subjects had 1of 6 defined patterns. Parenchymal, airway-centered, and mixed OP patterns were seen in 89 (55.6%), 14 (8.8%), and 32 (20%) respectively. AEP-like (6/160, 3.8%), DAD (9/160, 5.6%), DAH (6/160, 3.8%), and atypical (4/160, 2.5%) patterns were less common. Increased vaping frequency was associated with more severe injury (p=0.008). MVA showed negative association between vaping for >6 months and DAD pattern (p=0.03). Two subjects (1.25%) with DAD pattern died. There was no relation between pattern and injury severity and geographic location and state legality of THC.

CLINICAL RELEVANCE/APPLICATION

Vaping should be included in the history of all patients with ALI particularly if they are young and otherwise healthy. Some patients demonstrated CT findings less commonly reported in other causes of ALI, including superimposed upper lobe predominant CN and PBV sparing. .

SSMK10-2 The Role Of 3 Tesla MR Neurography, Diagnostic Accuracy And Therapeutic Effect Of 3T MR Guided Nerve Blocks For Meralgia Paresthetica

Participants

Jan Fritz, MD, New York, New York (*Presenter*) Institutional research support, Siemens AGScientific Advisor, Siemens AGPatent agreement, Siemens AGInstitutional research support, Johnson & JohnsonInstitutional research support, Zimmer Biomet Holdings, IncInstitutional research support, BTG Internation

PURPOSE

Lateral femoral cutaneous nerve (LFCN) blocks are frequently utilized to diagnose meralgia paresthetica (MP). Traditionally these are performed with Ultrasound or CT guidance at or distal to the inguinal ligament. However, the LFCN course has several known variants, which are poorly appreciable on traditional intra-procedural imaging methods, potentially limiting the diagnostic accuracy and efficacy of blocks. We prospectively tested the hypothesis that pre-ligamentous 3Tesla MR neurography-guided (MRNg) LFCN blocks are safe and effective for the diagnosis of MP.*Methods and Materials Our institutional review board approved this prospective study. Informed consent was obtained from all participants. Patients with intractable thigh pain and high clinical suspicion of LFCN neuropathy were included. Diagnostic MRNg LFCN blocks were performed using an anterior approach and clinical wide-bore 3T MRI system targeting the nerve proximal to the inguinal ligament. Outcome variables included technical success, complications, learning curve, pre- and post-procedural numerical visual analog scale (VAS) score (0=no discomfort to 10=worst discomfort), efficacy and patient satisfaction P-values=0.05 were considered statistically significant. Descriptive and binary logistic regression statistical analyses were performed.*Results 123 LFCN blocks were performed in 95 subjects (36 men, 59 women; mean age, 54 years; range, 18-91; mean body mass index (BMI), 30kg/m2, range 17-46kg/m2), all performed with an anterior needle path. Successful drug delivery was achieved in 100% of patients. No complications occurred. Total procedure time was 25 ± 10 minutes (range:6-53) in unilateral blocks; 29 ± 11minutes (range:23-42) in bilateral blocks. Mean pre-procedure VAS score was 5.91 ± 2.1 (range 1-10). Mean post-procedure VAS score was 1.68 ± 1.91 (0-8). LFCN blocks achieved appropriate anesthesia in 77/95 (81%) subjects and symptom relief on subsequent treatment in 75/95 (79%). The majority of patients (>80%) reported immediate pain relief, comfort, acceptable examination time and positioning.*Conclusions Selective pre-ligamentous MRNg LFCN blocks are safe and effective with high technical success and patient satisfaction in patients with MP.*Clinical Relevance/Application High spatial and contrast resolution 3T MRNg LFCN blocks are safe and technically feasible. It permits direct, precise targeting of the retroperitoneal course of the LFCN, proximal to the inguinal ligament maximizing anesthesia in post-operative or variant courses. Due to its safety profile and high patient satisfaction, the procedure can be repeated to optimise individual patient outcomes prior to more invasive treatments such as cryoablation or surgical decompression.

RESULTS

123 LFCN blocks were performed in 95 subjects (36 men, 59 women; mean age, 54 years; range, 18-91; mean body mass index (BMI), 30kg/m2, range 17-46kg/m2), all performed with an anterior needle path. Successful drug delivery was achieved in 100% of patients. No complications occurred. Total procedure time was 25 ± 10 minutes (range:6-53) in unilateral blocks; 29 ± 11minutes (range:23-42) in bilateral blocks. Mean pre-procedure VAS score was 5.91 ± 2.1 (range 1-10). Mean post-procedure VAS score was 1.68 ± 1.91 (0-8). LFCN blocks achieved appropriate anesthesia in 77/95 (81%) subjects and symptom relief on subsequent treatment in 75/95 (79%). The majority of patients (>80%) reported immediate pain relief, comfort, acceptable examination time and positioning.

CLINICAL RELEVANCE/APPLICATION

High spatial and contrast resolution 3T MRNg LFCN blocks are safe and technically feasible. It permits direct, precise targeting of the retroperitoneal course of the LFCN, proximal to the inguinal ligament maximizing anesthesia in post-operative or variant courses. Due to its safety profile and high patient satisfaction, the procedure can be repeated to optimise individual patient outcomes prior to more invasive treatments such as cryoablation or surgical decompression.

SSMK10-3 Long-term Outcome Of CT-guided Microwave Ablation In Patients With Osteoid Osteoma

Participants

Sebastien L. Aubry, MD, PhD, Besancon, France (*Presenter*) Nothing to Disclose

PURPOSE

To assess the long term efficacy of CT-guided microwave ablation (MWA) in the treatment of osteoid osteomas (OOs)*Methods and Materials Twenty-eight consecutive patients with a diagnosis of OO treated by CT-guided MWA between July 2013 to March 2020 were retrospectively included. The ablations were performed with a median power and time of 60W and 1m 30s respectively.

Pain referred to OO was assessed at predefined times using a 0-10 numeric pain rating scale (NRS) : before the procedure, per procedure if no general anesthesia, and post procedure (1 day, 1 week, 1 month, 3 months, 6 months, 1 year, then yearly). Post procedure side effects were reported. At one month, a contrast-enhanced follow-up MRI was performed to evaluate the nidus vascularization and the volume of necrosis induced by MWA. Technical success was defined by necrosis of the nidus on the one-month post-procedure MRI, and early success by the absence of OO-related pain at one month*Results Long term success rate was up to 92.86% (26/28) at the end of the follow-up (median 55.5 months). Early success rate was 96.43% (27/28) and technical success rate was 96.15% (25/26). Three minor complications were reported during the procedure: a transient injury to a sensitive nerve branch of the radial nerve and two skin burns. Only one late failure was observed after a patient had been declared cured at one month but the formal proof of a late recurrence of OO could not be brought. The median volume of MWA induced necrosis was 2.4 ml*Conclusions Clinical and technical success rates are excellent, with no late recurrence after that healing is asserted at one month both clinically and on contrast enhanced MRI*Clinical Relevance/Application CT-guided MWA can treat osteoid osteoma effectively and safely, with an excellent long term efficacy

RESULTS

Long term success rate was up to 92.86% (26/28) at the end of the follow-up (median 55.5 months). Early success rate was 96.43% (27/28) and technical success rate was 96.15% (25/26). Three minor complications were reported during the procedure: a transient injury to a sensitive nerve branch of the radial nerve and two skin burns. Only one late failure was observed after a patient had been declared cured at one month but the formal proof of a late recurrence of OO could not be brought. The median volume of MWA induced necrosis was 2.4 ml

CLINICAL RELEVANCE/APPLICATION

CT-guided MWA can treat osteoid osteoma effectively and safely, with an excellent long term efficacy

SSMK10-5   The Role Of Ultrasound-guided Infiltration Of The Greater Occipital Nerve For Pain Management In Occipital Neuralgia

Participants
Nicolas Ochoa Sambrizzi, MD, Barcelona, Spain (*Presenter*) Nothing to Disclose

PURPOSE

Occipital Neuralgia also knowns as Arnold's neuralgia is a rare yet highly debilitating pathology, whose treatment range from the use of various pharmacotherapeutic agents to occipital nerve blockade. The purpose of the study is to show the efficacy of US-guided infiltration of the GON in the treatment of Occipital Neuralgia.*Methods and Materials We present a controlled before and after study of patients diagnosed with Arnold's neuralgia in our center that received ultrasound (US) guided infiltration of the Greater Occipital nerve (GON) in the last year.12 patients received a total of 20 infiltrations of either botulinum toxin or a mixture of corticosteroid and local anesthetic. We compared the visual analogue scale (VSA) and "Neck Disability Index" (NDI) before and after the procedure. Considering the main outcome a statistically significant reduction of the VSA, as well as an improvement of the NDI. A secondary outcome was to compare the efficacy of the use of Botulinum toxin vs corticosteroid in terms of pain reduction and duration of the effect.Statistical analysis was through a t-test for paired samples.*Results All patients completed a minimum of 4 months follow-up period after the procedure.Statistical analysis showed a significant reduction of the VSA score after infiltration as well as a reduction of the NDI scale. There was a significant difference in the average of the VSA scores before and 7 days after the procedure ((p < 0.001)) with an average reduction of 4.9 points (95% CI [3.7, 6.1]), the mean duration of the effect was 3.4 months. There was also an important difference between the averages of NDI before and after the infiltrations (p < 0.001), with an average reduction of 24.5% after the procedure (95% CI [17.4, 31.5]).No statistical difference was found between the use of botulinum toxin or a corticosteroid mixture in terms of pain reduction or duration of the effect.*Conclusions US-guided infiltrations of the GON are a temporary yet effective way to manage cervical pain in patients with occipital neuralgia and should be considered among the therapeutic options when treating these patients.*Clinical Relevance/Application Minimally invasive procedures like US-guided infiltrations should be considered among the basic tools of every radiologist, demonstrating the role of the specialist not only in the diagnosis but also in the treatment of different and sometimes difficult to treat pathologies like Occipital neuralgia.

RESULTS

All patients completed a minimum of 4 months follow-up period after the procedure.Statistical analysis showed a significant reduction of the VSA score after infiltration as well as a reduction of the NDI scale. There was a significant difference in the average of the VSA scores before and 7 days after the procedure ((p < 0.001)) with an average reduction of 4.9 points (95% CI [3.7, 6.1]), the mean duration of the effect was 3.4 months. There was also an important difference between the averages of NDI before and after the infiltrations (p < 0.001), with an average reduction of 24.5% after the procedure (95% CI [17.4, 31.5]).No statistical difference was found between the use of botulinum toxin or a corticosteroid mixture in terms of pain reduction or duration of the effect.

CLINICAL RELEVANCE/APPLICATION

Minimally invasive procedures like US-guided infiltrations should be considered among the basic tools of every radiologist, demonstrating the role of the specialist not only in the diagnosis but also in the treatment of different and sometimes difficult to treat pathologies like Occipital neuralgia.

SSMK10-6   Image-guided Corticosteroid Injections For Musculoskeletal Pain During The Recovery Phases And Incidence Of Symptomatic COVID-19 Infections: A Prospective Observational Study

Participants
Joao Rafael Vicentini, MD, Boston, Massachusetts (*Presenter*) Nothing to Disclose

PURPOSE

Prior studies have shown no higher symptomatic COVID-19 infection in patients who received image-guided corticosteroid injections for musculoskeletal pain compared to the general population during the lockdown period. In the initial recovery period, when exposure to the virus is potentially higher, vaccination has not yet become available, and variants are developing, the risk of COVID-19 infection is presumably higher. The purpose of this study was to determine the incidence of symptomatic COVID-19 infection in patients receiving image-guided corticosteroid injections for musculoskeletal pain compared to the general population during the recovery period. We hypothesized that corticosteroid injection would not increase the risk of symptomatic COVID-19 infections.*Methods and Materials In this prospective study, adult patients undergoing image-guided corticosteroid injection for pain management between April 15 and December 26, 2020, were consecutively enrolled. Subjects were followed for a minimum of

28 days after their injection by electronic medical record (EMR), and if no records were available, by direct phone call to the patient, to screen for COVID-19-related symptoms or history of SARS-COV2 RT-PCR testing.*Results A total of 2123 steroid injections were performed in 1885 adult patients. Follow-up was available for 1696 (90%) of the patients, 885 (52%) females, and 811 (48%) males, ages 59 ± 15 (19-97) years. For 1225 (72%), follow-up was performed by EMR search and 471 (28%) by phone survey, performed 99 ± 33 (28-139) days after the injection. Thirty-nine (39/1696, 2.3%; 95% CI 1.6-3.1%) positive cases were identified. During the same period, 262,966 positive cases were documented among the general population in the state (262,966/6,892,503, 3.8%). The incidence of COVID-19 among corticosteroid injection patients was lower than the general population (p=0.0014). A sub-group of 181 patients, which had at least two injections during the study period, had a higher COVID-19 infection rate than the single injection group, but this difference was not statistically significant (p=0.4).*Conclusions Image-guided corticosteroid injections for pain management performed during the recovery period and prior to general vaccination was not associated with increased rates of COVID-19 infection compared to the general population.*Clinical Relevance/Application Musculoskeletal pain can be debilitating for a significant portion of the population, for which image-guided corticosteroid injections are an important treatment option. This study suggests that injections performed during the recovery phases of the COVID-19 pandemic do not carry an increased risk of symptomatic COVID-19 infection and are safe to perform.

RESULTS

A total of 2123 steroid injections were performed in 1885 adult patients. Follow-up was available for 1696 (90%) of the patients, 885 (52%) females, and 811 (48%) males, ages 59 ± 15 (19-97) years. For 1225 (72%), follow-up was performed by EMR search and 471 (28%) by phone survey, performed 99 ± 33 (28-139) days after the injection. Thirty-nine (39/1696, 2.3%; 95% CI 1.6-3.1%) positive cases were identified. During the same period, 262,966 positive cases were documented among the general population in the state (262,966/6,892,503, 3.8%). The incidence of COVID-19 among corticosteroid injection patients was lower than the general population (p=0.0014). A sub-group of 181 patients, which had at least two injections during the study period, had a higher COVID-19 infection rate than the single injection group, but this difference was not statistically significant (p=0.4).

CLINICAL RELEVANCE/APPLICATION

Musculoskeletal pain can be debilitating for a significant portion of the population, for which image-guided corticosteroid injections are an important treatment option. This study suggests that injections performed during the recovery phases of the COVID-19 pandemic do not carry an increased risk of symptomatic COVID-19 infection and are safe to perform.

SPR-MK-10   Prediction Of Osteoporosis Using Radiomics Analysis Derived From Single Source Dual Energy CT

Participants
Jinling Wang, Changsha, China (*Presenter*) Nothing to Disclose

PURPOSE

To develop and validate a radiomics model based on the monochromatic imaging of dual-energy CT for osteoporosis prediction.*Methods and Materials 124 patients underwent both single source dual-energy CT and QCT lumbar examination were enrolled in a study cohort including training datasets (n = 86 [44 normal bone mineral density ,19 low bone mineral density and 23 osteoporosis]) and validation datasets (n = 38 [19 normal bone mineral density ,8 low bone mineral density and 11 osteoporosis]). 129 radiomics features were extracted from 70-kev monochromatic CT images. Top important radiomics signatures were built by using the least absolute shrinkage and selection operator method on the basis of reproducible features. A radiomics model was constructed by incorporating the radiomics signatures and significant clinical parameters using multivariate logistic regression analysis. Prediction performance of radiomics analysis was calculated using diagnostic test and comparison of area under the receiver operating characteristic (AUC) curve performed between training and validation cohorts.*Results The 16 selected radiomics signature features showed good performance in both training (AUC, 0.997) and validation (AUC, 0.978) cohorts. The radiomics model, which incorporated the radiomics signatures and two significant clinical predictors (age and BMI), also showed good prediction performance (AUC, 0.999 in training cohort and 0.986 in validation cohort). The prediction performance of the radiomics analysis model to diagnose osteoporosis from normal, low bone mineral density patients in the training and validation cohorts showed high accuracy of 98.8% in the training cohort and 94.7% in the validation cohort.*Conclusions Prediction performance of osteoporosis using radiomics analysis model derived from single source dual energy CT showed high validity with more than 94% accuracy.*Clinical Relevance/Application Our proposed model can serve as a useful tool for osteoporosis prediction and has the potential to be applied in clinical treatment planning in the future.

RESULTS

The 16 selected radiomics signature features showed good performance in both training (AUC, 0.997) and validation (AUC, 0.978) cohorts. The radiomics model, which incorporated the radiomics signatures and two significant clinical predictors (age and BMI), also showed good prediction performance (AUC, 0.999 in training cohort and 0.986 in validation cohort). The prediction performance of the radiomics analysis model to diagnose osteoporosis from normal, low bone mineral density patients in the training and validation cohorts showed high accuracy of 98.8% in the training cohort and 94.7% in the validation cohort.

CLINICAL RELEVANCE/APPLICATION

Our proposed model can serve as a useful tool for osteoporosis prediction and has the potential to be applied in clinical treatment planning in the future.

SPR-MK-11   Deep Learning-based Metal Artifact And Noise Reduction In The Lumbar Spine CT

Participants
Hyoung In Choi, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the performance of deep learning (DL)-based metal artifact reduction (MAR) and denoising technique to enhance the image quality of the postoperative lumbar spine CT.*Methods and Materials The training set consisted of 15800 image pairs from 200 spine CTs without a prosthesis. We simulated images with metal artifacts through sinogram handling. A convolutional neural network (CNN) with an encoder-decoder structure was developed for MAR. We then applied DL-based denoising using U-net-based CNN, trained to generate denoised images from simulated noise-added images. For the test set, we used 50 spine CTs from patients with spinal instrumentation. For quantitative evaluation, the mean attenuation at the most hypodense artifacts, the area of the hyperdense artifacts within the spinal canal, the standard deviation of HU within the dural sac were calculated in the original, MAR for orthopedic implants (O-MAR), and DL images. For qualitative analysis, images were rated with a 5-point scale regarding the visualization of the dural sac, conspicuity of the posterior vertebral cortex, and bone-metal interface.*Results The metal artifacts were the most reduced in DL images, whereas the O-MAR introduced new hyperdense artifacts within the spinal canal. The mean attenuation at the most hypodense artifacts was -337 HU, -71 HU, and 6 HU (P < .001), and the mean area of hyperdense artifacts within the spinal canal was 68 mm2, 97 mm2, and 22 mm2 (P < .001) for original, O-MAR, and DL images, respectively. DL-based images (117 HU) showed a significant reduction of noise than original images (141 HU; P < .001), but there was no significant difference compared with O-MAR (127 HU; P = .23). In qualitative analysis, DL images showed better visualization of the dural sac, posterior vertebral cortex, and bone-metal interface compared to original and O-MAR images (P < .001). O-MAR caused bone deletion in many cases, worsening visualization of cortical bone compared to original and DL images (P < .001).*Conclusions The DL-based technique showed excellent MAR and denoising performance with the improved image quality of the postoperative lumbar spine CT.*Clinical Relevance/Application Deep learning can effectively reduce metal artifacts and noise in the postoperative spine CT, hence enabling its use in the diagnosis of postoperative complications of spinal instrumentation surgery.

RESULTS

The metal artifacts were the most reduced in DL images, whereas the O-MAR introduced new hyperdense artifacts within the spinal canal. The mean attenuation at the most hypodense artifacts was -337 HU, -71 HU, and 6 HU (P < .001), and the mean area of hyperdense artifacts within the spinal canal was 68 mm2, 97 mm2, and 22 mm2 (P < .001) for original, O-MAR, and DL images, respectively. DL-based images (117 HU) showed a significant reduction of noise than original images (141 HU; P < .001), but there was no significant difference compared with O-MAR (127 HU; P = .23). In qualitative analysis, DL images showed better visualization of the dural sac, posterior vertebral cortex, and bone-metal interface compared to original and O-MAR images (P < .001). O-MAR caused bone deletion in many cases, worsening visualization of cortical bone compared to original and DL images (P < .001).

CLINICAL RELEVANCE/APPLICATION

Deep learning can effectively reduce metal artifacts and noise in the postoperative spine CT, hence enabling its use in the diagnosis of postoperative complications of spinal instrumentation surgery.

SPR-MK-12   To Evaluate the Role Of 18f-fdg PET/CT In Determining The Disease Burden And Its Impact On Anti Tuberculous Treatment

Participants
Sikandar Shaikh, DMRD, Hyderabad, India (*Presenter*) Nothing to Disclose

PURPOSE

Tubercular arthritis is one of the most common and important arthritis after osteoarthritis in Indian subcontinent. We evaluated the role of the whole body 18F-FDG PET/CT to evaluate the extent of the disease, disease burden and response to Anti tuberculosis treatment*Methods and Materials We evaluated Forty five patients with diagnosed tubercular arthritis . PET-CT was done in all these patients in pretreatment scenarios .Whole body 18F FDG PET/CT scan was done before and after anti-tubercular treatment, PET/CT scans were before starting anti tuberculous treatment and also done at 2 months and 6 months after starting the antituberculous treatment . Depending on the various stages of the metabolic response to the treatment, PET-CT scans were further categorized into complete metabolic response(CR), partial metabolic response(PR), Stable disease(SD) and Progressive disease(PD). CR was defined as complete disappearance of metabolic activity, PR as disappearance of activity >30% reduction in the SUVmax. Thus Stable Disease means no significant change from the baseline and PD is categorised as appearance of new lesion or >30% increase in the SUVmax.*Results mong 45 patients, median age was 41 (range, 18-63) years, and M:F-1.3:1. Other than pain in the particular joints Whole body 18F FDG PET/CT revealed additional lymph nodes other than the primary diseases in Hip, Knee and upper extremity in all the patients with (average SUVmax- 6.4, size-16mm),24 patients with mediastinal lymph-nodes (average SUVmax- 5.3, size-16mm in size), 16 patients with abdominal lymph-nodes (average SUVmax- 4.3, size-15mm). Overlapping of these regions were seen due to various other pathologies were noted in12 patients, cervico-mediastinal region in 10 patients and mediastinal-abdominal regions in 12 patients. Additional findings such as Potts spine, lung involvement, liver to splenic reversal, bone marrow activation, psoas abscess were also noted. Post treatment Follow up was done after 2nd month of starting anti tubercular treatment(ATT) in 24 patients and 6 month of anti tubercular treatment in 16 out of 45 patients. After 2 months of ATT, 2 patients had CR, 20 had PR, 2 had progression. After 6 months of ATT, 1 patients had CR, 5 PR, 2 PD.*Conclusions Thus 18-F-FDG-PET/CT plays an important role in eliciting actual disease burden in systemic tubercular arthritis.*Clinical Relevance/Application PET-CT plays an important role in the evaluation of tuberculous arthritis.

RESULTS

mong 45 patients, median age was 41 (range, 18-63) years, and M:F-1.3:1. Other than pain in the particular joints Whole body 18F FDG PET/CT revealed additional lymph nodes other than the primary diseases in Hip, Knee and upper extremity in all the patients with (average SUVmax- 6.4, size-16mm),24 patients with mediastinal lymph-nodes (average SUVmax- 5.3, size-16mm in size), 16 patients with abdominal lymph-nodes (average SUVmax- 4.3, size-15mm). Overlapping of these regions were seen due to various other pathologies were noted in12 patients, cervico-mediastinal region in 10 patients and mediastinal-abdominal regions in 12 patients. Additional findings such as Potts spine, lung involvement, liver to splenic reversal, bone marrow activation, psoas abscess were also noted. Post treatment Follow up was done after 2nd month of starting anti tubercular treatment(ATT) in 24 patients and 6 month of anti tubercular treatment in 16 out of 45 patients. After 2 months of ATT, 2 patients had CR, 20 had PR, 2 had progression. After 6 months of ATT, 1 patients had CR, 5 PR, 2 PD.

CLINICAL RELEVANCE/APPLICATION

PET-CT plays an important role in the evaluation of tuberculous arthritis.

SPR-MK-14   3D-UNet For Automatic Volumetric Vertebral Segmentation From Body CT Images For Opportunistic Osteoporosis Screening

Participants
Jiyoung Song, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

We aimed to develop and validate a deep neural network applicable to body CT images for automatic volumetric segmentation and labeling of individual vertebrae.*Methods and Materials For model development, we retrospectively included CT images of 79 patients who underwent thin-section whole-body or torso 18F-fluorodeoxyglucose PET-CT scans. A radiologist semi-automatically segmented and labeled individual lumbar vertebrae, including body, vertebral arch, and processes. Input data was a bone mask obtained by a priori developed network that automatically segmented bony structures from body CT images with a dice similarity coefficient of 98.1 to 99.2%. 75 cases were used for 3D U-Net training, and 4 cases were used for validation to assess segmentation accuracy. The segmentation model was applied to a community-based cohort comprised of 381 individuals (women n=191, 50.4%; mean age, 60; age range, 40 to 93) who underwent a precontrast abdomen CT scan and dual-energy x-ray absorptiometry (DXA) scan on the same day. The 3D U-Net-driven volume and Hounsfield unit (HU) of individual lumbar vertebrae were clinically validated with average bone mineral density (aBMD) measured on DXA.*Results The 3D U-Net automatically segmented and labeled lumbar vertebrae with an average dice similarity coefficient of 93.4 to 97.0%. The 3D U-Net-driven average HU of lumbar area (L1-4) was 352 ± 71 and 367 ± 53 in women and men, respectively, with the lowest value at L1 and the highest at L4 (354 vs. 362, p<0.001). The annual decline of bone attenuation was 5.2 HU (95% CI, 4.6 to 5.7) in women and 1.7 HU (95% CI, 1.1 to 2.3) in men (p for interaction<0.001). Mean lumbar HU was positively correlated with lumbar aBMD (r=0.79, p<0.001). Thresholds for lumbar HU equivalent to DXA T-score -2.5 in linear regression models were 290 HU (women) and 300 HU (men), with

a sensitivity of 85% and specificity of 91% to detect DXA-based L-spine osteoporosis (T-score=-2.5; n=33, 8.7%). One unit decrease in average lumbar spine HU was associated with 9% elevated odds of DXA-based osteoporosis after adjustment for age, sex, and body mass index (adjusted OR 1.09, 95% CI 1.06 to 1.12, p<0.001).*Conclusions The 3D U-Net provided an automatic volumetric segmentation and labeling of lumbar vertebrae on body CT images. The average lumbar vertebral attenuation was well correlated to aBMD measured on DXA, and detected osteoporosis with high sensitivity and specificity. Further external validation is ongoing for generalizability.*Clinical Relevance/Application A deep neural network enables an automatic volumetric evaluation of lumbar vertebrae, potentially facilitating opportunistic osteoporosis screening on body CT images and adjunctive materialization of segmented vertebrae as virtual reality and 3D printing.

RESULTS

The 3D U-Net automatically segmented and labeled lumbar vertebrae with an average dice similarity coefficient of 93.4 to 97.0%. The 3D U-Net-driven average HU of lumbar area (L1-4) was 352 ± 71 and 367 ± 53 in women and men, respectively, with the lowest value at L1 and the highest at L4 (354 vs. 362, p<0.001). The annual decline of bone attenuation was 5.2 HU (95% CI, 4.6 to 5.7) in women and 1.7 HU (95% CI, 1.1 to 2.3) in men (p for interaction<0.001). Mean lumbar HU was positively correlated with lumbar aBMD (r=0.79, p<0.001). Thresholds for lumbar HU equivalent to DXA T-score -2.5 in linear regression models were 290 HU (women) and 300 HU (men), with a sensitivity of 85% and specificity of 91% to detect DXA-based L-spine osteoporosis (T-score=-2.5; n=33, 8.7%). One unit decrease in average lumbar spine HU was associated with 9% elevated odds of DXA-based osteoporosis after adjustment for age, sex, and body mass index (adjusted OR 1.09, 95% CI 1.06 to 1.12, p<0.001).

CLINICAL RELEVANCE/APPLICATION

A deep neural network enables an automatic volumetric evaluation of lumbar vertebrae, potentially facilitating opportunistic osteoporosis screening on body CT images and adjunctive materialization of segmented vertebrae as virtual reality and 3D printing.

SPR-MK-15 Multiparametric Analysis Of Monoexponential Diffusion-weighted Imaging, Intravoxel Incoherent Motion, And Diffusion Kurtosis Models For Differentiation Of Benign And Malignant Musculoskeletal Tumors

Participants
Sevtap Arslan, Ankara, Turkey (*Presenter*) Nothing to Disclose

PURPOSE

To compare the diagnostic performance of monoexponential DWI, IVIM, and DK models and their combinations in differentiating benign and malignant musculoskeletal tumors.*Methods and Materials Fifty patients with benign (n= 22) and malignant (n= 28) musculoskeletal tumors were included in this prospective study. Minimum and volumetric values of ADC, DIVIM, D*, f, DK, and K were measured and compared between all benign and malignant tumors. Mean values of each parameter were measured by drawing VOI (volume of interest) including the whole tumor volume with consensus, whereas minimum values were calculated independently by two observers by calculating the arithmetical mean of measurements on ROIs (region of interest) placed on a solid enhancing area with the lowest diffusivity. Subgroup analysis was performed for non-myxoid non-chondroid, myxoid and/or chondroid tumors as well.*Results ADCmin, DIVIM-min, D*vol, Kvol, and Kmin values showed significant difference between all malignant and benign tumors (P= 0.026, 0.015, 0.045, 0.002, and 0.001, respectively). ADCmin, DIVIM-min, D*vol, Kvol, DK-min, and Kmin values showed significant difference between benign and malignant non-myxoid non-chondroid tumors (P= 0.005, 0.002, 0.013, 0.035, 0.025, and 0.002, respectively). Kmin showed the highest diagnostic performance in differentiating benign and malignant tumors with AUCs of 0.760 and 0.825 (for all tumor groups and non-myxoid non-chondroid tumor groups, respectively). No significant difference was detected in DWI-, IVIM-, and DK-derived parameters for differentiating benign and malignant myxoid and chondroid tumors.*Conclusions ADCmin, DIVIM-min, D*vol, DK-min, Kvol, and Kmin values can be used to differentiate benign and malignant musculoskeletal tumors. Our findings suggest that added value of multiparametric approach in differentiating malignant versus benign tumors is not significant.*Clinical Relevance/Application In addition to well documented contribution of ADCmin, DIVIM-min in differentiation of benign and malignant musculoskeletal tumors, we found in this study comparable diagnostic values for DK-min and Kmin. More significantly, volumetric measurements (D*vol, Kvol) appeared to be promising parameters for specific and overall tumor types, respectively.

RESULTS

ADCmin, DIVIM-min, D*vol, Kvol, and Kmin values showed significant difference between all malignant and benign tumors (P= 0.026, 0.015, 0.045, 0.002, and 0.001, respectively). ADCmin, DIVIM-min, D*vol, Kvol, DK-min, and Kmin values showed significant difference between benign and malignant non-myxoid non-chondroid tumors (P= 0.005, 0.002, 0.013, 0.035, 0.025, and 0.002, respectively). Kmin showed the highest diagnostic performance in differentiating benign and malignant tumors with AUCs of 0.760 and 0.825 (for all tumor groups and non-myxoid non-chondroid tumor groups, respectively). No significant difference was detected in DWI-, IVIM-, and DK-derived parameters for differentiating benign and malignant myxoid and chondroid tumors.

CLINICAL RELEVANCE/APPLICATION

In addition to well documented contribution of ADCmin, DIVIM-min in differentiation of benign and malignant musculoskeletal tumors, we found in this study comparable diagnostic values for DK-min and Kmin. More significantly, volumetric measurements (D*vol, Kvol) appeared to be promising parameters for specific and overall tumor types, respectively.

SPR-MK-16 Imaging Utilization Patterns For The Post-Operative Follow-up Of Extremity Soft Tissue Sarcoma In The United States

Participants
Natalia Gorelik, MD, Montreal, Quebec (*Presenter*) Research Grant, General Electric Company

PURPOSE

No consensus exists on the most appropriate surveillance approach for extremity soft tissue sarcoma, and current follow-up practices have not been characterized nationally. This study aims to define patterns of imaging utilization after resection of extremity soft tissue sarcoma in the U.S., assess for potential disparities, and evaluate temporal trends.*Methods and Materials A retrospective analysis of a national database of private payer claims data was performed to determine the utilization rate of extremity MRI, CT, and ultrasound and chest CT and radiographs in a 5-year post-operative follow-up period for patients with extremity soft tissue sarcoma. 3816 patients (52% males; 48% 65 years and older; mean follow-up of 850 days) surgically treated for extremity soft tissue sarcoma between January 2007 and December 2019 were included. Imaging utilization rates were assessed

according to patient demographics, post-operative year, and calendar year of surgery. Trends were evaluated using Cochran-Armitage and unadjusted linear regression. Generalized linear regression evaluated the effect of calendar year of surgery and patient demographics on weighted imaging rates during follow-up.*Results Weighted mean imaging exams performed in the 365 days after surgery increased from 4.63 in 2007 to 5.29 in 2019 for all chest imaging and from 1.56 to 2.30 over that period for all extremity imaging. There was a significant increasing trend in the proportion of patients with any extremity imaging (p<0.001) and chest imaging (p<0.01) in the first post-operative year during the study period. The increasing trend in chest imaging was driven by an increase in patients with one or more chest CT (p<0.01), whereas there was a decline in the proportion of patients with one or more chest radiograph (p<0.001). Over the study period, there was also a significant increase in the weighted mean number of imaging exams during the first post-operative year and for 5-years for any extremity imaging (p<0.01), and for all individual imaging types (p<0.05), except chest radiograph. Patient age, region of residence, and death during the study period were significantly associated with weighted means for all imaging types during follow-up, whereas sex, race, and year of surgery were not.*Conclusions There has been significant growth in imaging utilization for extremity soft tissue sarcoma surveillance over the course of our study period. Imaging use rates are associated with patient age and region of residence.*Clinical Relevance/Application An initial step toward evaluating the cost-effectiveness of surveillance strategies for extremity soft tissue sarcoma is understanding current trends. The data presented are foundational to future studies that can inform follow-up guidelines.

RESULTS

Weighted mean imaging exams performed in the 365 days after surgery increased from 4.63 in 2007 to 5.29 in 2019 for all chest imaging and from 1.56 to 2.30 over that period for all extremity imaging. There was a significant increasing trend in the proportion of patients with any extremity imaging (p<0.001) and chest imaging (p<0.01) in the first post-operative year during the study period. The increasing trend in chest imaging was driven by an increase in patients with one or more chest CT (p<0.01), whereas there was a decline in the proportion of patients with one or more chest radiograph (p<0.001). Over the study period, there was also a significant increase in the weighted mean number of imaging exams during the first post-operative year and for 5-years for any extremity imaging (p<0.01), and for all individual imaging types (p<0.05), except chest radiograph. Patient age, region of residence, and death during the study period were significantly associated with weighted means for all imaging types during follow-up, whereas sex, race, and year of surgery were not.

CLINICAL RELEVANCE/APPLICATION

An initial step toward evaluating the cost-effectiveness of surveillance strategies for extremity soft tissue sarcoma is understanding current trends. The data presented are foundational to future studies that can inform follow-up guidelines.

SPR-MK-17 Magnetic Resonance Fingerprinting For Multicomponent Imaging In Articular Cartilage Of Knee

Participants
Seung Eun Lee, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the feasibility of magnetic resonance fingerprinting (MRF)-derived multicomponent mapping to probe temporal change in the composition of articular cartilage of the knee.*Methods and Materials In 23 osteoarthritis patients, sagittal fat-suppressed 3D fast spin-echo (FSE) sequence and 3D MRF-FISP with the hybrid radial-EPI were acquired at baseline (0M), three months (3M), and 12 months (12M). Normal cartilage, damaged cartilage, and synovial fluid were assumed as different components of the cartilage, and their fraction maps were generated with the partial volume MRF method. Total 138 focal regions were evaluated out of 6 divisions. We defined 3 groups according to cartilage changes in serial 3D FSE sequences: progressed (group A), stable abnormal (group B), and stable normal (group C). Group B and C regions were determined by division-matched selection to group A lesions. Averages with standard deviations of normal cartilage fraction (NCF), damaged cartilage fraction (DCF), and synovial fluid fraction (SFF) were obtained by drawing ROI. Two-way repeated measure ANOVA was used to reveal differences in component fractions between groups and between time-points.*Results Nine lesions were assigned to each group. In group A, NCF and DCF were decreased, while SFF was increased between 0M and 12M : NCF, DCF, and SFF - 69.3±20.4, 23.4±19.1, and 7.2±8.9% at 0M; 58.8±21.6, 19.2±19.7, and 21.2±14.8% at 12M. In group B and C, NCF, DCF, and SFF were stable throughout 3 time points. NCF and DCF were significantly higher in group C than group A and group B (P<0.05). SFF was significantly different between groups (p=0.001) and time points (p=0.003). In pairwise comparisons, SFF was different between 0M and 12M (p=0.025) and between group A and C (p=0.001).*Conclusions Multicomponent maps using MRF can demonstrate the fractional changes of normal cartilage, damaged cartilage, and synovial fluid in temporally progressing cartilage lesions.*Clinical Relevance/Application MRF-derived multicomponent maps can be used to probe fractional changes of different cartilage components in the knee.

RESULTS

Nine lesions were assigned to each group. In group A, NCF and DCF were decreased, while SFF was increased between 0M and 12M : NCF, DCF, and SFF - 69.3±20.4, 23.4±19.1, and 7.2±8.9% at 0M; 58.8±21.6, 19.2±19.7, and 21.2±14.8% at 12M. In group B and C, NCF, DCF, and SFF were stable throughout 3 time points. NCF and DCF were significantly higher in group C than group A and group B (P<0.05). SFF was significantly different between groups (p=0.001) and time points (p=0.003). In pairwise comparisons, SFF was different between 0M and 12M (p=0.025) and between group A and C (p=0.001).

CLINICAL RELEVANCE/APPLICATION

MRF-derived multicomponent maps can be used to probe fractional changes of different cartilage components in the knee.

SPR-MK-18 A Pilot Study On AI Based Kellgren-Lawrence Grading For Knee Osteoarthritis

Participants
Heewon Yoon, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To validate the diagnostic performance of an artificial intelligence model for automated Kellgren-Lawrence (KL) grading for knee osteoarthritis in a single institution.*Methods and Materials The model was trained with 54000 radiographs from the open dataset of the Osteoarthritis Initiative (OAI), using a convoluted neural network (CNN). Knee radiographs of 106 subjects (age 65.0 ± 11.8 years, 24/74 male/female, 94/93 right/left [= 187] knee split) who visited our hospital from January to June 2020 were interpreted by a musculoskeletal radiologist with 20 years' experience, serving as the reference standard; and the model's performance outlined by the sensitivity, specificity, precision, f1 score, and accuracy was assessed. Existing KL grading from real clinical practice for these patients were collected; and the model's grading, KL grading noted in real clinical practice, and the reference standard were

all compared.*Results The model achieved testing performance (sensitivity 0.818, specificity 0.938, precision 0.810, f1 score 0.811, accuracy 0.918). KL grading agreement between clinical practice and reference standard was at a kappa value of 0.82 (0.79-0.85) while agreement between the model and the reference standard was 0.93 (0.92-0.94).*Conclusions The results show that classification by this model was comparable to that of models published in the recent studies related to automated KL grading. Furthermore, this fully automated model appears to yield repeatable results at the level of human experts, superior to the KL grading of various human readers for knee osteoarthritis.*Clinical Relevance/Application Model could enhance the diagnostic accuracy and repeatability for knee osteoarthritis grading in clinical practice.

RESULTS

The model achieved testing performance (sensitivity 0.818, specificity 0.938, precision 0.810, f1 score 0.811, accuracy 0.918). KL grading agreement between clinical practice and reference standard was at a kappa value of 0.82 (0.79-0.85) while agreement between the model and the reference standard was 0.93 (0.92-0.94).

CLINICAL RELEVANCE/APPLICATION

Model could enhance the diagnostic accuracy and repeatability for knee osteoarthritis grading in clinical practice.

SPR-MK-19 T2-mapping MRI Evaluation Of Patellofemoral Cartilage In Patients Submitted To Intra-articular Platelet-rich-plasma (PRP) Injections

Participants
Flavia Cobianchi Bellisari, MD, Laquila, Italy (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the ability of T2 mapping magnetic resonance imaging (MRI) at 3T, in addition to morphological sequences, to assess efficacy of platelet-rich plasma (PRP) injections, characterizing qualitatively and quantitatively the grade of knee cartilage repair in patients with patellofemoral chondropathy.*Methods and Materials We retrospectively studied 34 patients (22 men, 12 women, mean age 41.8 years) with patellofemoral knee chondropathy, who underwent intra-articular PRP injections and completed a clinical and instrumental follow-up. As control group we evaluated 34 patients, matching pairwise for age, sex, BMI, chondropathy severity, who underwent conservative treatment. All patients were submitted to clinical (using VAS and WOMAC index) and imaging studies at 3T magnetic resonance (MR) including T2 mapping sequences for cartilage analysis at baseline and up to 12 months after treatment.*Results In the study group, mean pre-treatment T2 relaxation time values were 44.2±2.5ms, considering all articular cartilage compartments, with significant reduction at the follow-up (p<0.001). At the index compartment, mean pre-treatment T2 relaxation times values were 47.8±3.6ms, with statistically significant reduction at the follow-up (p<0.001). Evaluation of focal cartilage lesions reported pre-treatment mean T2 values of 70.1±13.0 ms and post-treatment mean values of 59.9±4.6ms (p<0.001). From a clinical point of view, the pre-treatment WOMAC and VAS scores were 18.3±4.5 and 7 (IQR:6-7.2), respectively; the post-treatment values were 7.3±3.2 and 2 (IQR: 1.7-3.0), respectively (p<0.001). In the control group, despite clinical improvement, we didn't find significant T2 values change during the follow-up period.*Conclusions T2 mapping is a valuable indicator for chondropathy and treatment-related changes over time.*Clinical Relevance/Application Our results confirm the positive clinical effect of PRP in patients affected by patellofemoral knee chondropathy. In addition to morphological sequences, 3T MRI with T2 mapping is a valuable tool for the evaluation of cartilage water content and thus PRP injections efficacy. Further, characterization of the cartilage matrix integrity with T2 mapping may help in the prevention of disease progression by enabling the identification of individuals with early osteoarthritis who may benefit from treatment before irreversible morphologic changes occur.

RESULTS

In the study group, mean pre-treatment T2 relaxation time values were 44.2±2.5ms, considering all articular cartilage compartments, with significant reduction at the follow-up (p<0.001). At the index compartment, mean pre-treatment T2 relaxation times values were 47.8±3.6ms, with statistically significant reduction at the follow-up (p<0.001). Evaluation of focal cartilage lesions reported pre-treatment mean T2 values of 70.1±13.0 ms and post-treatment mean values of 59.9±4.6ms (p<0.001). From a clinical point of view, the pre-treatment WOMAC and VAS scores were 18.3±4.5 and 7 (IQR:6-7.2), respectively; the post-treatment values were 7.3±3.2 and 2 (IQR: 1.7-3.0), respectively (p<0.001). In the control group, despite clinical improvement, we didn't find significant T2 values change during the follow-up period.

CLINICAL RELEVANCE/APPLICATION

Our results confirm the positive clinical effect of PRP in patients affected by patellofemoral knee chondropathy. In addition to morphological sequences, 3T MRI with T2 mapping is a valuable tool for the evaluation of cartilage water content and thus PRP injections efficacy. Further, characterization of the cartilage matrix integrity with T2 mapping may help in the prevention of disease progression by enabling the identification of individuals with early osteoarthritis who may benefit from treatment before irreversible morphologic changes occur.

SPR-MK-21 Gender And Age Related Changes In Bone Density, Fat, And Perfusion By DCE-MRI

Participants
Wing Pong Chan, MD, Taipei, Taiwan (*Presenter*) Nothing to Disclose

PURPOSE

Older women are at greater risk for osteoporosis and fragility fractures compared to men. There is little information with regards to the bone marrow composition changes that occur in aging men. The present study aims to investigate the differences in vertebral bone mineral density (BMD), fat, and blood perfusion between men and women of different ages.*Methods and Materials We prospectively recruited 120 healthy volunteers with BMI ?30kg/cm2. All participants were grouped by sex and age (20 ~ 34, 35 ~ 49, 50 ~ 64, and ?65). Axial MRI images at the L1 vertebral body level were obtained using a T1-weighted 3D spoiled gradient echo sequence and a gradient-echo fast low angle shot sequence (temporal resolution, 2s; total scan time, 7m 20s). We measured proton density fat fraction (PDFF), enhancement maximum (Emax), Ktrain, Kep, Ve, and Cmax. The data were analyzed using repeated-measures ANOVA. BMD was obtained by Dual-energy X-ray absorptiometry (DXA) scan.*Results Vertebral marrow perfusion (Emax) was highest in the 35-49 age group and was consistently higher in females than in males across all age groups. In women, BMD negatively correlated with PDFF though positively correlated with Emax in four of the age groups. BMD and Emax were significantly lower in the older group (>=65) compared to the two younger groups (20~34 and 35~49) (p<0.0001). PDFF values were also significantly higher in the older group compared to the younger groups. Men across all age groups showed no significant differences in BMD and PDFF (all comparisons yielded p>0.05). Emax, Ve, and Cmax values were however significantly lower in older men compared to men in the two younger groups.*Conclusions In women, BMD decreased with age, while PDFF increased with age.

For both men and women, Emax levels were the lowest in the older group. Older men also showed drops in Ve and Cmax. Therefore, it appears that the aging of bone in women is marked by structural losses and composition changes, while the aging of bone in men is marked more by perfusion abnormalities. Emax is the only measurement that can identify aging bone in both genders.*Clinical Relevance/Application Postmenopausal women are different from men in terms of vertebral marrow perfusion, fat and bone mineral density relationships. Emax is the only measurement that can identify aging bone in both genders.

RESULTS

Vertebral marrow perfusion (Emax) was highest in the 35-49 age group and was consistently higher in females than in males across all age groups. In women, BMD negatively correlated with PDFF though positively correlated with Emax in four of the age groups. BMD and Emax were significantly lower in the older group (>=65) compared to the two younger groups (20~34 and 35~49) (p<0.0001). PDFF values were also significantly higher in the older group compared to the younger groups. Men across all age groups showed no significant differences in BMD and PDFF (all comparisons yielded p>0.05). Emax, Ve, and Cmax values were however significantly lower in older men compared to men in the two younger groups.

CLINICAL RELEVANCE/APPLICATION

Postmenopausal women are different from men in terms of vertebral marrow perfusion, fat and bone mineral density relationships. Emax is the only measurement that can identify aging bone in both genders.

SPR-MK-26 High Contrast Cartilaginous Endplate Imaging Using A 3D Adiabatic Inversion Recovery Prepared Fat Saturated Ultrashort Echo Time (3D IR-FS-UTE) Sequence

Participants
Alecio Lombardi, MD, San Diego, California (*Presenter*) Nothing to Disclose

PURPOSE

To describe a 3D adiabatic inversion recovery fat-saturated ultrashort echo time (3D-IR-FS-UTE) MR sequence to highlight the cartilaginous endplate (CEP) of vertebral bodies.*Methods and Materials The 3D IR-FS-UTE sequence uses an adiabatic inversion pulse (hyperbolic secant type 1, duration = 8.64 ms, bandwidth = 1.15 kHz) centered in a frequency between water and fat to invert the longitudinal magnetization of long T2 tissues like the intervertebral disc (IVD), while only partially inverting the longitudinal magnetization of short T2 tissues like the CEP (1). A FatSat module is used to suppress fat from the bone marrow. After appropriate inversion recovery time (TI) to null long T2 tissues' signals, data acquisition starts detecting short T2 tissues' signals. A train of spokes is used to accelerate the scan. A slab-selective half pulse (Shinnar-Le Roux design, duration = 1132 µs, bandwidth = 16 kHz) with variable-rate selective excitation design (2) is used for signal excitation and a 3D cones trajectory is used to reduce sampling time. To investigate T1 variations among the CEP, annulus fibrosus (AF), and nucleus pulposus (NP), T1 relaxations were measured with the 3D UTE actual flip angle and variable flip angle method (UTE-AFI-VFA) (3) in a human cadaveric spine, that was later fixed and sliced for histology. Six healthy volunteers and three patients with back pain underwent T1w-FSE, T2w-FSE, and 3D IR-FS-UTE spine MRI. Contrast-to-noise ratios (CNR) between the CEP and BF and between the CEP and IVD were calculated as differences in signal divided by background noise.*Results The 3D UTE-AFI-VFA method showed a T1 of 360±12 ms in the CEP, 570±21 ms in the AF, and 870±28 ms in the NP. High CEP contrast was achieved with TIs ranging from 480 to 640 ms. The CEP was detected on the 3D IR-FS-UTE but not on the T1w- or T2w-FSE. A CEP fracture in the spine sample with NP herniation through the focal defect, later confirmed on histology, was only detected on the 3D IR-FS-UTE. CEP abnormalities such as reduced thickness, focal erosions, fractures, and fragmentation were observed among patients. The mean CNRs between the CEP and BF, and between the CEP and IVD for all six volunteers were 18.5±4.9 and 20.3±4.15, respectively.*Conclusions The 3D IR-FS-UTE MRI sequence can image the CEP with high contrast in healthy volunteers and patients with traumatic and degenerative spinal changes.*Clinical Relevance/Application The 3D IR-FS-UTE sequence allows for early detection of CEP abnormalities and can be applied in the study of the mechanisms involved in IVD degeneration and low back pain. 1. Magn Res Med. 2007;58(5):952-61; 2. Magn Res Med. 2004;52(3):590-7; 3 Magn Res Med. 2019;81(3):1634-44.

RESULTS

The 3D UTE-AFI-VFA method showed a T1 of 360±12 ms in the CEP, 570±21 ms in the AF, and 870±28 ms in the NP. High CEP contrast was achieved with TIs ranging from 480 to 640 ms. The CEP was detected on the 3D IR-FS-UTE but not on the T1w- or T2w-FSE. A CEP fracture in the spine sample with NP herniation through the focal defect, later confirmed on histology, was only detected on the 3D IR-FS-UTE. CEP abnormalities such as reduced thickness, focal erosions, fractures, and fragmentation were observed among patients. The mean CNRs between the CEP and BF, and between the CEP and IVD for all six volunteers were 18.5±4.9 and 20.3±4.15, respectively.

CLINICAL RELEVANCE/APPLICATION

The 3D IR-FS-UTE sequence allows for early detection of CEP abnormalities and can be applied in the study of the mechanisms involved in IVD degeneration and low back pain. 1. Magn Res Med. 2007;58(5):952-61; 2. Magn Res Med. 2004;52(3):590-7; 3 Magn Res Med. 2019;81(3):1634-44.

SPR-MK-27 Percutaneous Ultrasound Guided Needle Tenotomy For Treatment Of Chronic Tendinopathy: A Systematic Review And Meta-analysis

Participants
Firoozeh Shomal Zadeh, MD, Seattle, Washington (*Presenter*) Nothing to Disclose

PURPOSE

To systematically assess the efficacy of Percutaneous Ultrasound Guided Needle Tenotomy (PUNT) in the treatment of chronic tendinopathy.*Methods and Materials A literature search was conducted with the following search terms: Tendinopathy, Tenotomy, Needling, Tenex, Fasciotomy, Ultrasound guided, Percutaneous. Inclusion criteria consisted of original studies that assessed the pain and disability improvement using Visual Analog Scale (VAS), or Disability of the Arm, Shoulder and Hand (DASH) Index after PUNT. Cochrane Collaboration's tool was used to assess methodological quality assessment. Meta-analyses were performed and compared pain and disability improvement in three different time points.*Results Twenty-one studies with a total of 806 subjects were included in the meta-analysis. According to our meta-analysis, PUNT significantly alleviated pain and disability. Our baseline mean VAS was 6.26 (95% CI: 5.86-6.68) with improvement of 3.8 (95% CI: 3.23 - 4.32; P<0.001), 3.95 (95% CI: 2.98-4.92; P<0.001), and 4.56 (95% CI: 4.06-5.06; P<0.001) points in the first 3 months, 6 months, and long-term follow-up (12.6±1.8 months), respectively. PUNT is also associated with marked reductions in DASH score (24.7 [95% CI: 22.8-26.5; P<0.001]) in long-term follow-up (11.3±1.3 months). The most significant improvement in VAS and DASH scores was through the first 3 months of

follow-up. The mean difference of VAS (1.03 [95% CI: -0.907-2.970; P= 0.29]) and DASH score (3.19 [95% CI: -1.22-7.60; P=0.156]) after this period (3 months) was not significant.*Conclusions PUNT could significantly improve pain and function scores related to chronic resistant tendinopathy. The improvement was more significant during the short-term follow-up. PUNT could be considered as a suitable nonsurgical option for the treatment of chronic tendinopathy. Additionally, the included studies showed overall positive outcome for life quality, patient satisfaction, and sonographic findings.*Clinical Relevance/Application PUNT could be a less invasive and cost-effective substitute for surgical intervention in treatment of resistant chronic tendinopathies.

RESULTS

Twenty-one studies with a total of 806 subjects were included in the meta-analysis. According to our meta-analysis, PUNT significantly alleviated pain and disability. Our baseline mean VAS was 6.26 (95% CI: 5.86-6.68) with improvement of 3.8 (95% CI: 3.23 - 4.32; P<0.001), 3.95 (95% CI: 2.98-4.92; P<0.001), and 4.56 (95% CI: 4.06-5.06; P<0.001) points in the first 3 months, 6 months, and long-term follow-up (12.6±1.8 months), respectively. PUNT is also associated with marked reductions in DASH score (24.7 [95% CI: 22.8-26.5; P<0.001]) in long-term follow-up (11.3±1.3 months). The most significant improvement in VAS and DASH scores was through the first 3 months of follow-up. The mean difference of VAS (1.03 [95% CI: -0.907-2.970; P= 0.29]) and DASH score (3.19 [95% CI: -1.22-7.60; P=0.156]) after this period (3 months) was not significant.

CLINICAL RELEVANCE/APPLICATION

PUNT could be a less invasive and cost-effective substitute for surgical intervention in treatment of resistant chronic tendinopathies.

SPR-MK-3 Enthesis Assessment Using Ultrashort Echo Time Magnetic Resonance Imaging (UTE-MRI) Adiabatic T1 (UTE-Adiab-T1) And Magnetization Transfer (MT) Modeling

Participants
Saeed Jerban, PhD, San Diego, California (Presenter) Nothing to Disclose

PURPOSE

To determine if ultrashort echo time MRI (UTE-MRI) techniques (magnetization transfer (MT) modeling and adiabatic T1? (UTE-Adiab-T1?)) can detect the compositional differences between Achilles tendon and enthesis.*Methods and Materials Eight normal human cadaveric ankle specimens (52±18 years old) were imaged with on a 3T MRI scanner (MR750, GE) employing a T/R birdcage coil on the sagittal plane. An actual variable flip angle (AFI-VFA) sequence (AFI: TE=0.032ms, TRs=20,100ms, FA=45°; VFA: TE=0.032ms, TR=20ms, FAs=5, 10, 20, 30°) was performed to measure T1(1). A 3D-UTE-Cones-MT sequence (pulse power=400, 600, and 800°; frequency offset=2, 5, 10, 20, and 50kHz) was performed for the two-pool MT modeling (2,3). Additionally, a set of 3D UTE-Adiab-T1? sequences with 5 different spin-locking times (TSLs) (TR=500ms, TSL= 0, 12, 24, 36, and 48 ms) were performed (4). Field of view, matrix dimension, pixel size, slice thickness, and total scan time were 11cm, 340×340, 0.8mm, and 100 mins, respectively.For each specimen, average macromolecular proton fraction (MMF) was estimated using MT modeling performed on two sagittal slices 3 mm apart. T1 and UTE-Adiab-T1? values were calculated for each specimen using a single-component exponential fitting model. Measurements were performed within three regions of interest (ROIs) including enthesis, tendon, and the transition region between tendon and enthesis. Student's t-test was used to compare the calculated MRI markers between the three selected ROIs. P-values <0.05 were considered significant. . Data analysis was performed in MATLAB (2018, The Mathworks Inc., MA).*Results Fig.1A shows schematically the representative ROIs selected on a UTE-Adiab-T1? image performed on the sagittal plane. Estimated MMF and T1? values in the studied ROIs are presented in Fig.1B and 1C, respectively. MMF was significantly lower in enthesis compared with Achilles tendon, while T1? was significantly higher in enthesis compared with the tendon. Fig.1D and 1E illustrate representative MMF and T1? pixel maps, respectively, for a 62-year-old female donor.*Conclusions This study highlighted the UTE-MT modeling and UTE-Adiab-T1? technique as useful quantitative methods to assess enthesis and tendon. Significantly lower MMF and higher T1? may suggest lower macromolecular contents (i.e., collagen and proteoglycan) in enthesis compared with the tendon. Future studies will be required to investigate the correlations between our MRI biomarkers and the tissues' mechanical and histological properties.*Clinical Relevance/Application UTE-MRI-based techniques which can distinguish between entheses and tendons, and detect their changes, may help diagnose musculoskeletal diseases sooner and more specifically.

RESULTS

Fig.1A shows schematically the representative ROIs selected on a UTE-Adiab-T1? image performed on the sagittal plane. Estimated MMF and T1? values in the studied ROIs are presented in Fig.1B and 1C, respectively. MMF was significantly lower in enthesis compared with Achilles tendon, while T1? was significantly higher in enthesis compared with the tendon. Fig.1D and 1E illustrate representative MMF and T1? pixel maps, respectively, for a 62-year-old female donor.

CLINICAL RELEVANCE/APPLICATION

UTE-MRI-based techniques which can distinguish between entheses and tendons, and detect their changes, may help diagnose musculoskeletal diseases sooner and more specifically.

SPR-MK-4 Prediction Of Compression Fracture In Multiple Myeloma Patients Using CT Measures Of Muscle Mass And Density

Participants
Sanghee Kim, Seoul, Korea, Republic Of (Presenter) Nothing to Disclose

PURPOSE

To evaluate muscle area and muscle density on abdominal CT as predictors for compression fractures and survival in multiple myeloma patients.*Methods and Materials Patients with multiple myeloma who underwent abdomen CT between 2010 and 2019 were retrospectively included. The muscle area was semi-automatically segmented from an axial CT at the L3 lower endplate level. Muscle density was defined as the mean Hounsfield unit (HU) of segmented muscle mass. Additionally, age, body mass index (BMI), bone density measured on the vertebral body of L1 on CT, and international staging system (ISS) were considered for variables. Compression fracture and death were primary and secondary endpoints, respectively. Univariate survival analysis with Kaplan-Meyer (KM) plots was performed on each variable. Multivariate Cox proportional hazards models using different combinations of variables were developed and compared using the concordance index (C-index).*Results A total of 361 patients were included (mean age ± SD, 65.3 ± 9.49 years; 191 men and 170 women). On analysis of KM plots after each variable dichotomized by z-score, muscle area and muscle density were significant factors for the compression fracture (P=0.003, P<0.001). In contrast, ISS and muscle density were significant factors for the survival (P<0.001, P=0.02). Multivariate Cox proportional hazards models revealed that ISS and

muscle density were independent factors to predict compression fractures (P=0.002, P<0.001), and survival (P=0.001, P<0.001). There were significant differences in C-index between the base model, including age, BMI, bone density, and the models with additional variables (P<0.001) : base model (0.564, 95 % confidence interval (CI): 0.508-0.619), base model+muscle density (0.642, 95 % CI 0.591-0.693), base model+muscle area (0.637, 95 % CI 0.589-0.686), base model+muscle density+muscle area (0.648,95 % CI 0.599-0.697).*Conclusions Muscle density obtained from abdomen CT was an independent predictor for compression fracture and survival in multiple myeloma patients. The models, including muscle density and muscle area, performed better than the base model for predicting compression fracture.*Clinical Relevance/Application Sarcopenia-related parameters on opportunistic abdomen CT are predictors for compression fractures and survival in multiple myeloma patients.

RESULTS

A total of 361 patients were included (mean age ± SD, 65.3 ± 9.49 years; 191 men and 170 women). On analysis of KM plots after each variable dichotomized by z-score, muscle area and muscle density were significant factors for the compression fracture (P=0.003, P<0.001). In contrast, ISS and muscle density were significant factors for the survival (P<0.001, P=0.02). Multivariate Cox proportional hazards models revealed that ISS and muscle density were independent factors to predict compression fractures (P=0.002, P<0.001), and survival (P=0.001, P<0.001). There were significant differences in C-index between the base model, including age, BMI, bone density, and the models with additional variables (P<0.001) : base model (0.564, 95 % confidence interval (CI): 0.508-0.619), base model+muscle density (0.642, 95 % CI 0.591-0.693), base model+muscle area (0.637, 95 % CI 0.589-0.686), base model+muscle density+muscle area (0.648,95 % CI 0.599-0.697).

CLINICAL RELEVANCE/APPLICATION

Sarcopenia-related parameters on opportunistic abdomen CT are predictors for compression fractures and survival in multiple myeloma patients.

SPR-MK-5　Femoral Retroversion: Intra- And Extraarticular Anterior Subspine Hip Impingement During Flexion On 3D-CT Based Impingement Simulation

Participants
Till Lerch, MD, Bern, Switzerland (*Presenter*) Nothing to Disclose

PURPOSE

Symptomatic FAI patients have limitations in hip function and sports activity. Some patients report exacerbation of hip pain with sitting or maximal flexion.But the exact location of hip impingement in sitting position is unknown. We aimed to investigate impingement-free maximal flexion, the location of the impingement conflict in maximal flexion and if impingement is located intra- or extraarticular in patients with low femoral version(FV).*Methods and Materials An IRB-approved retrospective study involving 84 hips of 68 participants was performed. Of these, 58 hips of symptomatic patients with anterior FAI were compared with 26 asymptomatic hips with no FAI and normal FV. All patients with FAI were symptomatic and had anterior hip pain and a positive anterior impingement test. They underwent pelvic CT scans to measure FV and for dynamic impingement simulation. McKibbin index was calculated adding FV and acetabular version (AV). All 84 hips were evaluated by use of CT-based 3D models and a validated 3D range of motion and impingement simulation using the equidistant method. Simulation of maximal flexion was evaluated for all patients. Asymptomatic hips were contralateral normal hips of patients undergoing total hip arthroplasty.*Results Hips with FAI had a significantly (p<0.001) lower mean impingement-free flexion of 116° compared with the asymptomatic control group (125°). In a subgroup analysis, hips with decreased McKibbin index had a lower flexion of 113°, while hips with mixed-type FAI combined with decreased McKibbin index had 110° of flexion and hips with pincer-type FAI combined with decreased McKibbin index had 112°. Patients with Low McKibbin index had a significantly higher prevalence (59%) of extraarticular subspine impingement in 125° of flexion compared to the control group (29%). Location of femoral impingement conflict in maximal flexion was anterior between 3 to 5 o clock in 115° of flexion, while in 125° of flexion, it was located anterior-inferior between 4 and 6 o clock of the hips with FAI.*Conclusions For planning hip preservation surgery, the exact location of the hip impingement conflict is essential. Based on this study, impingement conflict in sitting position was located intra- and extraarticular. Patients with Low McKibbin index combined with mixed-type FAI had the lowest impingement-free flexion. Femoral impingement location was anterior inferior in maximal flexion.*Clinical Relevance/Application Exacerbation of hip pain in sitting position is common in FAI patients. This 3D simulation has implications for planning for hip arthroscopy and enables patient-specific treatment of the impingement conflict in maximal flexion.

RESULTS

Hips with FAI had a significantly (p<0.001) lower mean impingement-free flexion of 116° compared with the asymptomatic control group (125°). In a subgroup analysis, hips with decreased McKibbin index had a lower flexion of 113°, while hips with mixed-type FAI combined with decreased McKibbin index had 110° of flexion and hips with pincer-type FAI combined with decreased McKibbin index had 112°. Patients with Low McKibbin index had a significantly higher prevalence (59%) of extraarticular subspine impingement in 125° of flexion compared to the control group (29%). Location of femoral impingement conflict in maximal flexion was anterior between 3 to 5 o clock in 115° of flexion, while in 125° of flexion, it was located anterior-inferior between 4 and 6 o clock of the hips with FAI.

CLINICAL RELEVANCE/APPLICATION

Exacerbation of hip pain in sitting position is common in FAI patients. This 3D simulation has implications for planning for hip arthroscopy and enables patient-specific treatment of the impingement conflict in maximal flexion.

SPR-MK-6　Percutaneous CT-guided Corticosteroid For The Treatment Of Langerhans Cell Histiocytosis: A Retrospective Multi-institutional Study

Participants
Connie Y. Chang, MD, Boston, Massachusetts (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the safety and effectiveness of CT-guided corticosteroid injection for the treatment of Langerhans Cell Histiocytosis (LCH) in a multi-institutional study.*Methods and Materials This study was IRB-approved and HIPAA-compliant at all three participating institutions. We retrospectively reviewed clinical, procedural, and imaging data for corticosteroid injections performed to treat LCH at the participating institutions. Location of the lesion and lesion maximum dimension and volume, corticosteroid type and dose, and time interval between injection and partial/complete imaging resolution and symptomatic resolution were recorded. Groups were compared using the Kruskal-Wallis and Chi-Square tests. A Generalized Estimating Equation was used to evaluate the association between size of the lesion and steroid dose (accounting for multiple lesions per subject). This analysis was adjusted by

anatomic site. *Results 40 corticosteroid injections were performed in 36 subjects (20 (56%) females, and 16 (44%) males, ages 12 ± 11 (2-57) years). All patients had pathologic confirmation for LCH. All subjects underwent one injection per lesion. If additional injections were performed in the same subject, it was for a new site of disease. Lesion maximum dimension was 3.2±1.7 cm, and volume was 10±17cm3. There were 19 (56%) and 15 (44%) lesions in the appendicular and axial skeleton, respectively. Corticosteroid (methylprednisolone, triamcinolone) dose was 73 ± 24 (40-120) mg. Larger lesions were treated with higher corticosteroid doses (p = 0.02). Imaging and clinical follow-up were available for 22/40 (55%) and 34/40 (85%) of injections, respectively. Times to partial and complete imaging resolution were 13 ± 9 and 32 ± 13 weeks, respectively, and time to pain control was 22 ± 14 weeks. There were no complications.*Conclusions CT-guided corticosteroid injection is a safe and effective treatment for LCH. Pain resolution was achieved in all patients and imaging did not show progressive disease in any of the patients.*Clinical Relevance/Application CT-guided corticosteroid injection may be considered as a first-line therapy for LCH.

RESULTS

40 corticosteroid injections were performed in 36 subjects (20 (56%) females, and 16 (44%) males, ages 12 ± 11 (2-57) years). All patients had pathologic confirmation for LCH. All subjects underwent one injection per lesion. If additional injections were performed in the same subject, it was for a new site of disease. Lesion maximum dimension was 3.2±1.7 cm, and volume was 10±17cm3. There were 19 (56%) and 15 (44%) lesions in the appendicular and axial skeleton, respectively. Corticosteroid (methylprednisolone, triamcinolone) dose was 73 ± 24 (40-120) mg. Larger lesions were treated with higher corticosteroid doses (p = 0.02). Times to partial and complete imaging resolution were 13 ± 9 and 32 ± 13 weeks, respectively, and time to pain control was 22 ± 14 weeks. There were no complications.

CLINICAL RELEVANCE/APPLICATION

CT-guided corticosteroid injection may be considered as a first-line therapy for LCH.

SPR-MK-7   Development And Assessment Of A Robotic Telesonography System For Musculoskeletal Imaging

Participants
Scott Adams, MD, Saskatoon, Saskatchewan (*Presenter*) Nothing to Disclose

PURPOSE

Robotic telesonography systems have been developed to help patients in rural and remote communities overcome barriers to access diagnostic ultrasound. However, most previous robotic telesonography systems have been designed for performing only abdominal and obstetrical exams. The purpose of this study was to develop and assess a robotic telesonography system for performing musculoskeletal (MSK) ultrasound exams.*Methods and Materials We developed a 4-degrees-of-freedom robot to manipulate an ultrasound probe. The robot is remotely controlled by a radiologist operating a joystick at the master site. The robotic telesonography system was used to scan participants' forearms, and all participants were also scanned conventionally for comparison. Participants and radiologists were surveyed regarding their experience. Images from robotic and conventional scanning methods were independently assessed by an MSK radiologist and visualization scores were compared using Fisher's exact test.*Results All 10 ultrasound exams were successfully performed using our developed MSK robotic telesonography system, with no significant delay in movement. The mean (±standard deviation) duration of robotic and conventional exams was 4.6 (±0.9) and 1.4 (±0.5) minutes, respectively (p = 0.039). An MSK radiologist rated quality of real-time ultrasound images transmitted over an internet connection as "very good" for all telesonography exams, and participants rated communication with the radiologist as "very good" or "good" for all exams. Visualization of anatomic structures was similar between robotic and conventional images based on the radiologist's blinded assessment. No statistically significant differences were observed in the proportion of muscles, myotendinous junctions, tendons, neurovascular bundles, and bones which were completely (adequately) documented, partially documented, or not documented based on the representative images.*Conclusions The MSK robotic telesonography system developed in this study is feasible for remotely performing soft tissue ultrasound exams. The advancement of this system may allow MSK ultrasound exams to be performed over long distances, increasing access to ultrasound for patients in rural and remote communities.*Clinical Relevance/Application The remote provision of MSK ultrasound services using robotic telesonography may increase access to specialized ultrasound imaging for patients in underserved rural and remote communities. MSK robotic telesonography may reduce time to diagnosis, improve patient experience and satisfaction, and help improve health equity in rural and remote communities.

RESULTS

All 10 ultrasound exams were successfully performed using our developed MSK robotic telesonography system, with no significant delay in movement. The mean (±standard deviation) duration of robotic and conventional exams was 4.6 (±0.9) and 1.4 (±0.5) minutes, respectively (p = 0.039). An MSK radiologist rated quality of real-time ultrasound images transmitted over an internet connection as "very good" for all telesonography exams, and participants rated communication with the radiologist as "very good" or "good" for all exams. Visualization of anatomic structures was similar between robotic and conventional images based on the radiologist's blinded assessment. No statistically significant differences were observed in the proportion of muscles, myotendinous junctions, tendons, neurovascular bundles, and bones which were completely (adequately) documented, partially documented, or not documented based on the representative images.

CLINICAL RELEVANCE/APPLICATION

The remote provision of MSK ultrasound services using robotic telesonography may increase access to specialized ultrasound imaging for patients in underserved rural and remote communities. MSK robotic telesonography may reduce time to diagnosis, improve patient experience and satisfaction, and help improve health equity in rural and remote communities.

SPR-MK-8   Diagnostic Performance Of Deep Learning Algorithm In Detecting Anterior Cruciate Ligament Tear On Lateral Knee Radiography: Focusing On Lateral Femoral Notch Sign And Joint Effusion

Participants
Jihee Kang, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the diagnostic performance of deep learning algorithm in detecting acute anterior cruciate ligament (ACL) tear on lateral knee radiographs.*Methods and Materials A total of 987 cropped lateral knee radiographs (661 with ACL tear and 326 normal) was divided into training (80%), validation (10%), and test sets (10%). Firstly, a single binary classifier for diagnosing ACL tear was developed (algorithm 1). Secondly, two binary classification models were developed for detecting secondary signs of ACL tears on radiograph: lateral femoral notch sign (algorithm 2) and significant amount of knee joint effusion (anteroposterior diameter

= 5mm; algorithm 3). Finally, an ensemble model using algorithm 2 and 3 to make the diagnosis of ACL tear was developed (algorithm 4). Sensitivity, specificity, accuracy, positive predictive value (PPV), and negative predictive value (NPV) were calculated for each algorithm.*Results Sensitivity, specificity, accuracy, PPV, and NPV were 84.85, 66.67, 78.10, 81.16, and 72.22% for algorithm 1, 77.78, 85.51, 82.86, 73.68, and 88.06% for algorithm 2, and 91.07, 77.55, 84.76, 82.26, and 88.37% for algorithm 3. In the case of ensemble model, sensitivity, specificity, accuracy, PPV, and NPV was 86.36, 74.36, 81.90, 85.07, and 76.32%, respectively. Diagnostic performance of the ensemble model was significantly higher compared to the single model (area under the curve 0.902 vs 0.753; p=0.0004).*Conclusions The deep learning algorithm could accurately make the diagnosis of ACL tear on lateral knee radiographs.*Clinical Relevance/Application The proposed deep learning algorithm can be an efficient screening tool for ACL tear, facilitating early diagnosis and timely management. It might be useful especially in the emergency department.

RESULTS

Sensitivity, specificity, accuracy, PPV, and NPV were 84.85, 66.67, 78.10, 81.16, and 72.22% for algorithm 1, 77.78, 85.51, 82.86, 73.68, and 88.06% for algorithm 2, and 91.07, 77.55, 84.76, 82.26, and 88.37% for algorithm 3. In the case of ensemble model, sensitivity, specificity, accuracy, PPV, and NPV was 86.36, 74.36, 81.90, 85.07, and 76.32%, respectively. Diagnostic performance of the ensemble model was significantly higher compared to the single model (area under the curve 0.902 vs 0.753; p=0.0004).

CLINICAL RELEVANCE/APPLICATION

The proposed deep learning algorithm can be an efficient screening tool for ACL tear, facilitating early diagnosis and timely management. It might be useful especially in the emergency department.

SPR-MK-9   A Deep Learning Method Based On Multi-model Weighted Fusion To Distinguish Benign And Malignant Spinal Tumors With Magnetic Resonance Imaging

Participants
Hong Liu, DO, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate a deep learning method (DLM) based on multi-model weighted fusion strategy for identifying benign and malignant spinal tumors with sagittal MRI, and compare with one senior radiologist (D1), one senior orthopedist (D2) and one junior orthopedist (D3).*Methods and Materials The consecutive spinal tumor patients between Jan. 2006 and Dec. 2019 from collaborating hospital were all retrospectively reviewed, especially the sagittal MRI with final pathological diagnosis. This study recruited 585 spinal tumor patients including 270 benign and 315 malignant ones (over 20 histological subtypes). All the spinal tumor patients were randomly divided into training set (n=445; 180 benign, 265 malignant) and testing set (n=140; 90 benign, 50 malignant). MRI sagittal sequences of each patient including T1-weighted image (TIWI), T2WI and fat suppression T2WI were used. A multi-model weighted fusion method including Faster-RCNN and ResNet101 was proposed. Firstly, a tri-class Faster-RCNN model was used to detect benign and malignant lesions in MRI images, and patient-level results were obtained by fusing these region detection results. Then, a two-class sequence classification model based on ResNet101 was applied to classify the former detected lesion regions to get the patient-level result of benign or malignant. Finally, above results of two models were weighted fused to get final diagnosis results. On training set, four-fold cross-validation was applied to train and validate the proposed method DLM, and the proper hyper parameters of deep models and fused weights were selected. Metrics of AUC, ACC, sensitivity, specificity and diagnosis time were used to evaluate our method.*Results On testing set, the AUC (0.787) of DLM was similar to senior radiologist (D1:0.73, p=0.3) and higher than two orthopedic doctors (D2: 0.646, p=0.01, D3: 0.682, p<0.009). The ACC (80.0%, 112 in 140) of DLM was higher than doctors' (D1:75%, D2: 66.4%, D3: 61.4%). For malignant tumor identification, DLM's specificity (83.3%) was higher than doctors' (D1: 80.0%, D2: 71.1%, D3: 44.4%), and DLM's sensitivity (74.0%) was higher than most of doctors' (D1: 66.0%, D2: 58.0%, D3: 92.0%). Although doctor D3 had higher sensitivity (92.0%), he had lower ACC (61.4%) and specificity (44.4%). To diagnose benign or malignant of each patient with MRI sequences, DLM spent average 12.45 seconds and doctor spent average 47.86 seconds.*Conclusions The proposed method is effective to identify benign and malignant spinal tumor on patient MRI dataset with complex histological subtypes, and has higher performance than radiologist and orthopedist.*Clinical Relevance/Application This framework can provide a reference for early spinal tumor assisted diagnosis.

RESULTS

On testing set, the AUC (0.787) of DLM was similar to senior radiologist (D1:0.73, p=0.3) and higher than two orthopedic doctors (D2: 0.646, p=0.01, D3: 0.682, p<0.009). The ACC (80.0%, 112 in 140) of DLM was higher than doctors' (D1:75%, D2: 66.4%, D3: 61.4%). For malignant tumor identification, DLM's specificity (83.3%) was higher than doctors' (D1: 80.0%, D2: 71.1%, D3: 44.4%), and DLM's sensitivity (74.0%) was higher than most of doctors' (D1: 66.0%, D2: 58.0%, D3: 92.0%). Although doctor D3 had higher sensitivity (92.0%), he had lower ACC (61.4%) and specificity (44.4%). To diagnose benign or malignant of each patient with MRI sequences, DLM spent average 12.45 seconds and doctor spent average 47.86 seconds.

CLINICAL RELEVANCE/APPLICATION

This framework can provide a reference for early spinal tumor assisted diagnosis.

SSPH03-1 Utility Of A New Phantom For Quantitative Imaging Performance Evaluation Of CT Scanners

Participants
Mahadevappa Mahesh, PHD, Baltimore, Maryland (*Presenter*) Nothing to Disclose

PURPOSE

Evaluation of advanced multi-detector CT (MDCT) scanners with isotropic resolution and nonlinear image reconstruction presents a challenge to current QA standards. Existing CT phantoms are not designed to quantify contrast-dependent 3D spatial resolution (MTF), noise power spectrum (NPS), or cone-beam effects (Zmod).*Methods and Materials We used a phantom (CorgiTM, The Phantom Lab) previously developed for evaluation of cone-beam CT (CBCT) - extended to 16 cm and 32 cm diameters for diagnostic MDCT - to evaluate 3D spatial resolution (MTF in axial and non-axial planes), NPS, uniformity, linearity, CNR, and cone-beam artifacts. Three MDCT systems were evaluated (Siemens Edge, Canon One, and Canon Precision) using head and body scan protocols in longitudinal studies over a period of 6 months.*Results The phantom provided objective evaluation of imaging performance via automated software and a structured report. Important characteristics were brought to light in the study that would not be captured by existing test phantoms - e.g., the contrast dependence (non-linearity) of the MTF, the (non-) isotropic nature of the 3D MTF for various reconstruction protocols, and the magnitude of cone-beam artifact (Zmod) for fully volumetric scan protocols. For example, the Precision CT exhibited protocols with varying levels of non-isotropic MTF [e.g., f10 = 1.7 mm-1 (axial) and 1.0 mm-1 (at 45o)], 3D NPS showing longitudinal (z) interpolation, high zmod (~75%) for helical protocols, and a high degree of longitudinal constancy in all metrics. By contrast, the Canon One clearly exhibited a drop in zmod from 81% (at z = 0.4 cm) to 36% (at z = 4.4 cm) for volumetric scan protocols.*Conclusions The phantom and automated analysis provide a reliable tool for quantitative evaluation of MDCT imaging performance pertinent to the current and emerging generation of MDCT.*Clinical Relevance/Application Automated, quantitative evaluation of MDCT imaging performance in a manner that is sensitive to important characteristics of modern CT scanners will improve acceptance and QA testing, reduce scanner downtime, and improve quality of care.

RESULTS

The phantom provided objective evaluation of imaging performance via automated software and a structured report. Important characteristics were brought to light in the study that would not be captured by existing test phantoms - e.g., the contrast dependence (non-linearity) of the MTF, the (non-) isotropic nature of the 3D MTF for various reconstruction protocols, and the magnitude of cone-beam artifact (Zmod) for fully volumetric scan protocols. For example, the Precision CT exhibited protocols with varying levels of non-isotropic MTF [e.g., f10 = 1.7 mm-1 (axial) and 1.0 mm-1 (at 45o)], 3D NPS showing longitudinal (z) interpolation, high zmod (~75%) for helical protocols, and a high degree of longitudinal constancy in all metrics. By contrast, the Canon One clearly exhibited a drop in zmod from 81% (at z = 0.4 cm) to 36% (at z = 4.4 cm) for volumetric scan protocols.

CLINICAL RELEVANCE/APPLICATION

Automated, quantitative evaluation of MDCT imaging performance in a manner that is sensitive to important characteristics of modern CT scanners will improve acceptance and QA testing, reduce scanner downtime, and improve quality of care.

SSPH03-2 The American College Of Radiology Fluoroscopy Dose Index Registry Pilot: Dose Indices From Fluoroscopically-Guided Interventional Procedures

Participants
A. Kyle Jones, PhD, Houston, Texas (*Presenter*) Nothing to Disclose

PURPOSE

The most recent published dataset of dose indices from U.S. fluoroscopically-guided interventions (FGI) is the RAD-IR study, which collected data 20 years ago and was published in 2003. The ACR Fluoroscopy Dose Index Registry (DIR) is designed to be a living normative dataset for fluoroscopy dose indices.*Methods and Materials During the pilot phase of the ACR Fluoroscopy DIR, dose indices for FGI were collected from 9 pilot sites through the ACR TRIADTM server. Participating sites were academic medical centers and regional hospitals; fluoroscopes from all major manufacturers were included. FGI were mapped to one of over 200 standard procedure descriptions in the ACR Common lexicon. Procedural dose index data were analyzed by individual Common ID. Three rounds of data validation were performed to ensure accurate procedure mapping.*Results Dose indices for 53,626 FGI were collected during the pilot. Fluoroscopy time in min. (FT), cumulative air kerma in mGy (Ka,r), and kerma area product in Gy-cm2 (PKA) are reported here as (N; mean [interquartile range]) for select ACR Common IDs. IVC filter insertion (1675; FT: 2.9 [1.9-4.3]; Ka,r: 57.2 [28.45-124.3]; PKA: 14.6 [7.4-32.85]); IVC filter retrieval (471; FT: 5.2 [3.1-12.0]; Ka,r: 188.3 [73.25-437.9]; PKA:

33.65 [12.8-85.88]); visceral angiography (1488; FT: 15.2 [8.8-26.1]; Ka,r: 789.0 [359.3-1636.4]; PKA: 152.4 [70.80-308.6]); visceral embolization (742; FT: 20.8 [11.7-36.4]; Ka,r: 851.9 [374.8-1679.0]; PKA: 152.7 [72.45-304.8]); nephrostomy placement (1826; FT: 4.6 [2.3-9.2]; Ka,r: 45.95 [16.7-139.2]; PKA: 8.35 [2.9-26.40]); gastrostomy placement (1568; FT: 3.3 [2.1-5.4]; Ka,r: 29.1 [13.5-68.55]; PKA: 7.3 [3.0-18.30]); percutaneous biliary drainage (921; FT: 12.9 [5.3-25.2]; Ka,r: 170.3 [48.9-470.1]; PKA: 23.20 [7.70-69.20]); transjugular intrahepatic portosystemic shunt placement (323; FT: 35.9 [24.2-54.6]; Ka,r: 836.3 [361.7-1530.9]; PKA: 192.2 [93.40-423.2]); CVC placement, tunneled (4426; FT: 0.9 [0.5-1.7]; Ka,r: 2.8 [1.4-6.3]; PKA: 0.7 [0.3-1.5]); central venous catheter (CVC) placement, non-tunneled (3827; FT: 0.9 [0.4-1.6]; Ka,r: 6.3 [2.5-16.6]; PKA: 1.8 [0.7-5.3]).*Conclusions The ACR Fluoroscopy DIR collected dose indices from 9 pilot sites across the country. Data were analyzed by Common ID, allowing similar procedures all sites to be analyzed in aggregate.*Clinical Relevance/Application Quality control of radiation use during FGI requires current and continuously updated normative datasets so sites can benchmark performance against their peers. The ACR Fluoroscopy DIR provides this dataset.

RESULTS

Dose indices for 53,626 FGI were collected during the pilot. Fluoroscopy time in min. (FT), cumulative air kerma in mGy (Ka,r), and kerma area product in Gy-cm2 (PKA) are reported here as (N; mean [interquartile range]) for select ACR Common IDs. IVC filter insertion (1675; FT: 2.9 [1.9-4.3]; Ka,r: 57.2 [28.45-124.3]; PKA: 14.6 [7.4-32.85]); IVC filter retrieval (471; FT: 5.2 [3.1-12.0]; Ka,r: 188.3 [73.25-437.9]; PKA: 33.65 [12.8-85.88]); visceral angiography (1488; FT: 15.2 [8.8-26.1]; Ka,r: 789.0 [359.3-1636.4]; PKA: 152.4 [70.80-308.6]); visceral embolization (742; FT: 20.8 [11.7-36.4]; Ka,r: 851.9 [374.8-1679.0]; PKA: 152.7 [72.45-304.8]); nephrostomy placement (1826; FT: 4.6 [2.3-9.2]; Ka,r: 45.95 [16.7-139.2]; PKA: 8.35 [2.9-26.40]); gastrostomy placement (1568; FT: 3.3 [2.1-5.4]; Ka,r: 29.1 [13.5-68.55]; PKA: 7.3 [3.0-18.30]); percutaneous biliary drainage (921; FT: 12.9 [5.3-25.2]; Ka,r: 170.3 [48.9-470.1]; PKA: 23.20 [7.70-69.20]); transjugular intrahepatic portosystemic shunt placement (323; FT: 35.9 [24.2-54.6]; Ka,r: 836.3 [361.7-1530.9]; PKA: 192.2 [93.40-423.2]); CVC placement, tunneled (4426; FT: 0.9 [0.5-1.7]; Ka,r: 2.8 [1.4-6.3]; PKA: 0.7 [0.3-1.5]); central venous catheter (CVC) placement, non-tunneled (3827; FT: 0.9 [0.4-1.6]; Ka,r: 6.3 [2.5-16.6]; PKA: 1.8 [0.7-5.3]).

CLINICAL RELEVANCE/APPLICATION

Quality control of radiation use during FGI requires current and continuously updated normative datasets so sites can benchmark performance against their peers. The ACR Fluoroscopy DIR provides this dataset.

SSPH03-3   Measurement Of Low-contrast Detectability Using Channelized Hotelling Observer On ACR Accreditation Phantom: Optimization And Repeatability

Participants
Mingdong Fan, Rochester, Minnesota (*Presenter*) Nothing to Disclose

PURPOSE

Current CT quality control (QC) for low-contrast detectability relies on visual inspection and measurement of contrast-to-noise ratio, which was demonstrated to be inappropriate for non-linear reconstruction methods. Channelized Hotelling observer (CHO)-based method is promising. However, a large number of repeated scans are typically required to achieve acceptable accuracy and precision, which is not feasible in practice. In this work, we aim to optimize the CHO measurement process for the most widely used ACR accreditation phantom and to evaluate its robustness in a repeatability test.*Methods and Materials For CHO optimization, the ACR low-contrast module was repeatedly scanned 100 times on a 192-slice CT scanner (Force, Siemens), using identical techniques and phantom position. The optimal set of channel filters, number of slices, and number of background regions of interest (ROI) were determined to reduce the required number of repeated scans, using the index of detectability (d') calculated from the 100 repeated scans as the reference standard. To evaluate the robustness of the optimized CHO at reduced number of scans, we scanned the phantom on another scanner for 10 times, each with independent repositioning of the phantom. For each repositioning, a single scan was acquired at 3 dose levels (CTDIvol = 6, 12, and 24 mGy). The optimized CHO method was used to calculate d' for each of the 10 independent measurements, 3 dose levels, and 2 reconstruction methods.*Results With the optimal CHO calculation (4 channel filters, 50 slices per objects, and 2 sets of background ROIs), the bias was within 2.1% and the relative standard deviation was within 9.8% for the 4-, 5-, and 6-mm objects from a single-scan measurement. The d' calculated by 10 independent measurements using this optimal CHO calculation were precise for all object sizes, reconstruction methods, and dose levels. The d' of the 6 mm low-contrast object from the IR reconstruction was 2.92±0.19, range: [2.56, 3.24]; 2.30±0.18, range: [1.95, 2.69]; 1.67±0.20, range: [1.39, 2.01] at 24, 12, and 6 mGy, respectively.*Conclusions A CHO-based method was optimized for routine CT QC of low-contrast detectability using the ACR accreditation phantom. This method was demonstrated to be robust in a repeatability test.*Clinical Relevance/Application The optimized CHO-based method provides an efficient, quantitative, and reproducible approach to routine QC of low-contrast detectability on the most widely used ACR accreditation phantom.

RESULTS

With the optimal CHO calculation (4 channel filters, 50 slices per objects, and 2 sets of background ROIs), the bias was within 2.1% and the relative standard deviation was within 9.8% for the 4-, 5-, and 6-mm objects from a single-scan measurement. The d' calculated by 10 independent measurements using this optimal CHO calculation were precise for all object sizes, reconstruction methods, and dose levels. The d' of the 6 mm low-contrast object from the IR reconstruction was 2.92±0.19, range: [2.56, 3.24]; 2.30±0.18, range: [1.95, 2.69]; 1.67±0.20, range: [1.39, 2.01] at 24, 12, and 6 mGy, respectively.

CLINICAL RELEVANCE/APPLICATION

The optimized CHO-based method provides an efficient, quantitative, and reproducible approach to routine QC of low-contrast detectability on the most widely used ACR accreditation phantom.

SSPH03-4   Quantitative Image Quality Comparison Between Photon Counting And Conventional CT Systems: Noise, Resolution And Quantitative Accuracy

Participants
Richard Thompson, PhD, Hawthorn Woods, Illinois (*Presenter*) Employee, Canon Medical Research, USA

PURPOSE

Recent studies have shown that photon counting CT (PCCT) has the potential to provide better contrast and noise performance compared to conventional CT systems using scintillator-based energy integrating detectors (EID), and enable material decomposition for spectral imaging. In this work, we compare the image quality of a prototype PCCT to EID-CT at comparable scan protocols and analyze the performance in terms of noise, spatial resolution and material quantification accuracy.*Methods and

Materials The prototype PCCT is based on a Canon Aquilion ONE ViSION™ system. The smallest detector pixel size is 342μm, and each pixel can output measurements up to 6 energy bins starting from 20keV. The readout can be configured into various macro-pixel schemes to reconstruct images at different spatial resolutions. The 3x3 macro-pixel mode generates a similar detection pitch as the typical EID-CT, and the resulting images were evaluated here. A 40cm water phantom and a Gammex™ multi-energy phantom were scanned on PCCT with 120kVp, from 50 to 400mA, 1s rotation. Counting images were generated based on total counts per pixel, and spectral images were generated using 5 energy bin counts. For EID-CT, the phantoms were scanned at 120kVp and dual energy mode at dose matched to the PCCT scans. For both systems, images were reconstructed using FBP without noise reduction. Image resolution, noise, and quantitative accuracy were compared between PCCT and EID-CT in both counting and spectral images.*Results Compared to EID-CT, PCCT counting images have reduced noise at low dose levels. The PCCT images have significantly higher MTF than EID-CT. In monoenergetic images, PCCT and EID-CT have similar material quantification accuracy for iodine. PCCT also has similar noise performance with reduced noise at high keV.*Conclusions We compared quantitative image quality between a prototype PCCT and a commercial EID-CT. The results demonstrate that PCCT has potential benefits of reducing noise and improving resolution in both counting and spectral modes.*Clinical Relevance/Application The initial performance of a prototype PCCT system in both counting and spectral imaging modes demonstrates its potential to achieve better diagnostic performance with reduced dose.

RESULTS

Compared to EID-CT, PCCT counting images have reduced noise at low dose levels. The PCCT images have significantly higher MTF than EID-CT. In monoenergetic images, PCCT and EID-CT have similar material quantification accuracy for iodine. PCCT also has similar noise performance with reduced noise at high keV.

CLINICAL RELEVANCE/APPLICATION

The initial performance of a prototype PCCT system in both counting and spectral imaging modes demonstrates its potential to achieve better diagnostic performance with reduced dose.

SSPH03-5   Search, Recognition, And Decision Errors In Liver Metastasis Detection At Contrast-enhanced Abdominal CT

Participants
Scott Hsieh, Rochester, Minnesota (*Presenter*) Nothing to Disclose

PURPOSE

A better understanding of false negative exams (FNs) is needed to reduce interobserver variability and improve patient care. FNs can be characterized as a failure to search for a lesion; a failure to subconsciously recognize a lesion after glancing briefly at it; or a conscious decision error in rejecting the lesion after considering it. We conducted a 25-reader study for the task of liver metastasis detection in abdominal CT using eye tracking technology and characterized the relative frequency of search, recognition, and decision errors.*Methods and Materials In this IRB-approved study, 25 radiologists examined 40 CT exams containing 91 hepatic metastases, marking all suspected liver metastasis. Ground truth was determined using histopathology or progression. An eye tracking device (Eyelink Portable Duo) measured total gaze time within 40 pixels (approximately 25 mm in DICOM coordinates) of each true lesion. Unmarked metastases, or FNs, were categorized by total gaze time as follows: search errors, less than 0.5 seconds; recognition errors, between 0.5 and 2 seconds; decision errors, greater than 2 seconds. Total time gazing within each liver segment, across all cases, was also measured.*Results On average, radiologists missed 15.1 of 91 metastases (range, 6 - 36). Of these FNs, 37% were search, 32% were recognition, and 31% were decision errors. Half of the FNs occurred in 9 of 91 metastases. The errors in the 9 most difficult metastases were different from the remaining metastases (p < 10-5); the 9 most difficult metastases contained more search and recognition errors (45% and 38%, respectively) than the remaining metastases (29% and 27%, respectively). Time spent gazing within individual liver segments were associated with fewer FNs in a univariate analysis (p < 0.05) except for segment VIII (p = 0.14). This association became nonsignificant in a model that included mean interpretation time per case. Of the segments containing metastases, segments II and III had the lowest average gaze time, with a median gaze time of 12 seconds per case in both segments. Readers spending more than 12 seconds in these segments had fewer FNs than those with less than 12 seconds (0.5 vs 2.1 FNs, p = 0.0001).*Conclusions Search, recognition, and decision errors occurred in similar proportion over the entire dataset. Individual lesions showed a tendency towards specific error types. Increased attention in segments II and III was associated with fewer false negatives in these segments.*Clinical Relevance/Application Missed liver metastases can be categorized as search, recognition, and decision errors, with a similar proportion of each type of error. Reduced time gazing in segments II and III was associated with more false negatives in these segments.

RESULTS

On average, radiologists missed 15.1 of 91 metastases (range, 6 - 36). Of these FNs, 37% were search, 32% were recognition, and 31% were decision errors. Half of the FNs occurred in 9 of 91 metastases. The errors in the 9 most difficult metastases were different from the remaining metastases (p < 10-5); the 9 most difficult metastases contained more search and recognition errors (45% and 38%, respectively) than the remaining metastases (29% and 27%, respectively). Time spent gazing within individual liver segments were associated with fewer FNs in a univariate analysis (p < 0.05) except for segment VIII (p = 0.14). This association became nonsignificant in a model that included mean interpretation time per case. Of the segments containing metastases, segments II and III had the lowest average gaze time, with a median gaze time of 12 seconds per case in both segments. Readers spending more than 12 seconds in these segments had fewer FNs than those with less than 12 seconds (0.5 vs 2.1 FNs, p = 0.0001).

CLINICAL RELEVANCE/APPLICATION

Missed liver metastases can be categorized as search, recognition, and decision errors, with a similar proportion of each type of error. Reduced time gazing in segments II and III was associated with more false negatives in these segments.

SSBR01-2   A Decade Of Digital Breast Tomosynthesis: How Has It Performed?

Participants
Liane E. Philpotts, MD, Madison, Connecticut (*Presenter*) Nothing to Disclose

PURPOSE

Digital breast tomosynthesis (DBT) was approved for commercial use in February 2011. Many studies have shown superiority of DBT over 2D mammography, particularly in terms of recall and cancer detection rates. With any new technology, long-term performance must be established. The purpose of this study was to assess screening mammography metrics over a 10-year period since adopting DBT.*Methods and Materials Our facility started offering DBT for screening in August 2011 at the main hospital of an academic breast center. Over the next several years we obtained DBT at our 3 satellite offices. We performed DBT screening at no charge to patients resulting in data unbiased by breast density, risk factors, insurance coverage, or other factors. A search of our electronic breast imaging database (PenRad, MN) was performed to identify all screening mammograms performed with DBT during one-year periods (8/1/11 - 7/31/12, 8/1/12 to 7/31/13,? present) and interpreted by dedicated breast radiologists. The recall rate (RR), cancer detection rate (CDR), and false negative rate (FN) (supplemental screening detected and interval cancers) was determined. The metrics were assessed for the entire cohort and sub-group analyzed by breast density (non-dense vs dense).*Results Over the 10 years 207,128 DBT mammograms were performed: 130,114 non-dense and 77,014 dense. The recall rate averaged 7.5% and, other than year 2, fluctuated between 7-8%: 8%,9%,8%,7%,7%,7%,7%, 7%, 7%, 8%. The CDR averaged 5.4 and maintained a stable range of 5-6 cancers (per 1000) for each of 10 years: 6,5,5,5,5,6,5,6,5,6,5. The FN rate (for the first 9 years) averaged 0.8 per 1000: 1.8, 1, 0.5, 0.8, 0.9, 0.7, 0.8, 0.7, 1.2. For non-dense women the RR averaged 6.8% (7,8,7,7,6,6,6,7,7,7) and the CDR 5.2 (4,6,4,6,6,5,6,5,6,4). For dense women the RR averaged 8.1% (8,11,10,8,7,7,7,7,7,9) and the CDR 5.1 (7,4,6,4,6,5,5,5,4,5).*Conclusions DBT screening metrics have held steady throughout the 10 years since the adoption of this new technology with maintained favorable RR, CDR and FN rates. The favorable metrics are noted for both non-dense and dense women.*Clinical Relevance/Application The maintained benefits of DBT support use of this technology for screening.

RESULTS

Over the 10 years 207,128 DBT mammograms were performed: 130,114 non-dense and 77,014 dense. The recall rate averaged 7.5% and, other than year 2, fluctuated between 7-8%: 8%,9%,8%,7%,7%,7%,7%, 7%, 7%, 8%. The CDR averaged 5.4 and maintained a stable range of 5-6 cancers (per 1000) for each of 10 years: 6,5,5,5,5,6,5,6,5,6,5. The FN rate (for the first 9 years) averaged 0.8 per 1000: 1.8, 1, 0.5, 0.8, 0.9, 0.7, 0.8, 0.7, 1.2. For non-dense women the RR averaged 6.8% (7,8,7,7,6,6,6,7,7,7) and the CDR 5.2 (4,6,4,6,6,5,6,5,6,4). For dense women the RR averaged 8.1% (8,11,10,8,7,7,7,7,7,9) and the CDR 5.1 (7,4,6,4,6,5,5,5,4,5).

CLINICAL RELEVANCE/APPLICATION

The maintained benefits of DBT support use of this technology for screening.

SSBR01-3   Follow-up Study Of Lymph Node Response Induced By M-RNA COVID-19 Vaccination

Participants
Alba Cristina Igual Rouilleault, MD, Pamplona, Spain (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the imaging presentation and main characteristics of axillary adenopathy response induced by mRNA COVID-19 vaccination.*Methods and Materials Ninety-one volunteer employees from our center were prospectively ruled-out between February to April 2021. The study was conducted with the approval of our IRB and all participants provided written consent to participate. Patients recruited were Pfizer-BioNTech COVID-19 vaccine recipients and each one underwent a total of three axillary ultrasound (US) evaluations of the ipsilateral vaccinated arm. The first axillar US exam was obtained within the week before vaccine administration, the second one the week after the first dose and the last one, the week after the second dose. Findings recorded were: the total number of visible nodes, the maximum measurements of the long-axis size and cortical thickness (mm), Bedi's classification (grade 1 to 6) and color Doppler evaluation (grade 0 to 3, being 0 no color signal and 3 high intense color signal). Finally, data collected were compared using paired-sample Student's t-test for quantitative continuous variables and Wilcoxon rank-sum test for ordinal variables. Variables with a p value < 0.05 were considered statistically significant.*Results Comparative analyses between the basal and the first US control showed a statistically significant augmentation of total visible nodes (mean 2.96 vs 4.77 nodes; p<0.001), maximum long-axis size (mean 15.84 vs 21.34 mm; p<0.001), cortical thickness (mean 1.6 vs 3.7 mm; p<0.001), grade of Bedi's classification and color Doppler signal (p<0.001). In addition, same statistically significant differences were found comparing the first and the second control: total visible nodes (mean 4.77 vs 6.21 nodes), long-axis size (mean 21.1 vs 24.0 mm), cortical thickness (3.7 vs 4.6 mm), grade of Bedi's classification and color Doppler signal (p<0.001).*Conclusions According to our results, both doses of COVID-19 vaccine induced an increase of all axillary lymph node parameters with

statistically significant differences.*Clinical Relevance/Application The main differential diagnosis of unilateral axillary adenopathy is malignancy but, in the setting of recent COVID-19 vaccination, radiologists should consider induced ipsilateral hyperplasic axillary nodes since the first vaccination dose.

RESULTS

Comparative analyses between the basal and the first US control showed a statistically significant augmentation of total visible nodes (mean 2.96 vs 4.77 nodes; p<0.001), maximum long-axis size (mean 15.84 vs 21.34 mm; p<0.001), cortical thickness (mean 1.6 vs 3.7 mm; p<0.001), grade of Bedi's classification and color Doppler signal (p<0.001). In addition, same statistically significant differences were found comparing the first and the second control: total visible nodes (mean 4.77 vs 6.21 nodes), long-axis size (mean 21.1 vs 24.0 mm), cortical thickness (3.7 vs 4.6 mm), grade of Bedi's classification and color Doppler signal (p<0.001).

CLINICAL RELEVANCE/APPLICATION

The main differential diagnosis of unilateral axillary adenopathy is malignancy but, in the setting of recent COVID-19 vaccination, radiologists should consider induced ipsilateral hyperplasic axillary nodes since the first vaccination dose.

SSBR01-4   Optimizing The Pairs Of Radiologists That Double-read Screening Mammograms

Participants
Jessie Gommers, MSc, Nijmegen, Netherlands (*Presenter*) Nothing to Disclose

PURPOSE

To investigate how radiologist performance characteristics can be leveraged to identify optimal pairs of radiologists for double-reading of screening mammograms.*Methods and Materials We retrospectively analyzed 990,802 screening examinations of women who underwent screening mammography as part of a regional program between 2008 and 2015. In total, 37 radiologists were involved. Any examination that was flagged by any radiologist became subject to consensus discussion. We evaluated sensitivity and specificity for individual radiologists and pairs of radiologists in terms of their flagging of women diagnosed with cancer within 12 months. The individual radiologists were divided into four performance categories involving cancer detection and recall rates, using the group average as cut-off for each metric. Therefore, radiologists were classified into: high sensitivity & high specificity (HH), high sensitivity & low specificity (HL), low sensitivity & high specificity (LH), or low sensitivity & low specificity (LL). We compared random pair performance to specific class-pair performance.*Results A difference in performance was found when individual readers were paired with a specific class of reader vs. with a random reader. Specific class-pairs involving only readers with a high sensitivity, i.e. readers HH and HL, achieved a significantly higher cancer detection rate (CDR), compared to random pairs at the same given recall rate (HH+HH CDR 3.6 vs. 2.7 per 1000 exams, HH+HL CDR 4.5 vs. 3.5 per 1000 exams, HL+HL CDR 4.9 vs. 4.1 per 1000 exams). On the other hand, class-pairs involving only readers with a low sensitivity (LH and LL), performed worse compared to randomly paired readers. Furthermore, low-specificity pairs performed worse than random pairs, unless both readers were highly sensitive.*Conclusions Pairing radiologists based on sensitivity/specificity characteristics, as opposed to randomly, may improve screening performance. Pairs of high-sensitivity readers outperform random pairs, even if low-specificity readers are involved. Depending on what type of readers and how many of them are involved in the double-reading, the feasibility of using performance metrics to pair radiologists may be considered.*Clinical Relevance/Application Optimizing the pairs of radiologists that double-read screening mammograms may improve cancer detection and reduce the number of false-positives, with no new technology or training costs.

RESULTS

A difference in performance was found when individual readers were paired with a specific class of reader vs. with a random reader. Specific class-pairs involving only readers with a high sensitivity, i.e. readers HH and HL, achieved a significantly higher cancer detection rate (CDR), compared to random pairs at the same given recall rate (HH+HH CDR 3.6 vs. 2.7 per 1000 exams, HH+HL CDR 4.5 vs. 3.5 per 1000 exams, HL+HL CDR 4.9 vs. 4.1 per 1000 exams). On the other hand, class-pairs involving only readers with a low sensitivity (LH and LL), performed worse compared to randomly paired readers. Furthermore, low-specificity pairs performed worse than random pairs, unless both readers were highly sensitive.

CLINICAL RELEVANCE/APPLICATION

Optimizing the pairs of radiologists that double-read screening mammograms may improve cancer detection and reduce the number of false-positives, with no new technology or training costs.

SSBR01-6   Digital Breast Tomosynthesis And Digital Mammography Recall Rates And Time Of Day: Was There Improvement During COVID-19?

Participants
Grayson Baird, PhD, Providence, Rhode Island (*Presenter*) Nothing to Disclose

PURPOSE

To determine how Digital Breast Tomosynthesis (DBT) and Digital Mammography (DM) recall and false positive rates varied by time of day of study interpretation before COVID-19 during normal caseload as compared to during COVID-19 with reduced caseload.*Methods and Materials Retrospective review of all 103,065 screening DBT and DM from 3/2019-3/2021 at 13 outpatient centers with 17 radiologists. Screens were batch read. Data were extracted from a tracking database and included: exam type (DBT or DM), interpreting radiologist, time of day of interpretation, BI-RADS, and outcome (false positive [FP], true positive [TP]). All radiologists read DM and DBT during the 2 years. An interrupted time series design was used. Generalized linear mixed modeling was used to model recall and FP over time of day, before vs. during COVID-19, where each radiologist had an intercept and slope.*Results As illustrated in Figure 1, before COVID-19, for every hour increase during the day, the odds of recall increased 5% for DBT (Red) (OR: 1.05, 95% CI[1.01, 1.09], p=0.01) but not for DM (Blue), which increased (insignificantly) 2% for every hour (OR: 1.02, 95% CI[0.99, 1.09], p=0.49). Conversely, during COVID-19, for every hour increase, the odds of recall were 0 (flat) for both DBT and DM (OR: 1.00, 95% CI[0.97, 1.02], p=0.75 and (OR: 1.00, 95% CI[0.95, 1.04], p=0.91, respectively). The mean (flat) recall rates for DBT and DM were 9.8% and 11.3%, respectively, regardless of the time of day, a significant difference of 1.5% (p=.02). The relationship between recall rate and time of day before COVID-19 versus during COVID-19 was significantly different, p<.01, as seen comparing column 1 with 2 in Figure 1. All findings for recall are mirrored for FP. TP before COVID-19 was 5.2 per 1000 for DBT and 3.6 per 1000 for DM; TP during COVID-19 was 5.2 per 1000 for DBT and 5.3 per 1000 for DM, p=.18.*Conclusions Recall and FP rates increased over the course of the day for DBT interpretation before COVID-19. During COVID-19, when caseloads reduced, no relationship was observed for recall and FP and time of day. These results indicate that the time-of-day effect (as the day increased, recall increased perhaps due to fatigue) disappeared after caseloads declined due to COVID-

19.*Clinical Relevance/Application Lower interpretation volumes, as observed during COVID-19, may reduce recall and FP rates in DBT without affecting TP rate.

RESULTS

As illustrated in Figure 1, before COVID-19, for every hour increase during the day, the odds of recall increased 5% for DBT (Red) (OR: 1.05, 95% CI[1.01, 1.09], p=0.01) but not for DM (Blue), which increased (insignificantly) 2% for every hour (OR: 1.02, 95% CI[0.99, 1.09], p=0.49). Conversely, during COVID-19, for every hour increase, the odds of recall were 0 (flat) for both DBT and DM (OR: 1.00, 95% CI[0.97, 1.02], p=0.75 and (OR: 1.00, 95% CI[0.95, 1.04], p=0.91, respectively). The mean (flat) recall rates for DBT and DM were 9.8% and 11.3%, respectively, regardless of the time of day, a significant difference of 1.5% (p=.02). The relationship between recall rate and time of day before COVID-19 versus during COVID-19 was significantly different, p<.01, as seen comparing column 1 with 2 in Figure 1. All findings for recall are mirrored for FP. TP before COVID-19 was 5.2 per 1000 for DBT and 3.6 per 1000 for DM; TP during COVID-19 was 5.2 per 1000 for DBT and 5.3 per 1000 for DM, p=.18.

CLINICAL RELEVANCE/APPLICATION

Lower interpretation volumes, as observed during COVID-19, may reduce recall and FP rates in DBT without affecting TP rate.

SSCA08-2   Multiparametric Cardiac MRI In Acute Myocarditis With Endocardial Myocardial Biopsy: A Verification Of Lake Louise Criteria 2009 And 2018

Participants

Shuang Li, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

The aim of this study was to evaluate the value of the Original Lake Louise Criteria (LLC) and the 2018 LLC for the diagnosis of acute myocarditis at 3 T and provide the cutoff value for cardiac magnetic resonance (CMR) imaging technique.*Methods and Materials Seventy-three patients (32±32 years, 60.5% men) with clinically suspected myocarditis underwent endocardial myocardial biopsy (EMB) and CMR at 3.0 Tesla were enrolled in the study. Patients were divided into two groups according to EMB results. CMR protocol included cine-SSFP, T2 STIR, T2 mapping, early and late gadolinium enhancement and pre- and post-contrast T1 mapping. Their potential diagnostic ability was assessed with receiver operating characteristic (ROC) curves.*Results Myocardial T1 and T2 relaxation times were significantly prolonged in patients with myocarditis than in control group (1252±42ms vs. 1195±43ms, p<0.001; 63.2±6.1ms vs. 54.5±3.7ms, p<0.001).Optimal cutoff value was 1228ms for T1 relaxation times and 58.5ms for T2 relaxation times with sensitivity of 86.0% and 83.7%, specificity of 93.3% and 93.3%, respectively. All the patients diagnosed as myocarditis by the original LLC were correctly identified by 2018 LLC. For the diagnostic accuracy, 2018 LLC was the highest (91.8%) compared with single parameters or those combined parameters, followed with T1 mapping (89.0%) and T2 mapping (87.7%).*Conclusions Emerging technologies such as T1/ T2 mapping have significantly improved the diagnostic performance of CMR for the diagnosis of acute myocarditis. The 2018LLC provides the overall best diagnostic performance in acute myocarditis compared with those single standard CMR parameters or combined parameters.*Clinical Relevance/Application CMR is a promising tool for the diagnosis of patients with myocarditis. With the addition of new parameter imaging technology, the diagnostic efficiency of 2018 LLC has been significantly improved.

RESULTS

Myocardial T1 and T2 relaxation times were significantly prolonged in patients with myocarditis than in control group (1252±42ms vs. 1195±43ms, p<0.001; 63.2±6.1ms vs. 54.5±3.7ms, p<0.001).Optimal cutoff value was 1228ms for T1 relaxation times and 58.5ms for T2 relaxation times with sensitivity of 86.0% and 83.7%, specificity of 93.3% and 93.3%, respectively. All the patients diagnosed as myocarditis by the original LLC were correctly identified by 2018 LLC. For the diagnostic accuracy, 2018 LLC was the highest (91.8%) compared with single parameters or those combined parameters, followed with T1 mapping (89.0%) and T2 mapping (87.7%).

CLINICAL RELEVANCE/APPLICATION

CMR is a promising tool for the diagnosis of patients with myocarditis. With the addition of new parameter imaging technology, the diagnostic efficiency of 2018 LLC has been significantly improved.

SSCA08-3   Free-breathing High Resolution Modified Dixon Steady-state Angiography For The Assessment Of The Thoracic Vasculature In Pediatric Patients With Congenital Heart Disease

Participants

Narine Mesropyan, Bonn, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Magnetic resonance imaging including angiography (MRA) of the thoracic vasculature in small pediatric patients with congenital heart disease (CHD) remains challenging. Thus, the aim of this study was to evaluate the diagnostic utility of a respiratory- and electrocardiogram-gated steady-state MRA with modified Dixon (mDixon) fat suppression in comparison to standard first-pass MRA in sedated pediatric patients with CHD at 3.0 T.*Methods and Materials Pediatric CHD patients, who underwent cardiac MRI with first-pass MRA followed by mDixon steady-state MRA at 3 T were retrospectively analyzed. Image quality was assessed using a Likert grading scale from 5 (excellent) to 1 (non-diagnostic). Additionally, blood-to-tissue ratio, quality of fat suppression as well as quantitative measurements of the thoracic vasculature were assessed. Measurements were performed separately and/or in consensus by two radiologists. Paired t test, Wilcoxon test and Bland-Altman method were used for statistical analysis.*Results 32

patients with CHD (mean age: 3.2±1.6 years, 13 female) were included. Overall image quality of steady-state mDixon MRA was higher compared to first-pass MRA (4.5±0.5 vs. 3.3±0.5; P<0.001). Blood-to-tissue contrast ratio of steady-state mDixon MRA was comparable to first-pass MRA (7.85±4.75 vs. 6.35±2.23; P=0.133). Fat suppression of steady-state mDixon MRA was perfect in 30/32 (93.8 %) cases. First-pass MRA showed significantly greater diameters at all measurement points with the greatest differences at the level pulmonary arteries and veins, e.g. 10.4±2.4 vs. 9.9±2.3 (P<0.001) for right pulmonary artery. Steady-state mDixon MRA had higher interobserver agreements of vessel measurements (e.g. for ascending aorta: bias -0.06±0.2; 95% limits of agreement -0.56 - 0.44). In 4/32 (12.5 %) cases additional vascular abnormalities were detected on steady-state mDixon MRA (e.g. partial anomalous venous return), which could not be depicted in the first-pass MRA.*Conclusions Steady-state mDixon MRA with compressed sensing offers a robust fat suppression and a high image quality for the assessment of the thoracic vasculature in pediatric CHD patients at 3.0 T, insensitive to the magnetic field inhomogeneities.*Clinical Relevance/Application Our study results support the clinical application of described sequence in sedated pediatric patients with CHD at 3.0 T.

RESULTS

32 patients with CHD (mean age: 3.2±1.6 years, 13 female) were included. Overall image quality of steady-state mDixon MRA was higher compared to first-pass MRA (4.5±0.5 vs. 3.3±0.5; P<0.001). Blood-to-tissue contrast ratio of steady-state mDixon MRA was comparable to first-pass MRA (7.85±4.75 vs. 6.35±2.23; P=0.133). Fat suppression of steady-state mDixon MRA was perfect in 30/32 (93.8 %) cases. First-pass MRA showed significantly greater diameters at all measurement points with the greatest differences at the level pulmonary arteries and veins, e.g. 10.4±2.4 vs. 9.9±2.3 (P<0.001) for right pulmonary artery. Steady-state mDixon MRA had higher interobserver agreements of vessel measurements (e.g. for ascending aorta: bias -0.06±0.2; 95% limits of agreement -0.56 - 0.44). In 4/32 (12.5 %) cases additional vascular abnormalities were detected on steady-state mDixon MRA (e.g. partial anomalous venous return), which could not be depicted in the first-pass MRA.

CLINICAL RELEVANCE/APPLICATION

Our study results support the clinical application of described sequence in sedated pediatric patients with CHD at 3.0 T.

SSCA08-4   Noninvasive Left Ventricular Filling Pressure With 4D Flow MRI: Scan-Rescan Reproducibility

Participants
Paul Roos, MSc, Leiden, Netherlands (*Presenter*) Nothing to Disclose

PURPOSE

Left ventricular (LV) filling pressure represents diastolic function and is often estimated using E/e'. While this is widely used, it is proven unreliable in patients with severe heart failure and mitral valve insufficiency [1]. Intra-LV relative pressure fields can be obtained by combining flow velocity with fluid dynamics. Intra-LV velocity is measured using 4D Flow MRI. Relative pressure is then calculated according to [2].Relative pressure fields can be used to calculate LV filling pressure differences and to assess diastolic function. We have investigated scan-rescan reproducibility of this approach, which could open the door to full noninvasive pressure-volume loop estimation.[1] SF Nagueh et al. J. Am. Soc. Echocardiogr. 2016. [2] T Ebbers et al. J. Biomech. Eng. 2002.*Methods and Materials Cardiovascular MRI was performed twice for ten (N=10) healthy volunteers (age 27?±?3 years). This included multi-slice cine short axis scan for LV endocardial contour segmentation and 4D Flow MRI. Pressure gradients (?p) were calculated from 4D Flow MRI using the Navier-Stokes equation:?p = -? ?V/?t -?V*?V+µ?^2 V+Fwhich was transformed into a pressure Poisson equation and solved iteratively. Density ? = 1060 kg/m3, viscosity µ = 0.004 Ns/m2 and external forces F was neglected.Apex and mitral valve were manually identified. In the sampling locations pressures were averaged within a radius of 3 voxels. The pressure in the apex was then subtracted from the mitral valve pressure to determine pressure difference. This was plotted over time and peak relative filling pressure difference was identified. Reproducibility was tested by Pearson correlation.*Results For all subjects, the curves of the relative pressure difference of the first and second scan showed close agreement. Strong correlation (r=0.83, P=0.003) was found between peak relative filling pressure differences of first and second scan. Paired sample t-test showed no significant difference between scan and rescan (p=0.57) with average absolute error 0.071±0.066 mmHg.*Conclusions Noninvasive measurement of LV peak filling pressure differences derived from 4D flow MRI showed good reproducibility. Accurate segmentation of endocardial contours and careful selection of sampling locations are crucial for accuracy. This technique may prove its use in diastolic function evaluation when E/e' estimation is inaccurate.*Clinical Relevance/Application Noninvasive measurement of LV peak filling pressure differences derived from 4D flow MRI may prove its use in diastolic function evaluation.

RESULTS

For all subjects, the curves of the relative pressure difference of the first and second scan showed close agreement. Strong correlation (r=0.83, P=0.003) was found between peak relative filling pressure differences of first and second scan. Paired sample t-test showed no significant difference between scan and rescan (p=0.57) with average absolute error 0.071±0.066 mmHg.

CLINICAL RELEVANCE/APPLICATION

Noninvasive measurement of LV peak filling pressure differences derived from 4D flow MRI may prove its use in diastolic function evaluation.

SSCA08-6   Short Fixed Inversion Time Magnetic Resonance Late Gadolinium Enhancement In Infarct Patients With Concomitant Non-ischemic Fibrosis

Participants
Malgorzata Polacin, Zurich, Switzerland (*Presenter*) Nothing to Disclose

PURPOSE

Short LGE, a 3D single breath-hold inversion recovery late gadolinium enhancement sequence with fixed, short inversion time (TI =110 ms at 1.5 Tesla) has a different image impression with dark scar, light grey blood pool and very bright remote myocardium. After better contrast between ischemic scars and blood pool has been proven in short LGE and infarct patients might have concomitant non-ischemic LGE, this study examined the visibility of non-ischemic fibrosis in infarct patients in short LGE compared to clinically used LGE sequence (standard LGE).*Methods and Materials Short LGE and standard LGE (same spatial resolution 1.2 x 1.2 mm², slice-thickness 8 mm; field of view 350 x 350 mm², 3D, single breath-hold) were acquired in 37 infarcts patients (17 female, mean age 59 ±8 years) with concomitant non-ischemic fibrosis (21 patients with septal fibrosis, 10 with epicardial fibrosis, 6 with fibrosis at the basal RV junction) at 1.5 T. For short LGE inversion time (TI) was fixed at 110 ms, standard LGE was acquired with adjusted TI. Three independent readers evaluated 629 segments (17-segment model) in short LGE and standard LGE in a blinded manner, using a 5-point Likert scale for evaluation of image quality (1= excellent, 5= non-diagnostic) and fibrosis visibility.

Standard LGE was considered reference standard.*Results Non-ischemic fibrosis was present in 117 segments (18,6%). All segments with fibrosis in standard LGE were detected in short LGE by all readers. Image quality was equal in short LGE compared to standard LGE (2 vs. 1.9, p=0.78) and visibility of fibrosis was not inferior (1.7 vs. 1.5, p=0.4) in short LGE. Agreement between the readers was good (ICC=0.899 and ICC=0.843).*Conclusions Short LGE was not inferior to standard LGE in detecting non-ischemic fibrosis in infarct patients. Short LGE does not require myocardial nulling and displays ischemic and non-ischemic fibrosis with equal visibility.*Clinical Relevance/Application Same fibrosis visibility in short LGE, a fast, 3D, one breath-hold sequence with fixed inversion time (no myocardial nulling required)

RESULTS

Non-ischemic fibrosis was present in 117 segments (18,6%). All segments with fibrosis in standard LGE were detected in short LGE by all readers. Image quality was equal in short LGE compared to standard LGE (2 vs. 1.9, p=0.78) and visibility of fibrosis was not inferior (1.7 vs. 1.5, p=0.4) in short LGE. Agreement between the readers was good (ICC=0.899 and ICC=0.843).

CLINICAL RELEVANCE/APPLICATION

Same fibrosis visibility in short LGE, a fast, 3D, one breath-hold sequence with fixed inversion time (no myocardial nulling required)

SSIN07-2   Deep Reinforcement Learning-based Image Classification Achieves Perfect Testing Set Accuracy For MRI Brain Tumors With A Training Set Of Only 30 Images

Participants

Joseph Stember, MD, PhD, New York, New York (*Presenter*) Founder, Authera, LLC;Patent holder, Authera, LLC

PURPOSE

Image classification may be the fundamental task in imaging artificial intelligence. We have recently shown that reinforcement learning can achieve high accuracy for lesion localization and segmentation even with minuscule training sets. Here, we introduce reinforcement learning for image classification. In particular, we apply the approach to normal vs. tumor-containing 2D MRI brain images.*Methods and Materials We applied multi-step image classification to allow for combined Deep Q learning and TD(0) Q learning. We trained on a set of 30 images (15 normal and 15 tumor-containing). We tested on a separate set of 30 images (15 normal and 15 tumor-containing). For comparison, we also trained and tested a supervised deep learning classification network on the same set of training and testing images.*Results Whereas the supervised approach quickly overfit the training data and as expected performed poorly on the testing set (57% accuracy, just over random guessing), the reinforcement learning approach achieved an accuracy of 100%.*Conclusions We have shown a proof-of-principle application of rein- forcement learning to classification of brain tumors. We achieved perfect testing set accuracy with a training set of merely 30 images.*Clinical Relevance/Application Up until now, radiology AI has required hundreds to thousands of training images to achieve accurate classification. We have shown that our novel approach reaches very high accuracy with only 30 training set images. This can allow automated classification for rare diseases, for which only a handful of cases (and images) exist.

RESULTS

Whereas the supervised approach quickly overfit the training data and as expected performed poorly on the testing set (57% accuracy, just over random guessing), the reinforcement learning approach achieved an accuracy of 100%.

CLINICAL RELEVANCE/APPLICATION

Up until now, radiology AI has required hundreds to thousands of training images to achieve accurate classification. We have shown that our novel approach reaches very high accuracy with only 30 training set images. This can allow automated classification for rare diseases, for which only a handful of cases (and images) exist.

SSIN07-5   Clinical Decision Support AI System For Live Differential-diagnostic Guidance

Participants

Ewoud Pons, MD, Rotterdam, Netherlands (*Presenter*) Researcher, Reed Elsevier;

PURPOSE

Live AI systems can aid the radiologist at the time of reporting without leaving the reporting workflow. We developed such live system that automatically retrieves the most relevant differential-diagnostic guidance from STATdx® when reporting the finding section. The system can retrieve 126 relevant topics corresponding to chest X-ray radiographic findings.*Methods and Materials 126 selected chest STATdx® topics were annotated in 600 randomly selected chest X-ray reports from MIMIC CXR 2.0 by a board-certified radiologist and two radiology residents in training. This gold standard corpus was only used for tuning and validation of 16 different unsupervised AI and NLP methods, such as transformer-sentence and Radlex concept embeddings. All methods were combined in an optimised ensemble system. During each phase of development at least 20% of gold standard reports was withheld to prevent overfitting of the system. Area under the precision-recall curve (AUPCR) was calculated for system performance on the gold as well as inter-annotated agreement (IAA) on 100 reports. For additional evaluation the final system was applied to 100 never seen reports, scoring all retrieved topics for factual correctness and clinical relevance of the diagnostic guidance on a scale of 1-to-5*Results IAA for 100 reports of the gold standard was 0.752 AUPCR, which corresponds to "substantial agreement" in kappa. The optimised ensemble system performed 0.773 AUPCR. The system scored 4.26/5 for correctness and 3.25/5 for clinical relevance of retrieved topics.*Conclusions Performance of the system matched expert agreement and provided both correct and largely relevant topics, confirming feasibility of live diagnostic guidance by AI on for chest X-ray. Because the ensemble consists of unsupervised methods, generalisation to other specialty areas is realistic.*Clinical Relevance/Application Compared to existing systems the amount of identified observations is increased to 126 compared to 14 for CheXpert. This granularity of findings proved to be clinically important. Providing content in context improves utilisation of important information sources with the potential to

reduce uncertainty in diagnostic reporting, improve the quality of care and provide a powerful experience for radiology education. Such systems transform the process of seeking diagnostic guidance from a passive search outside the reporting workflow to an interactive user experience. Contextual retrieval of relevant guidelines and publications is faster and richer than traditional key word search. Future work should be directed at integrating more patient context from the EHR as well as epidemiological knowledge to enrich diagnostic recommendations by AI systems.

RESULTS

IAA for 100 reports of the gold standard was 0.752 AUPCR, which corresponds to "substantial agreement" in kappa. The optimised ensemble system performed 0.773 AUPCR. The system scored 4.26/5 for correctness and 3.25/5 for clinical relevance of retrieved topics.

CLINICAL RELEVANCE/APPLICATION

Compared to existing systems the amount of identified observations is increased to 126 compared to 14 for CheXpert. This granularity of findings proved to be clinically important. Providing content in context improves utilisation of important information sources with the potential to reduce uncertainty in diagnostic reporting, improve the quality of care and provide a powerful experience for radiology education. Such systems transform the process of seeking diagnostic guidance from a passive search outside the reporting workflow to an interactive user experience. Contextual retrieval of relevant guidelines and publications is faster and richer than traditional key word search. Future work should be directed at integrating more patient context from the EHR as well as epidemiological knowledge to enrich diagnostic recommendations by AI systems.

SSIN07-6   Deep Anatomical Federated Network (DAFNE) For Self-improving Segmentation Of Mr Images.

Participants
Francesco Santini, PhD, Basel, Switzerland (*Presenter*) Research Consultant, F. Hoffmann-La Roche Ltd

PURPOSE

To implement a new software tool for medical image segmentation based on deep neural networks trained through incremental and federated learning. Thanks to these concepts, the software performance continuously improves and adapts to different users' requirements without transfer of medical data.*Methods and Materials The software consists of a (free and open source) stand-alone program and a central server. In our software, each client performs an automatic segmentation of their dataset, which can be checked and refined in the user interface. The client then locally updates the models through a stochastic gradient descent algorithm based on the refinement and finally the server aggregates the clients' updates to build an improved model. The software is easily extensible by implementing an intuitive Python API to add new deep learning models. We provided pretrained models for the segmentation of the muscles of the leg and thigh, a task that is inherently complex because of their deformable anatomy and pathological involvement. We opened the usage to external users in March 2021 for free usage without restriction to a particular workflow. We collected performance metrics from the clients at every usage (Dice scores), and we performed local validation of the updated models against datasets with similar and different contrasts as the pretraining data.*Results After 62 incremental/federated learning epochs, the visual performance on our validation sets improved noticeably on T2-weighted images with minimal change in the proton-density datasets (original training contrast). The clients reported consistently high Dice scores (> 0.85) except for few outliers that reduced in number as the epochs progressed. An overall model improvement at each iteration can be observed.*Conclusions We demonstrated a free and open-source approach to medical image segmentation that is respectful of patient privacy (as no data are transferred) and is capable of continuous improvement and adaptation to the needs of the users by learning to recognize different contrasts and different pathologies.*Clinical Relevance/Application Segmentation of anatomical features is a necessary task to extract quantitative biomarkers. The presented method enables fast and reliable self-improving adaptive segmentation.

RESULTS

After 62 incremental/federated learning epochs, the visual performance on our validation sets improved noticeably on T2-weighted images with minimal change in the proton-density datasets (original training contrast). The clients reported consistently high Dice scores (> 0.85) except for few outliers that reduced in number as the epochs progressed. An overall model improvement at each iteration can be observed.

CLINICAL RELEVANCE/APPLICATION

Segmentation of anatomical features is a necessary task to extract quantitative biomarkers. The presented method enables fast and reliable self-improving adaptive segmentation.

SSPH13-1   Dose-Efficient Assessment Of Trabecular Microstructure Using Whole-Body Photon-Counting CT

Participants
Stefan Sawall, PhD, Heidelberg, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the potential of ultra-high resolution (UHR) photon-counting computed tomography (PCCT) for the assessment of trabecular microstructure in comparison to conventional, energy-integrating CT (EICT) and high-resolution peripheral quantitative CT (HR-pQCT).*Methods and Materials The pixels of clinical PC detectors are much smaller compared to conventional EICT detectors. Often, the resulting ultra-high resolution is not required and reconstructions are performed to the resolution of today's EICTs. From e.g. [Invest. Radiol. 55(2):111-119, 2020] it is known that acquisitions using smaller pixels can reduce noise compared to acquisitions with larger pixels. We herein investigate if this effect can be used to reduce the administered dose in examinations aimed at quantifying trabecular microstructure. Five human vertebral bodies were scanned in an abdomen phantom (QRM, Germany) using an experimental dual-source CT (Siemens Healthineers, Germany) housing an EI detector (0.60 mm pixel size at iso) and a PC detector (0.25 mm pixel size). A tube voltage of 120 kV was used. Tube current for EICT was 355 mAs (23.8 mGy CTDI32cm). Dose-matched UHR-PCCT (UHRdm, 23.8 mGy) and noise-matched acquisitions (UHRnm, 10.5 mGy) were performed and reconstructed to a voxel size of 0.156 mm using a sharp kernel. Trabecular separation (Tb.Sp) and bone mineral density (BMD) were quantified and compared to HR-pQCT (Xtreme CT, SCANCO Medical, Switzerland, 5.5 mGy CTDI10cm).*Results Noise in EICT was 113 HU on average. UHRdm acquisitions (same dose as EICT) showed a noise level of 71 HU while UHRnm (45% dose of EICT) showed the same noise level as EICT at the same spatial resolution. For BMD/(mg/cm³), the overall Mean±StdDev for EI, UHRdm and UHRnm were 171.27±28.94, 173.55±27.90 and 172.88±27.99, while for Tb.Sp/mm they were 1.250±0.245, 1.648±0.481 and 1.463±0.325. Tb.Sp and BMD did not show any significant differences between the investigated protocols. Tb.Sp showed a high agreement with XtremeCT.*Conclusions UHR-PC detectors allow for an accurate characterization of trabecular microstructure even when acquired at 55% less dose compared to a clinical EICT reference.*Clinical Relevance/Application PCCT allows for the assessment of trabecular microstructure at reduced dose.

RESULTS

Noise in EICT was 113 HU on average. UHRdm acquisitions (same dose as EICT) showed a noise level of 71 HU while UHRnm (45% dose of EICT) showed the same noise level as EICT at the same spatial resolution. For BMD/(mg/cm³), the overall Mean±StdDev for EI, UHRdm and UHRnm were 171.27±28.94, 173.55±27.90 and 172.88±27.99, while for Tb.Sp/mm they were 1.250±0.245, 1.648±0.481 and 1.463±0.325. Tb.Sp and BMD did not show any significant differences between the investigated protocols. Tb.Sp showed a high agreement with XtremeCT.

CLINICAL RELEVANCE/APPLICATION

PCCT allows for the assessment of trabecular microstructure at reduced dose.

SSPH13-2   First Results From A Prototype Full-size Photon Counting CT System: Counting And Spectral Imaging Performance At Clinical Dose Levels

Participants
Xiaohui Zhan, Vernon Hills, Illinois (*Presenter*) Employee, Canon Medical Systems Corporation

PURPOSE

In recent years, the semiconductor-based photon counting detectors have gained increasing interest in clinical CT applications. With the thresholding detection and energy selecting capability, the PCD measurements have the potential to provide better contrast and noise performance compared to the scintillator-based EID systems, and enable material decomposition for spectral imaging. In this work, we introduce our first prototype CdZnTe-based full size photon counting CT system, and present its initial performance on both counting and spectral imaging tasks at clinical dose levels.*Methods and Materials This system is designed based on a Canon Aqilion ONE ViSION™ (Fig. 1). The smallest detector pixel size is 342um, and each micro-pixel can output up to 6 energy bins of measurements. The readout can be configured into various macro-pixel schemes to reconstruct images at different spatial resolutions. The 3x3 macro-pixel mode generates a similar detection pitch as the typical EID system, and the resulted normal resolution images were evaluated here. Three 16cm phantoms were scanned with 120kVp, 50/100mA, 1s rotation. The counting images were generated based on events with photon energy >20keV, and the spectral images were generated using multiple energy bin counts (Fig. 2).*Results At both dose levels, the counting images demonstrate excellent HU accuracy and uniformity (Fig. 3), and are free of artifacts. The spectral images, presented as in basis material images and monoenergetic images (Fig. 4 - 6), demonstrate similar image quality and accurate material quantification capability (Tab. 1 - 3). The studies of larger phantoms with higher dose are underway, and results will be reported in the final submission.*Conclusions We have designed and built a prototype

full-size photon counting CT system, and acquired its first rotational counting and spectral images with various phantoms. The images evaluated so far prove its capability to scan at clinical dose levels and generate almost artifact free images with excellent quantitative accuracy.*Clinical Relevance/Application The initial performance of our first prototype PCCT system on both counting and spectral imaging tasks demonstrates its potential to reach diagnostic level image quality at clinical dose levels.

RESULTS

At both dose levels, the counting images demonstrate excellent HU accuracy and uniformity (Fig. 3), and are free of artifacts. The spectral images, presented as in basis material images and monoenergetic images (Fig. 4 - 6), demonstrate similar image quality and accurate material quantification capability (Tab. 1 - 3). The studies of larger phantoms with higher dose are underway, and results will be reported in the final submission.

CLINICAL RELEVANCE/APPLICATION

The initial performance of our first prototype PCCT system on both counting and spectral imaging tasks demonstrates its potential to reach diagnostic level image quality at clinical dose levels.

SSPH13-3   Optimal Virtual Monoenergetic Energy Level (keV) For Photon-counting-detector (PCD) CT Angiography

Participants
Chelsea Dunning, Rochester, Minnesota (*Presenter*) Nothing to Disclose

PURPOSE

To determine the optimal energy level (keV) for virtual monoenergetic images (VMI) in CT angiography (CTA) using photon-counting detector (PCD) CT.*Methods and Materials Under IRB approval, ten patients (abdominal, n=4; lower extremity, n=3; head & neck, n=3) referred for clinical CTA were scanned on an investigational whole-body PCD-CT (SOMATOM Count Plus, Siemens, Forchheim, Germany) at 120 or 140kV with CTDIvol matched to the clinical scan. All images were reconstructed using iterative reconstruction, a vascular kernel (Bv48), and 2mm slice thickness. Axial VMIs and coronal maximum intensity projections were created for 40-65keV in 5keV increments, with 65keV VMI serving as a surrogate for 120kV single energy CT. Contrast-to-noise ratio (CNR) was measured in the aorta, femoral, or carotid arteries over ten slices in each VMI series using soft tissue as the background. Two radiologists blindly ranked the six VMI series (1=best, 6=worst), focusing on overall image quality and visualization of small vessels and pathology. The mean rank and standard deviation for each energy level were calculated. Readers were asked to identify any VMI series that distinguished itself from others in terms of vessel/pathology visualization and artifacts.*Results Mean iodine CNR was highest in 40keV VMIs for all evaluated arteries, with an average CNR increase of 17% to 55% at 40keV compared to at 65keV. Across readers, the 50keV VMI series had the highest combined rank (2.3±1.1). Reader 1 ranked 40keV best (1.9±1.4), and Reader 2 ranked 50keV best (1.8±0.7). Among different body parts, the 45keV VMI was ranked the highest for head & neck (1.8±0.7) and lower extremity (2.3±1.4) PCD-CTA. Meanwhile, 50keV VMI was ranked highest for abdominal (2.4±1.4) PCD-CTA. The 40keV VMI received the highest score from the readers for iodine visualization in vessels, and the 65keV VMI for reduced metal and calcium-blooming artifacts.*Conclusions VMI at 40keV is best for visualizing specific contrast-enhanced arterial vasculature using PCD-CTA, in the absence of metal and calcium artifacts. Overall, the 45keV VMI is optimal for small body parts (e.g. head & neck and lower extremity) while 50keV is best for large body parts (e.g. abdomen).*Clinical Relevance/Application VMI series generated from PCD-CTA at lower energy levels (40-50keV) enables better visualization of small vessels. This can be used to reduce radiation or iodine-contrast dose.

RESULTS

Mean iodine CNR was highest in 40keV VMIs for all evaluated arteries, with an average CNR increase of 17% to 55% at 40keV compared to at 65keV. Across readers, the 50keV VMI series had the highest combined rank (2.3±1.1). Reader 1 ranked 40keV best (1.9±1.4), and Reader 2 ranked 50keV best (1.8±0.7). Among different body parts, the 45keV VMI was ranked the highest for head & neck (1.8±0.7) and lower extremity (2.3±1.4) PCD-CTA. Meanwhile, 50keV VMI was ranked highest for abdominal (2.4±1.4) PCD-CTA. The 40keV VMI received the highest score from the readers for iodine visualization in vessels, and the 65keV VMI for reduced metal and calcium-blooming artifacts.

CLINICAL RELEVANCE/APPLICATION

VMI series generated from PCD-CTA at lower energy levels (40-50keV) enables better visualization of small vessels. This can be used to reduce radiation or iodine-contrast dose.

SSPH13-5   Development And Application Of A Virtual Imaging Trial Platform To Evaluate And Optimize State-of-the-art Photon-counting CT

Participants
Ehsan Abadi, Durham, North Carolina (*Presenter*) Nothing to Disclose

PURPOSE

To develop and validate a virtual imaging trial platform that models the physics and geometry of a new investigational PCCT system to enable its evaluation and optimization across various diagnostic tasks.*Methods and Materials We extended a previously validated CT simulation platform (DukeSim) to model the scanner-specific geometry and physics of a new full field of view investigational dual-source PCCT system (NAEOTOM Alpha, Siemens Healthineers) equipped with CdTe photon-counting detectors (QuantaMax) with 290 μm pixel size (151x176μm at iso center) and 60 mm beam collimation. The platform was provisioned to simulate projections of computational phantoms using a ray-tracing module for primary signal and a Monte Carlo module for dose and scatter signal. A separate Monte Carlo-based detector response model accounted for the signal, noise, and crosstalk processes (K escape, K reabsorption, charge sharing, and electronic noise). Postprocessing was applied for water calibration and beam hardening correction. The developed simulation platform was validated by virtually reproducing images of ACR and multi-energy Gammex phantoms acquired using the investigational PCCT system at multiple dose levels. The real and simulated data were compared in terms of signal (HU), noise (magnitude, NPS), and resolution (MTF). To demonstrate clinical potential, anthropomorphic phantoms (XCAT phantom) were further virtually imaged with the scanner and with the models of two energy-integrating CT systems (Flash and Force). The resulting images were compared in terms of spatial resolution and HU accuracy.*Results The simulations closely reproduced the signal, noise, and resolution of the actual images with errors <5%. Compared to energy integrating CT, the new system demonstrated improved spatial resolution in terms of f50 from 0.33 1/mm up to 1.39 1/mm. The developed platform generated realistic images of computational phantoms across various image acquisition settings (e.g., spectra, detector energy threshold, reconstruction setting) and improved image contrast by 10 HU in the liver parenchyma for 20 keV

detector threshold, compared with Flash and FORCE scanners.*Conclusions A CT simulator can effectively represent the scanner-specific image quality attributes of a modeled investigational PCCT scanner. This tool enables systematic evaluation and optimization of the emerging technology for targeted quantitative performance in the clinic.*Clinical Relevance/Application Photon-counting CT is an emerging CT technology with great potential for improved quality, the effective use of which requires clinical evaluation and optimization. In the context of limited clinical availability, virtual imaging trials uniquely enable such evaluations.

RESULTS

The simulations closely reproduced the signal, noise, and resolution of the actual images with errors <5%. Compared to energy integrating CT, the new system demonstrated improved spatial resolution in terms of f50 from 0.33 1/mm up to 1.39 1/mm. The developed platform generated realistic images of computational phantoms across various image acquisition settings (e.g., spectra, detector energy threshold, reconstruction setting) and improved image contrast by 10 HU in the liver parenchyma for 20 keV detector threshold, compared with Flash and FORCE scanners.

CLINICAL RELEVANCE/APPLICATION

Photon-counting CT is an emerging CT technology with great potential for improved quality, the effective use of which requires clinical evaluation and optimization. In the context of limited clinical availability, virtual imaging trials uniquely enable such evaluations.

SSPH13-6   Whole-body Dual-source Photon-counting Detector (PCD) CT: Technical Assessment And Initial Experience

Participants
Shuai Leng, PHD, Rochester, Minnesota (*Presenter*) License agreement, Siemens AG

PURPOSE

The purpose of this study was to evaluate the performance of a new whole-body, dual-source PCD-CT system using phantoms and first patient scans.*Methods and Materials A 25 μm wire and 25 μm foil were scanned to measure modulation transfer function (MTF) and section sensitivity profile (SSP), respectively, using standard (144 x 0.4 mm) and high resolution (HR, 120 x 0.2 mm) modes of the investigational PCD-CT system (NAEOTOM Alpha, Siemens Healthineers). Images were reconstructed using sharp kernels and minimum possible slice thicknesses (standard: Hr76, 0.4 mm; HR: Hr84, 0.2 mm). The uniformity module of the ACR CT accreditation phantom was scanned using the HR mode and images reconstructed with and without iterative reconstruction (IR) to assess noise power spectra (NPS). A multi-energy (ME) CT phantom containing iodine (2, 5, 10, and 15mg/cc) was scanned using the standard mode (120 kV, CTDIvol 36 mGy) to evaluate material decomposition. A head phantom was scanned using the HR protocol (120 kV, CTDIvol 37 mGy, Hr84 kernel, 0.2 mm slice thickness) to demonstrate high resolution imaging. Under IRB, 18 patients referred for clinical CT exams were scanned on the PCD-CT system (non-contrast breast (2), coronary CTA (4), low-dose whole body (1), head/neck CTA (2), low-dose chest (7), abdominal CTA (1), and runoff CTA (1). Scan and reconstruction parameters were tailored to clinical indication.*Results MTF measurements showed a cut-off spatial frequency of 32 cm-1 (29 cm-1 at 10% MTF) for HR mode (Hr84 kernel) and 24 cm-1 (21 cm-1 at 10% MTF) for standard mode (Hr76 kernel). SSP measurements showed a full-width-half-maximum value of 0.34 mm (0.2 mm slice thickness, HR mode) and 0.63 mm (0.4 mm slice thickness, standard mode). NPS showed lower noise from IR without a shift in the peak frequency compared to conventional filtered back projection. MECT phantom results showed accurate iodine quantification (0.26 mg/cc root-mean-squared-error). Head phantom HR images showed delineation of bony anatomy. Patient images demonstrated a range of benefits, particularly increased spatial resolution for visualization of small structures and pathology, increased iodine contrast, and the availability of spectral data for all exams, including the 66 ms temporal resolution cardiac scans.*Conclusions The new PCD-CT system demonstrated improved spatial resolution compared to state-of-the-art conventional CT and accurate iodine quantification. First patient scans demonstrated improved image quality and capabilities.*Clinical Relevance/Application Comprehensive assessment of a new CT system and first patient scans show similar or improved performance relative to current scanners, providing evidence for its readiness for clinical adoption.

RESULTS

MTF measurements showed a cut-off spatial frequency of 32 cm-1 (29 cm-1 at 10% MTF) for HR mode (Hr84 kernel) and 24 cm-1 (21 cm-1 at 10% MTF) for standard mode (Hr76 kernel). SSP measurements showed a full-width-half-maximum value of 0.34 mm (0.2 mm slice thickness, HR mode) and 0.63 mm (0.4 mm slice thickness, standard mode). NPS showed lower noise from IR without a shift in the peak frequency compared to conventional filtered back projection. MECT phantom results showed accurate iodine quantification (0.26 mg/cc root-mean-squared-error). Head phantom HR images showed delineation of bony anatomy. Patient images demonstrated a range of benefits, particularly increased spatial resolution for visualization of small structures and pathology, increased iodine contrast, and the availability of spectral data for all exams, including the 66 ms temporal resolution cardiac scans.

CLINICAL RELEVANCE/APPLICATION

Comprehensive assessment of a new CT system and first patient scans show similar or improved performance relative to current scanners, providing evidence for its readiness for clinical adoption.

SSBR10-1   Reducing False-positive Recalls By Adding Temporal Changes Information To An AI System For Breast Cancer Detection

Participants
Pierre Fillard, PhD, Paris, France (*Presenter*) Employee, Therapixel SA;Stockholder, Therapixel SA

PURPOSE

In breast cancer detection, change in findings throughout time is one of the major biomarkers for the presence of malignancy. In this study we evaluate the addition of temporal context information to an artificial intelligence (AI) system (called temporal AI) with the purpose of improving its specificity.*Methods and Materials A dataset of 2D mammograms was retrospectively collected from 5,848 patients from one radiology site in the United States and acquired between 2006 and 2019. Among them only examinations with at least one prior available within 18 months were kept. Cancer-positive examinations were confirmed by biopsy/surgery within 6 months after the acquisition, while negative screens were confirmed by a negative follow-up. A further selection was done in order to keep only cases deemed normal or benign (BIRADS 1 or 2) by the reader who had initially read the mammogram but who's prior was deemed suspicious (BIRADS 0), while both examinations were considered suspicious by an AI system. Final selection included 536 positive and 322 negative cases. We designed a new temporal AI able to output a level of suspicion from a pair of mammograms and its prior. Predictions of this new AI were compared with those of the reference AI (i.e., the commercially available version of the system). Comparison was carried out in terms of sensitivity at 100% Positive Predictive Value (PPV) and area under the precision-recall curve (AUCPRC).*Results Sensitivity at 100% PPV was 12.5% (95% CI: 8.3% to 17.6%) for the reference AI and 22.7% (95% CI: 19.2% to 27%) for the temporal AI, giving a sensitivity gain of 10.2% (95% CI: 4.4% to 15%). The AUCPRC shows an improvement from 79.7% (95% CI: 76.5% to 82.7%) for the reference AI to 84.2% (95% CI: 81.8% to 86.7%) for the temporal AI.These results indicate that the temporal AI can separate complex benign cases from cancer-positive ones hardly distinguishable from those when assessed without the prior, but clearly distinguishable when comparison with the prior can be done.*Conclusions The introduction of temporal change into an AI system was shown to improve specificity. We showed that temporal AI can detect about 20% of cancer-positive cases without producing any false positive, which is twice as much as a standard AI. This result, if confirmed by larger studies, could represent an important step towards the integration of AI as standalone systems into breast cancer screening programs. For instance, it could be used to detect high-risk patients before they leave the facility for an immediate diagnosis, or to prioritize patient recall for screening in backlogs that extended due to Covid19.*Clinical Relevance/Application AI can be integrated into screening practice to support or improve cancer detection without increasing false positive recalls.

RESULTS

Sensitivity at 100% PPV was 12.5% (95% CI: 8.3% to 17.6%) for the reference AI and 22.7% (95% CI: 19.2% to 27%) for the temporal AI, giving a sensitivity gain of 10.2% (95% CI: 4.4% to 15%). The AUCPRC shows an improvement from 79.7% (95% CI: 76.5% to 82.7%) for the reference AI to 84.2% (95% CI: 81.8% to 86.7%) for the temporal AI.These results indicate that the temporal AI can separate complex benign cases from cancer-positive ones hardly distinguishable from those when assessed without the prior, but clearly distinguishable when comparison with the prior can be done.

CLINICAL RELEVANCE/APPLICATION

AI can be integrated into screening practice to support or improve cancer detection without increasing false positive recalls.

SSBR10-2   The Potential Of Ai To Reduce Interval Cancer In A Middle Income Country Breast Cancer Screening Program

Participants
Erkin Aribal, Istanbul, Turkey (*Presenter*) Research Consultant, ScreenPoint Medical BV

PURPOSE

To evaluate the performance of an artificial intelligence (AI) system in detecting interval cancers among women with negative screening exams attending a national screening program of a middle income country.*Methods and Materials This retrospective study was performed with a data cohort between 2016-2019 derived from women between 40-69 who attended the national breast cancer screening program. During this period, the recall rate was on average 5.3%. The negative screening exams of 406 women who developed interval cancers before the next screening round were collected, and 446 women with normal follow-up. The pathological outcome and time-to-diagnosis were retrieved. All mammograms were processed by an AI cancer detection system (Transpara v 1.6, ScreenPoint Medical), assigning a score between 1-10 to the exam, representing an increasing likelihood of malignancy. The performance of the AI system for detection of interval cancers on negative screening exams was estimated in

terms of the area under the receiver operating characteristic curve (AUC), and sensitivity at 90% and 95.0% specificity, with 95% confidence intervals cancers.*Results More than half of all interval cancers (53%) were flagged by the highest AI score 10. The AUC of AI to detect signs of IC on negative screening exams was 0.80 (95% CI = 0.77-0.83). The sensitivity was 53.7% and 38.5% at specificity of 90% and 95.0%, respectively. The highest performance of AI was found for cases that were diagnosed within 6 months after screening (AUC: 0.85 (95% CI = 0.78-0.92), compared to cases diagnosed within 24 months after screening (AUC: 0.74 (95% CI = 0.67-0.81).*Conclusions AI has the potential to reduce rate of interval cancers, in case AI is applied as a second or third independent reader within a national breast cancer screening program.*Clinical Relevance/Application Middle income countries have limited human and financial resources for a screening program where AI have a potential to reduce the interval cancers and can be added as a second reader.

RESULTS

More than half of all interval cancers (53%) were flagged by the highest AI score 10. The AUC of AI to detect signs of IC on negative screening exams was 0.80 (95% CI = 0.77-0.83). The sensitivity was 53.7% and 38.5% at specificity of 90% and 95.0%, respectively. The highest performance of AI was found for cases that were diagnosed within 6 months after screening (AUC: 0.85 (95% CI = 0.78-0.92), compared to cases diagnosed within 24 months after screening (AUC: 0.74 (95% CI = 0.67-0.81).

CLINICAL RELEVANCE/APPLICATION

Middle income countries have limited human and financial resources for a screening program where AI have a potential to reduce the interval cancers and can be added as a second reader.

SSBR10-3   A Deep Learning Algorithm For Reducing False Positives In Screening Mammography

Participants
Stefano Pedemonte, PhD, Santa Clara, California (*Presenter*) Researcher, whiterabbit.ai

PURPOSE

Mammography screening improves outcomes for breast cancer by enabling early detection and treatment. While many countries have developed breast cancer screening systems, these systems have important limitations. High rates of false positives result in unnecessary procedures, patient anxiety and added costs. In this work, we evaluate a breast cancer rule-out system that reduces false positives by identifying non-suspicious cases.*Methods and Materials We trained a machine learning model to rule-out cancer and operate at high sensitivity, using 123,270 full-field digital mammograms (6,172 cancers) acquired in the US and the UK. The model is composed of 22 deep neural networks combined to achieve high performance in a meta-learning architecture. The operating point was chosen at 99% sensitivity on a cross-validation set to minimize false negatives. This algorithm was evaluated in a retrospective clinical study based on 11,594 held out screening exams (102 cancers) acquired at a major academic hospital in the US using two scanner models: Hologic Selenia Dimensions (SD: 7,586 exams, 88 cancers) and Hologic Selenia (HS: 4,008 exams, 14 cancers).*Results The rule-out device performance was found to depend on the number of cancer examples used in training for each scanner model (4,874 cancer cases in the training set were acquired on HS and 1,298 on SD). Overall sensitivity was 100% [95% confidence interval: 96.5%, 100%], in particular 100% [76.8%, 100%] for HS and 100% [95.5%, 100%] for SD. Recalls for diagnostic exams were reduced by 44.5% [40.4%, 48.8%] for HS and by 23.2% [20.0%, 25.9%] for SD. The number of benign needle biopsies was reduced by 9.5% [2.4%, 21.5%] for HS and by 6.8% [3.4%, 12.3%] for SD. The potential number of screening exams requiring radiologist's interpretation was reduced by 54.0% [52.4%, 55.5%] for HS and by 34.6% [33.7%, 35.8%] for SD.*Conclusions Devices that identify non suspicious mammograms can provide an important aid to radiologists and directly benefit patients and healthcare systems overall by reducing false positives, unnecessary procedures, and costs. Quality assurance mechanisms and improved training methods to guarantee uniformity of performance and studies based on large data sets will be critical to enable safe operation of these devices.*Clinical Relevance/Application Some studies report that more than half of women screened in the US are subjected to false positives and more than 20% to unnecessary procedures over their lifetime. Rule-out devices can change this.

RESULTS

The rule-out device performance was found to depend on the number of cancer examples used in training for each scanner model (4,874 cancer cases in the training set were acquired on HS and 1,298 on SD). Overall sensitivity was 100% [95% confidence interval: 96.5%, 100%], in particular 100% [76.8%, 100%] for HS and 100% [95.5%, 100%] for SD. Recalls for diagnostic exams were reduced by 44.5% [40.4%, 48.8%] for HS and by 23.2% [20.0%, 25.9%] for SD. The number of benign needle biopsies was reduced by 9.5% [2.4%, 21.5%] for HS and by 6.8% [3.4%, 12.3%] for SD. The potential number of screening exams requiring radiologist's interpretation was reduced by 54.0% [52.4%, 55.5%] for HS and by 34.6% [33.7%, 35.8%] for SD.

CLINICAL RELEVANCE/APPLICATION

Some studies report that more than half of women screened in the US are subjected to false positives and more than 20% to unnecessary procedures over their lifetime. Rule-out devices can change this.

SSBR10-4   A Benchmarking Study To Evaluate The Performance Of Two Artificial Intelligence Algorithms For Interval Cancer Detection In A UK Breast Screening Setting

Participants
Sarah Hickman, MBBS, Cambridge, United Kingdom (*Presenter*) Research collaboration, VaraResearch collaboration, ScreenPoint Medical BVResearch collaboration, Lunit IncResearch collaboration, Kheiron Medical Technologies LtdResearch collaboration, Alphabet IncResearch collaboration, Volpara Health Technologies Limi

PURPOSE

To investigate artificial intelligence (AI) algorithms for interval cancer (IC) detection in a UK breast screening programme (BSP).*Methods and Materials Two commercial AI algorithms were evaluated using retrospectively collected data from four mammographic system vendors from 2011-2020 in a single UK National Health Service (NHS) breast screening center. The study sample was screening mammograms of consecutive ICs from women with confirmed histological diagnosis together with age and year matched confirmed normal controls. Both AI algorithms were evaluated using their continuous score outputs, with a higher score indicating greater suspicion of cancer with performance investigated at two prespecified thresholds of specificity; one at 96%, based on NHSBSP data, and a lower threshold of 90% appropriate for subsequent consensus reading. A prespecified threshold of sensitivity was set to 30% - the estimated percentage of ICs detectable on the prior screening mammogram.*Results 2,077 four-view digital screening mammogram cases, including 528 (25.42%) interval cancers, were analyzed. For both algorithms the median score assigned to IC cases was higher than the median for normal cases (p < 0.01). At 96% specificity, sensitivities of

23.49% and 23.86% were achieved by AI-1 and AI-2, respectively with sensitivities of 37.50% and 35.80% at 90% specificity. At the 30% sensitivity threshold, the specificity was 93.87% and 92.45% respectively. The area under the receiver operating characteristic curve (AUC) of AI-1 and AI-2 was 0.72 and 0.71 respectively (p = 0.44), using both AI tools together resulted in an AUC of 0.74.*Conclusions By setting the threshold of the algorithm we were able to simulate performance within a UK screen reading workflow. Single reading with an AI algorithm to triage cases to the second reader at a 10% threshold, could improve IC detection. Use of ICs allows for separate testing to determine if significant improvements can be made at an acceptable specificity and should be included in benchmarking. As this study was limited to one screening center further testing is required.*Clinical Relevance/Application Testing artificial intelligence (AI) with datasets of interval cancers and normals using screening programme thresholds can give an indication of performance in an adaptive screen reading.

RESULTS

2,077 four-view digital screening mammogram cases, including 528 (25.42%) interval cancers, were analyzed. For both algorithms the median score assigned to IC cases was higher than the median for normal cases (p < 0.01). At 96% specificity, sensitivities of 23.49% and 23.86% were achieved by AI-1 and AI-2, respectively with sensitivities of 37.50% and 35.80% at 90% specificity. At the 30% sensitivity threshold, the specificity was 93.87% and 92.45% respectively. The area under the receiver operating characteristic curve (AUC) of AI-1 and AI-2 was 0.72 and 0.71 respectively (p = 0.44), using both AI tools together resulted in an AUC of 0.74.

CLINICAL RELEVANCE/APPLICATION

Testing artificial intelligence (AI) with datasets of interval cancers and normals using screening programme thresholds can give an indication of performance in an adaptive screen reading.

SSBR10-5 Deep Learning Predicts Interval And Screen-detected Cancer From Negative Screening Mammograms: A Case-case-control Study In 6369 Women

Participants
Lambert Leong, MS, Honolulu, Hawaii (*Presenter*) Nothing to Disclose

PURPOSE

The ability of deep learning models to classify women as at risk for either screen-detected by mammography or interval cancer (not detected on mammography) has not been comprehensively studied in the literature. Our goal was to examine the ability of deep learning models to estimate the risk of interval and screening detected breast cancers with and without clinical risk factors.*Methods and Materials This case-case-control study was performed on 25096 prospectively collected negative digital screening mammograms, ascertained from 2006 to 2014, a median of 2.8 years prior to any cancer. A total 1609 women had screen-detected breast cancer, 351 interval invasive breast cancer and 4409 were cancer free. A deep learning model was trained and validated on the negative mammograms prior to cancer to classify women into either as not having developed cancer or developed screening-detected or interval invasive cancer. Model effectiveness was evaluated as a matched concordance statistic (c-statistic) in a held-out (29.2%, 1669 out of 5708 women) test set of the mammograms. Deep learning models were bench marked against models using clinical risk factors including breast density. All models were adjusted for clinical risk factors including age (continuous), BMI (continuous, inverse BMI), first degree family history of breast cancer, history of biopsy, and race.*Results The c-statistics for comparing screen-detected cancers versus matched controls waw 0.66 (95% CI: 0.63, 0.69) with odds ratios (OR) 1.25 (1.17, 1.33) for the deep learning model, 0.62 (0.59, 0.65) for the clinical risk factors with BIRADS density model, and 0.66 (0.63, 0.69) for the combined deep learning and clinical risk factors model. For comparing interval cancers versus controls, the c-statistics were 0.64 (0.58, 0.71) with ORs 1.26 (1.10, 1.45) for the deep learning model, 0.71 (0.65, 0.77) for the risk factors with BIRADS density model, and 0.72 (0.66, 0.78) for the combined deep learning and clinical risk factors model.*Conclusions The deep learning model underperformed for interval cancer risk when compared to clinical risk factors including BIRADS density but outperformed in determining screen-detected cancer risk.*Clinical Relevance/Application Deep learning demonstrated the ability to predict three clinically relevant outcomes (no cancer, screening-detected cancer risk, and interval cancer risk) from negative mammograms and clinical risk factors.

RESULTS

The c-statistics for comparing screen-detected cancers versus matched controls waw 0.66 (95% CI: 0.63, 0.69) with odds ratios (OR) 1.25 (1.17, 1.33) for the deep learning model, 0.62 (0.59, 0.65) for the clinical risk factors with BIRADS density model, and 0.66 (0.63, 0.69) for the combined deep learning and clinical risk factors model. For comparing interval cancers versus controls, the c-statistics were 0.64 (0.58, 0.71) with ORs 1.26 (1.10, 1.45) for the deep learning model, 0.71 (0.65, 0.77) for the risk factors with BIRADS density model, and 0.72 (0.66, 0.78) for the combined deep learning and clinical risk factors model.

CLINICAL RELEVANCE/APPLICATION

Deep learning demonstrated the ability to predict three clinically relevant outcomes (no cancer, screening-detected cancer risk, and interval cancer risk) from negative mammograms and clinical risk factors.

SSBR10-6 I Spy With My AI: The Importance Of Thorough Retrospective Performance Evaluation Prior To AI Implementation.

Participants
Gerald Lip, MBBCh, Aberdeen, United Kingdom (*Presenter*) Nothing to Disclose

PURPOSE

Mammography hardware vendors provide significant software updates and/or changes to mammography machines every 3-5 years. These updates go largely unnoticed by human readers. This retrospective study hypothesizes that such updates can have a significant impact on the performance of an artificial intelligence (AI) tool. AI performance can be corrected if local validation is performed prior to implementation.*Methods and Materials We describe the evaluation of an AI tool over a 4-year period of consecutively acquired national screening mammograms. Images were acquired from two static unit machines and two mobile unit machines from a single breast screening centre. The centre is accredited as part of a national screening programme. Clinical outcomes and machine information were blinded until after the AI was run.*Results A high AUC (95.8) indicates strong AI performance. A rise in recall rate was observed after a specific point in time (an "event") for each machine (See figure: Aug 2016 for machine D; Jan 2019 for A and B; April 2019 for C). This event corresponds with additional DICOM tags being observed suggesting that software updates were added to these machines at these times. The dataset was split into two: one dataset before the event [no. of cases: all | positive = 9670 | 113]; a second dataset after the event [all | positive = 6339 | 99]. Use of

an updated threshold post-event allows for an acceptable recall rate (~10%) to be recovered. Note that the AI is being evaluated standalone and that recall rate would drop further when used in a double reading workflow.*Conclusions The existing literature on AI performance uses standard test metrics and human comparisons. We flag the importance of considering the impact that updates to mammography machines can have on AI performance. Local validation prior to implementation demonstrated that an updated threshold, optimized after a suspected software update event, would be more clinically appropriate for live use. Once live, in order to detect any changes as soon as possible, AI implementation must be followed by robust quality assurance, feedback and fallback processes.*Clinical Relevance/Application Large scale temporal review demonstrated that it is important to conduct a review of performance of AI over time, especially if hardware/ software updates are known to have or may have taken place.

RESULTS

A high AUC (95.8) indicates strong AI performance. A rise in recall rate was observed after a specific point in time (an "event") for each machine (See figure: Aug 2016 for machine D; Jan 2019 for A and B; April 2019 for C). This event corresponds with additional DICOM tags being observed suggesting that software updates were added to these machines at these times. The dataset was split into two: one dataset before the event [no. of cases: all | positive = 9670 | 113]; a second dataset after the event [all | positive = 6339 | 99]. Use of an updated threshold post-event allows for an acceptable recall rate (~10%) to be recovered. Note that the AI is being evaluated standalone and that recall rate would drop further when used in a double reading workflow.

CLINICAL RELEVANCE/APPLICATION

Large scale temporal review demonstrated that it is important to conduct a review of performance of AI over time, especially if hardware/ software updates are known to have or may have taken place.

SSBR09-1   BI-RADS Reading Of Non-mass Lesions On DCE-MRI And Differential Diagnosis Performed By Radiomics And Deep Learning

Participants

Yang Zhang, New Brunswick, New Jersey (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the morphological distribution and internal enhancement pattern of benign and malignant lesions demonstrating non-mass enhancement on DCE-MRI, and to investigate the diagnostic performance of radiomics and deep learning using ResNet50.*Methods and Materials 150 patients with 104 malignant and 46 benign NME were analyzed. Three radiologists performed reading for morphological distribution and internal enhancement using the 5th BI-RADS lexicon. For each case, the 3D tumor mask was generated using Fuzzy-C-Means segmentation. Three DCE parametric maps related to wash-in, maximum, and wash-out were generated, and PyRadiomics was applied to extract features. The radiomics model was built using 5 machine learning algorithms. ResNet50 was implemented using three parametric maps as input. Approximately 70% of earlier cases were used for training, and 30% later cases held-out for testing.*Results The diagnostic BI-RADS in the original MRI report showed that 104/104 malignant and 36/46 benign lesions had BI-RADS score of 4A-5. For category reading, the kappa coefficient was 0.83 for morphological distribution (excellent), and 0.52 for internal enhancement (moderate). Segmental and Regional distribution were the most prominent for the malignant group, and focal distribution for the benign group. Eight radiomics features were selected by SVM. Among the 5 machine learning algorithms, SVM yielded the highest accuracy of 80.4% in training, 77.5% in testing datasets. ResNet50 had a better diagnostic performance, 91.5% in training, and 83.3% in testing datasets.*Conclusions BI-RADS scores and descriptors showed a substantial overlap; computer-aided methods with sophisticated machine learning and deep learning algorithms can be further developed to help solving the difficult problem in the diagnosis of NME on MRI.*Clinical Relevance/Application Deep learning using ResNet50 algorithm yielded a high diagnostic accuracy around 90%, which could provide a feasible tool for the difficult diagnosis of NME on MRI.

RESULTS

The diagnostic BI-RADS in the original MRI report showed that 104/104 malignant and 36/46 benign lesions had BI-RADS score of 4A-5. For category reading, the kappa coefficient was 0.83 for morphological distribution (excellent), and 0.52 for internal enhancement (moderate). Segmental and Regional distribution were the most prominent for the malignant group, and focal distribution for the benign group. Eight radiomics features were selected by SVM. Among the 5 machine learning algorithms, SVM yielded the highest accuracy of 80.4% in training, 77.5% in testing datasets. ResNet50 had a better diagnostic performance, 91.5% in training, and 83.3% in testing datasets.

CLINICAL RELEVANCE/APPLICATION

Deep learning using ResNet50 algorithm yielded a high diagnostic accuracy around 90%, which could provide a feasible tool for the difficult diagnosis of NME on MRI.

SSBR09-2   Application Of Two Deep Learning Networks For Diagnosis Of Breast Cancer On MRI: Automatic Detection Using Mask R-CNN Followed By Classification Using ResNet50

Participants

Yang Zhang, New Brunswick, New Jersey (*Presenter*) Nothing to Disclose

PURPOSE

We have previously developed a fully-automatic breast cancer detection method on MRI using Mask Regional-Convolutional Neural Network (R-CNN). We have also developed a deep learning model using ResNet50 to estimate the malignancy probability. In this study, these two deep learning networks were combined to test its diagnostic validity in clinical practice.*Methods and Materials The developed detection/classification network was tested in two datasets, performed on a 3T system. The first one had 176 cases, 103 cancer and 73 benign. The second one had 84 cases, 53 cancers and 31 benign. All slices were evaluated by a pre-

trained Mask R-CNN framework using ResNet101 as the backbone. The pre-contrast image, and the subtraction images of both breasts were used as inputs, so the symmetry could be utilized as reference. The detected suspicious area was further characterized by ResNet50. Three DCE parametric maps (F2-F1, F3-F1, F6-F3) were used as inputs. The evaluation was done using slice-based analysis, and then the obtained results from all slices of a lesion were combined to give a lesion-based diagnosis.*Results In the first dataset, 101 of 103 cancers were detected by Mask R-CNN as suspicious, and 99 of 101 were correctly classified by ResNet50 as cancer. 48 of 73 benign lesions, and 130 normal areas, were identified by Mask R-CNN as suspicious. Following classification by ResNet50, only 32 of these 178 remained as suspicious of malignancy. The overall sensitivity is 99/103=96%, with 32/153=21% false positive rates. The second dataset had more non-mass enhancing large lesions, and the performance was worse. 49 of 53 cancers were detected by Mask R-CNN as suspicious, and 43 were classified as cancer. The sensitivity is 43/53=81%. 6 of 31 benign lesions and 22 normal tissue areas were considered as suspicious of malignancy, with false positive rate of 28/84=33%.*Conclusions The previously developed Mask R-CNN detection model followed by ResNet50 classification model was directly applied to two new datasets, and achieved a high sensitivity. The false positive diagnosis, especially from the normal parenchymal enhancements, can be further eliminated by other algorithms.*Clinical Relevance/Application AI-based diagnostic tool has gradually become mature for clinical use. A combined Mask R-CNN and ResNet50 algorithm has the potential to provide a fully-automatic system for diagnosis of breast cancer on MRI.

RESULTS

In the first dataset, 101 of 103 cancers were detected by Mask R-CNN as suspicious, and 99 of 101 were correctly classified by ResNet50 as cancer. 48 of 73 benign lesions, and 130 normal areas, were identified by Mask R-CNN as suspicious. Following classification by ResNet50, only 32 of these 178 remained as suspicious of malignancy. The overall sensitivity is 99/103=96%, with 32/153=21% false positive rates. The second dataset had more non-mass enhancing large lesions, and the performance was worse. 49 of 53 cancers were detected by Mask R-CNN as suspicious, and 43 were classified as cancer. The sensitivity is 43/53=81%. 6 of 31 benign lesions and 22 normal tissue areas were considered as suspicious of malignancy, with false positive rate of 28/84=33%.

CLINICAL RELEVANCE/APPLICATION

AI-based diagnostic tool has gradually become mature for clinical use. A combined Mask R-CNN and ResNet50 algorithm has the potential to provide a fully-automatic system for diagnosis of breast cancer on MRI.

SSBR09-3   An AI System For Lesion Detection Using Multi-institutional Digital Breast Tomosynthesis Data

Participants
Julia Goldberg, MD, New York, New York (*Presenter*) Nothing to Disclose

PURPOSE

To train an AI lesion detection system jointly on internal and external DBT datasets and evaluate its performance in the SPIE-AAPM-NCI DAIR Digital Breast Tomosynthesis Lesion Detection (DBTex) Challenge.*Methods and Materials We collected a dataset of 100,420 internal DBT exams (N=85,896 patients [pts], 397 malignant, 726 benign) along with pixel-level lesion annotations of biopsied lesions. We also utilized 229,282 internal digital mammograms (N=141,397 pts, 849 malignant, 3,058 benign) and 700 DBT exams from the DBTex challenge (N=693 pts, 39 malignant, 62 benign) in training our models. All DBT exams were acquired with the Hologic Selenia Dimensions. We trained our deep convolutional neural networks to detect biopsy-proven lesions in DBT exams and evaluated them using 180 DBT exams (N=175 pts) from the test dataset of the DBTex challenge. Model performance of predicting bounding-boxes for lesions was assessed using Free-Response Operating Characteristic (FROC) curve analysis. Our final model is an ensemble of EfficientDet models trained on all available data and then fine-tuned on the exams from the DBTex challenge.*Results The mean age was 59.5, range 21.3 - 99.5. Internal DBT dataset density was 9.0% fatty, 40.4% scattered fibroglandular, 45.0% heterogeneously dense, and 5.4% extremely dense. Our model can output the slice where the lesion is most clearly visible.Our model ranked first in the DBTex Challenge by achieving the highest scores on the test set. Our model had a sensitivity of 91.2% at a threshold that leads to 2 false positive (FP) bounding box predictions per view on average, meaning that the model can detect 91.2% of all masses and architectural distortions at this threshold. This sensitivity was 49.2 percentage points higher than the baseline provided by the challenge organizers. In addition, among the subset of images with biopsy-confirmed lesions, the mean sensitivity at 4 different thresholds which lead to 1, 2, 3, and 4 FP predictions per view was 91.2%. This was the main evaluation metric of the competition in which our model outperformed all other participants.*Conclusions Our model trained on multi-institutional datasets produced the most accurate bounding-box lesion predictions in the DBTex Challenge.*Clinical Relevance/Application Aside from the most accurate lesion prediction, our model outputs the slice where the lesion is most clearly visible, potentially improving AI decision support and synthesizing AI-processed 2D images to maximize lesion conspicuity.

RESULTS

The mean age was 59.5, range 21.3 - 99.5. Internal DBT dataset density was 9.0% fatty, 40.4% scattered fibroglandular, 45.0% heterogeneously dense, and 5.4% extremely dense. Our model can output the slice where the lesion is most clearly visible.Our model ranked first in the DBTex Challenge by achieving the highest scores on the test set. Our model had a sensitivity of 91.2% at a threshold that leads to 2 false positive (FP) bounding box predictions per view on average, meaning that the model can detect 91.2% of all masses and architectural distortions at this threshold. This sensitivity was 49.2 percentage points higher than the baseline provided by the challenge organizers. In addition, among the subset of images with biopsy-confirmed lesions, the mean sensitivity at 4 different thresholds which lead to 1, 2, 3, and 4 FP predictions per view was 91.2%. This was the main evaluation metric of the competition in which our model outperformed all other participants.

CLINICAL RELEVANCE/APPLICATION

Aside from the most accurate lesion prediction, our model outputs the slice where the lesion is most clearly visible, potentially improving AI decision support and synthesizing AI-processed 2D images to maximize lesion conspicuity.

SSBR09-4   Triaging Women From MRI To Mammography To Adapt Screening To Changes In Breast Density Using Artificial Intelligence

Participants
Bas van der Velden, PhD, Utrecht, Netherlands (*Presenter*) Nothing to Disclose

PURPOSE

Magnetic resonance imaging (MRI) is effective to screen women with extremely dense breasts, but it is more resource intensive than mammography. Breast density decreases with age, but density on MRI is not identical to mammographic density, raising the question when to return women to conventional mammography screening in future MRI-only screening setting. This study assesses

the feasibility of artificial intelligence (AI) to triage women from MRI-screening back to mammographic screening when appropriate.*Methods and Materials Women with extremely dense breasts in the multi-institutional DENSE trial received mammography and MRI in biennial screening rounds. We trained a regression convolutional neural network (CNN) to predict the mammographic density percentage (VolparaDensity version 1.5) from MRI only.We used data from the first two screening rounds to train the CNN. Input were precontrast 3D T1-weighted MRI, output was mammographic density percentage. Data were split in train (60%), validation (20%), and hold-out test (20%) set on participant level.Correlation between AI-predicted mammographic density based on MRI and actual mammographic density was assessed using Spearman's ?.Triaging from MRI to mammographic screening was assessed in the hold-out test set of the second screening round. Triaging was defined 'correct' when VolparaDensity and AI agreed on a density <15.5% for both breasts. We registered how often the AI correctly triaged these women at 95% specificity.*Results 4300 MRIs from 2867 women were included. Median mammographic density (interquartile range) was 19% (17%-22%) in the first round and 18% (15%-21%) in the second round. In the hold-out test set (N=860), correlation between AI-predicted mammographic density and VolparaDensity was ?=0.76 (P<0.001). In the hold-out test set of the second round (N=380), mammographic density of both breasts decreased to <15.5% in 69/380 (18%) women. The AI correctly identified this decrease in 40/69 (58%) women.*Conclusions AI shows potential to correctly triage more than half the number of women with decreased breast density from MRI-only screening back to mammographic screening at high specificity.*Clinical Relevance/Application AI-based triaging of women with extremely dense breasts from MRI-only screening back to mammography screening is feasible, enabling radiologists to reduce workload and re-allocate resources.

RESULTS

4300 MRIs from 2867 women were included. Median mammographic density (interquartile range) was 19% (17%-22%) in the first round and 18% (15%-21%) in the second round. In the hold-out test set (N=860), correlation between AI-predicted mammographic density and VolparaDensity was ?=0.76 (P<0.001). In the hold-out test set of the second round (N=380), mammographic density of both breasts decreased to <15.5% in 69/380 (18%) women. The AI correctly identified this decrease in 40/69 (58%) women.

CLINICAL RELEVANCE/APPLICATION

AI-based triaging of women with extremely dense breasts from MRI-only screening back to mammography screening is feasible, enabling radiologists to reduce workload and re-allocate resources.

SSBR09-5   AI-Triaging Of Breast MRI For Radiological Review In The Screening Of Women With Extremely Dense Breasts

Participants
Kenneth G. Gilhuijs, PhD, Amsterdam, Netherlands (*Presenter*) Nothing to Disclose

PURPOSE

Supplemental screening with MRI in women with extremely dense breasts proved to be beneficial. As expected, most screening MRIs showed normal anatomical and physiological variation that does not require expert radiologist's review. We pursued automated triaging to dismiss examinations without lesions for radiological review, while still identifying all examinations with malignant disease.*Methods and Materials In this re-analysis of data from the DENSE trial (a randomized controlled trial into the additional value of MRI screening in women aged 50-75 years with extremely dense breasts and negative mammography, ClinicalTrials.gov NCT01315015), we included 4581/4783 (96%) dynamic contrast-enhanced T1-weighted breast MRI examinations from the first screening round, and 2901/3436 (84%) from the second round. Examinations were excluded if data were not available in full for artificial intelligence (AI) analysis. A convolutional neural network was trained using the examinations from the first round to distinguish between breasts with lesions (i.e., BI-RADS 2-5), and normal breasts without lesions (i.e., BI-RADS 1). Eight-fold internal-external validation and receiver-operating characteristic (ROC) analysis were applied. At 100% sensitivity, we established the fraction of examinations (bilateral) that could be dismissed from radiological review. The examinations from the second screening round were subsequently used to validate the AI.*Results The area under the ROC curve (AUC) in the first screening round was 0.81. Of the 785 examinations with lesions, 755 (96.2%; 95%CI 94.6%-97.4%) were considered non-normal (i.e., containing lesions, 77 of which were malignant), and would triage to radiological review. Conversely, 728 of 3796 examinations (19.2%; 95%CI 17.9%-20.5%) without lesions could be dismissed. All 77 examinations with cancer were detected. In the second screening round, the AUC was 0.79. All 20 examinations with cancer were detected. Of the 303 examinations with lesions, 278 (91.8%; 95%CI 88.1%-94.6%) were considered non-normal and would triage to radiological review. Conversely, 550 of 2598 examinations (21.2%; 95%CI 17.9%-20.5%) without lesions could be dismissed.*Conclusions AI-triaging of screening breast MRI in women with dense breasts shows potential to dismiss approximately 20% of normal examinations from radiological review without dismissing malignant disease.*Clinical Relevance/Application AI-triaging of screening breast MRI in women with dense breasts may reduce the workload of radiologists by automatically dismissing examinations that show normal anatomical and physiological variation, thus optimizing the use of resources.

RESULTS

The area under the ROC curve (AUC) in the first screening round was 0.81. Of the 785 examinations with lesions, 755 (96.2%; 95%CI 94.6%-97.4%) were considered non-normal (i.e., containing lesions, 77 of which were malignant), and would triage to radiological review. Conversely, 728 of 3796 examinations (19.2%; 95%CI 17.9%-20.5%) without lesions could be dismissed. All 77 examinations with cancer were detected. In the second screening round, the AUC was 0.79. All 20 examinations with cancer were detected. Of the 303 examinations with lesions, 278 (91.8%; 95%CI 88.1%-94.6%) were considered non-normal and would triage to radiological review. Conversely, 550 of 2598 examinations (21.2%; 95%CI 17.9%-20.5%) without lesions could be dismissed.

CLINICAL RELEVANCE/APPLICATION

AI-triaging of screening breast MRI in women with dense breasts may reduce the workload of radiologists by automatically dismissing examinations that show normal anatomical and physiological variation, thus optimizing the use of resources.

SSBR09-7   Artificial Intelligence For Digital Breast Tomosynthesis To Detect Breast Cancer: Validation Across Different Patient Populations And Mammography Vendors

Participants
Ki Hwan Kim, MD,PhD, Seoul, Korea, Republic Of (*Presenter*) Employee, Lunit Inc

PURPOSE

Use of artificial intelligence (AI) for mammography improves radiologists' performance in breast cancer detection, but most existing algorithms are based on conventional 2D digital mammography. This study aimed to develop an AI algorithm for the detection of

breast cancer on digital breast tomosynthesis (DBT) and to investigate the performance of the algorithm among women of different ethnicities and with different mammography vendors.*Methods and Materials An AI algorithm based on a deep convolutional neural network was trained and validated to detect breast cancer using 13435 DBT examinations performed on mammography machines from two different vendors (Hologic and GE) and collected from South Korea and the United States. The examinations included 3606 cancer cases confirmed by biopsy, 6863 benign cases confirmed by biopsy or at least two-year follow-up imaging, and 2966 normal cases. In addition, the developed AI algorithm was further validated with an independent external dataset that was not used for training, consisting of 700 DBT cases (39 cancers, 241 benign, and 420 normal) from the United States. The diagnostic performance of the AI algorithm was evaluated using receiver operating characteristic (ROC) curve analyses.*Results The AI algorithm demonstrated an area under the ROC curve (AUC) of 0.943 with sensitivity and specificity of 84.5% and 91.6%, respectively. In the South Korean dataset, the AUC was 0.935, sensitivity was 82.8%, and specificity was 93.2%. In the United States dataset, the AUC was 0.944, sensitivity was 84.8%, and specificity was 91.2%. In the Hologic dataset, the AUC was 0.943, sensitivity was 83.3%, and specificity was 91.8%. In the GE dataset, the AUC was 0.944, sensitivity was 87.1%, and specificity was 91.0%. The performance metrics of the AI algorithm on the external validation dataset were similar to those of the internal validation dataset (AUC of 0.940, sensitivity of 82.6%, and specificity of 92.0%).*Conclusions The AI algorithm developed with large-scale DBT data demonstrated high diagnostic performance in breast cancer detection with comparable performance across datasets from South Korea and the United States and across different mammography vendors.*Clinical Relevance/Application An AI algorithm using a large dataset of DBT may improve breast cancer detection and has the potential to show consistent performance across different patient populations and mammography vendors.

RESULTS

The AI algorithm demonstrated an area under the ROC curve (AUC) of 0.943 with sensitivity and specificity of 84.5% and 91.6%, respectively. In the South Korean dataset, the AUC was 0.935, sensitivity was 82.8%, and specificity was 93.2%. In the United States dataset, the AUC was 0.944, sensitivity was 84.8%, and specificity was 91.2%. In the Hologic dataset, the AUC was 0.943, sensitivity was 83.3%, and specificity was 91.8%. In the GE dataset, the AUC was 0.944, sensitivity was 87.1%, and specificity was 91.0%. The performance metrics of the AI algorithm on the external validation dataset were similar to those of the internal validation dataset (AUC of 0.940, sensitivity of 82.6%, and specificity of 92.0%).

CLINICAL RELEVANCE/APPLICATION

An AI algorithm using a large dataset of DBT may improve breast cancer detection and has the potential to show consistent performance across different patient populations and mammography vendors.

SSMK04-1   In-vivo Assessment Of Trapezio-metacarpal Joint Kinematics Using 4-D CT.

Participants
Nico Buls, DSc, PhD, Jette, Belgium (*Presenter*) Nothing to Disclose

PURPOSE

Advances in CT scanning procedures that combine temporal information and high-resolution volumetric data can be useful in the evaluation of diseases such as osteoarthritis (OA). The purpose of this study is to establish a quantitative analysis of the trapezio-metacarpal joint (TMCJ) kinematics using 4D-CT.*Methods and Materials Following approval from the ethical committee board of our institution, 4D-CT cine images (256-slice Revolution CT, GE Healthcare) were acquired on 5 healthy asymptomatic adults while they performed a cyclic movement of thumb opposition-reposition. Two scans were taken for each subject, one with free motion, and one with hindered motion induced by an elastic band between the thumb and the fifth phalanx to simulate disturbed motion. Image processing of the resulting images was done using custom code written in Python and based on the insight segmentation and registration toolkit (ITK). Image sequences were registered to calculate the transformations that describe the absolute and relative motion of the trapezium (Tz) and metacarpal (MC) bone in a local coordinate system (LCS) defined by anatomic landmarks. Optimization of the registration was performed for different similarity metrics (mean squares, normalized correlation, mutual information) and masks (fixed mask with dilation sizes ranging 1 to 5 voxels) by calculating Dice scores. Travelled distance of bone landmarks, range of motion (ROM) along the axes and areas of the motion coordinates projected on the LCS planes were computed to analyze the joint kinematics. Difference in kinematics between free motion and hindered motion was evaluated by paired t-tests.*Results Normalized correlation metric and a 5-voxel dilation mask yielded the best registration results (average dice score 0.917 and 0.972 for MC and Tz respectively) Movement disturbances and longer trajectories were visually noticed on the 2D and 3D kinematics for the cases hindered by the elastic band. Significantly higher values for travelled distance (p=0.027), volar ROM (p=0.002) and projected areas (p=0.002) were found on the hindered motion, revealing differences between the motion trajectories.*Conclusions Our study showed the feasibility of acquiring, processing and registering the images of 4D-CT on the TMCJ. The kinematic parameters and the motion visualization allowed observing differences between hindered and non-hindered thumb opposition-reposition.*Clinical Relevance/Application Quantitative imaging modalities are becoming increasingly useful in the understanding and evaluation of MSK conditions with dynamic CT being a promising tool. Such quantitative assessment could increase the clinical value of radiologic examinations as it adds a functional dimension to morphological data.

RESULTS

Normalized correlation metric and a 5-voxel dilation mask yielded the best registration results (average dice score 0.917 and 0.972 for MC and Tz respectively) Movement disturbances and longer trajectories were visually noticed on the 2D and 3D kinematics for the cases hindered by the elastic band. Significantly higher values for travelled distance (p=0.027), volar ROM (p=0.002) and projected areas (p=0.002) were found on the hindered motion, revealing differences between the motion trajectories.

CLINICAL RELEVANCE/APPLICATION

Quantitative imaging modalities are becoming increasingly useful in the understanding and evaluation of MSK conditions with dynamic CT being a promising tool. Such quantitative assessment could increase the clinical value of radiologic examinations as it adds a functional dimension to morphological data.

SSMK04-2   Comparison Of 3-dimensional Magnetic Resonance Imaging And Computed Tomography For Evaluation Of Glenoid Deformity In Shoulder Arthritis

Participants
Mohammad Samim, MD, MRCS, Eastchester, New York (*Presenter*) Nothing to Disclose

PURPOSE

3-dimentional (3-D) computed tomography (CT) is the imaging modality of choice for preoperative assessment of glenoid morphology in primary shoulder osteoarthritis. However, it is limited in its ability to evaluate the rotator cuff (RC) and also exposes patients to radiation. The aim of this study was to compare 3-D magnetic resonance imaging (MRI) and 3-D CT with respect to assessment of glenoid wear and RC integrity in osteoarthritic shoulders.*Methods and Materials CT and MRI were performed on the same day on 31 patients with osteoarthritic shoulders scheduled for shoulder arthroplasty and 3-D CT and 3-D MRI reconstructions were generated as per study protocol. Two reviewers independently performed glenoid morphometric measurements (inclination and version), and evaluated other parameters including glenoid erosion patterns, RC tear, integrity and RC muscle fatty infiltration grade. Mean differences between the two imaging modalities were calculated. Interobserver agreement was calculated using kappa coefficient (k).*Results 29 patients met the inclusion criteria. There were 5 A1, 7 A2, 8 B2 and 9 B3 glenoid morphology. The combined mean absolute difference in glenoid version between 3-D CT and 3-D MRI was 2.7°± 1.6° (range 0.15 to 7.85, P- value =

0.7). The combined mean absolute difference in glenoid inclination between 3-D CT and 3-D MR was 6.8° ± 4.1° (range 0.8° to 15.75°, P-value = 0.17). No significant inter-reader variation in glenoid version and inclination measurements on 3-D CT and 3-D MRI was found (P >0.05). The inter-reader reliability for both CT and MRI was strong and almost perfect for the Walch grading of glenoid bone loss (k= 1 k= 0.86, respectively). The accuracy of CT, compared to MRI, in determining any RC tear was excellent for full thickness tears (100%). Agreement between CT and MRI on Goutallier grading of fatty infiltration of the RC muscle was substantial for supraspinatus (k=0.65), moderate for infraspinatus (k=0.5) and fair for subscapularis (k=0.38).*Conclusions 3-D MR is comparable to 3-D CT and can be used as alternative for preoperative assessment of glenoid wear in arthritic shoulders. CT is comparable to MRI for detection of full thickness tears, but MRI provides more detailed evaluation of RC integrity.*Clinical Relevance/Application 3-D MRI can be used in lieu of 3-D CT for the assessment of glenoid bone loss in preoperative planning of shoulder arthroplasty ???????and has the advantage of better assessing the soft tissue pathologies, including rotator cuff tears and muscle atrophy.

RESULTS

29 patients met the inclusion criteria. There were 5 A1, 7 A2, 8 B2 and 9 B3 glenoid morphology. The combined mean absolute difference in glenoid version between 3-D CT and 3-D MRI was 2.7°± 1.6° (range 0.15 to 7.85, P- value = 0.7). The combined mean absolute difference in glenoid inclination between 3-D CT and 3-D MR was 6.8° ± 4.1° (range 0.8° to 15.75°, P-value = 0.17). No significant inter-reader variation in glenoid version and inclination measurements on 3-D CT and 3-D MRI was found (P >0.05). The inter-reader reliability for both CT and MRI was strong and almost perfect for the Walch grading of glenoid bone loss (k= 1 k= 0.86, respectively). The accuracy of CT, compared to MRI, in determining any RC tear was excellent for full thickness tears (100%). Agreement between CT and MRI on Goutallier grading of fatty infiltration of the RC muscle was substantial for supraspinatus (k=0.65), moderate for infraspinatus (k=0.5) and fair for subscapularis (k=0.38).

CLINICAL RELEVANCE/APPLICATION

3-D MRI can be used in lieu of 3-D CT for the assessment of glenoid bone loss in preoperative planning of shoulder arthroplasty ???????and has the advantage of better assessing the soft tissue pathologies, including rotator cuff tears and muscle atrophy.

SSMK04-3   High-resolution Photon-counting Detector (PCD) CT Of Small Joints

Participants
Kishore Rajendran, PhD, Rochester, Minnesota (*Presenter*) Nothing to Disclose

PURPOSE

To demonstrate improved spatial resolution of wrist and ankle CT exams using high-resolution (HR), photon-counting detector (PCD) CT.*Methods and Materials Patients who underwent clinically-indicated wrist or ankle exams were scanned on conventional energy-integrating detector (EID) CT with a comb filter at 120 kV and using the non-comb-based HR mode of an investigational whole-body PCD-CT (SOMATOM Count Plus, Siemens Healthineers) at 120 kV. EID-CT images were reconstructed using routine clinical protocol (Ur70 or Ur73 kernel, iterative reconstruction [IR] strength 2, minimum slice thickness, 0.4 or 0.6 mm), and PCD-CT images were reconstructed using HR kernel (Br84), IR strength 3, 0.4 mm slice thickness. Two musculoskeletal (MSK) radiologists blindly evaluated randomized and paired EID-CT and PCD-CT images, comparing visualization of predetermined critical joint structures using a 5-pt Likert scale; images were randomly labeled as candidate and reference, with readers assigning scores to the candidate images in comparison to the reference (1-worse visualization, poor diagnostic confidence, 2-worse visualization, no change in diagnostic confidence, 3-comparable image quality and confidence, 4-improved image quality, no change in confidence, 5 - improved confidence and visualization). A post-hoc assignment of reader scores was performed so they reflected PCD-CT visualization relative to EID-CT. Wilcoxon rank sum test was used to evaluate the relative image quality of PCT-CT compared to EID-CT using the quality comparison scores for visualization.*Results 12 patients underwent wrist CT (EID-CT mean CTDIvol = 19 mGy; PCD-CT mean CTDIvol = 9.6 mGy), and 7 patients underwent ankle CT (EID-CT mean CTDIvol = 18 mGy; PCT-CT CTDIvol = 13.8 mGy). MSK radiologists graded PCD-CT images as significantly better than EID-CT for critical structure visualization and diagnostic confidence (p < 0.001) with a median score of 4 for both ankles and wrists. Intraarticular gas, subchondral fracture, trabecular architecture, cystic changes in scaphoid, and metatarsal pseudoarthrosis were better delineated on PCD-CT.*Conclusions Despite a 24-50% dose reduction, PCD-CT in UHR mode demonstrated significantly better visualization of critical structures of the wrists and ankles compared to conventional EID-CT.*Clinical Relevance/Application Using PCD-CT with dose-efficient UHR, patient radiation dose can be reduced by up to 50% while simultaneously improving the image quality and diagnostic confidence for imaging of small joints.

RESULTS

12 patients underwent wrist CT (EID-CT mean CTDIvol = 19 mGy; PCD-CT mean CTDIvol = 9.6 mGy), and 7 patients underwent ankle CT (EID-CT mean CTDIvol = 18 mGy; PCT-CT CTDIvol = 13.8 mGy). MSK radiologists graded PCD-CT images as significantly better than EID-CT for critical structure visualization and diagnostic confidence (p < 0.001) with a median score of 4 for both ankles and wrists. Intraarticular gas, subchondral fracture, trabecular architecture, cystic changes in scaphoid, and metatarsal pseudoarthrosis were better delineated on PCD-CT.

CLINICAL RELEVANCE/APPLICATION

Using PCD-CT with dose-efficient UHR, patient radiation dose can be reduced by up to 50% while simultaneously improving the image quality and diagnostic confidence for imaging of small joints.

SSMK04-4   Significant Variability Exists In Preoperative Planning Software Measures Of Glenoid Morphology For Shoulder Arthroplasty

Participants
Nicholas Laucis, MD, Westland, Michigan (*Presenter*) Nothing to Disclose

PURPOSE

Total shoulder arthroplasty (TSA) and reverse total shoulder arthroplasty (RTSA) are mainstays of definitive management of both degenerative and acute shoulder conditions. Glenoid component malpositioning in TSA and in RTSA have been shown to adversely affect both clinical and radiographic outcomes. Preoperative planning 3D imaging has become increasingly relied upon to improve component positioning in shoulder arthroplasty with multiple vendors offering shoulder arthroplasty planning software. We assessed the reliability of four shoulder arthroplasty 3D preoperative planning programs with comparison to manual measurements conducted by two fellowship-trained musculoskeletal radiologists.*Methods and Materials 76 CT scans of patients undergoing shoulder arthroplasty were separately analyzed for glenoid version and inclination by four software systems (VIP, Blueprint, TrueSight,

ExactechGPS). Inter-rater reliability (IRR) was assessed via intra-class correlation coefficient (ICC). For those shoulders with glenohumeral arthritis (58 of 76), ICC was also calculated when sub-grouping by modified Walch classification. Lin's concordance correlation coefficient (CCC) was calculated for each system with the radiologists' measurements.*Results IRR for the radiologists' measurements of glenoid version were excellent, 0.987 (95% CI: 0.966-0.995) and 0.937 (95% CI: 0.843-0.975). IRR for the radiologists' measurements of glenoid inclination were also excellent, 0.950 (95% CI: 0.840-0.982) and 0.966 (95% CI: 0.915-0.987). Measurements of glenoid version and inclination differed between at least two programs by 5º-10º in 75% and 92% of glenoids respectively, and by >10º in 18% and 45% respectively. ICC was excellent for version but only good for inclination. ICC was highest among Walch A glenoids for both version (near excellent) and inclination (good), and lowest among Walch D for version (near poor) and Walch B for inclination (moderate). For version, VIP had the highest concordance with radiologists' measurements; Blueprint had the lowest. For inclination, Blueprint had the highest concordance while ExactechGPS had the lowest.*Conclusions Significant variability in CT-based measures of glenoid version and inclination between four frequently utilized shoulder arthroplasty templating software worsens with glenoid deformity. Software concordance with radiologists' measurement is variable.*Clinical Relevance/Application Glenoid deformity had a strong influence on both version and inclination measurement reliability of the four software packages investigated. Further research is needed to understand how this variability should be accounted for during shoulder arthroplasty preoperative planning.

RESULTS

IRR for the radiologists' measurements of glenoid version were excellent, 0.987 (95% CI: 0.966-0.995) and 0.937 (95% CI: 0.843-0.975). IRR for the radiologists' measurements of glenoid inclination were also excellent, 0.950 (95% CI: 0.840-0.982) and 0.966 (95% CI: 0.915-0.987). Measurements of glenoid version and inclination differed between at least two programs by 5º-10º in 75% and 92% of glenoids respectively, and by >10º in 18% and 45% respectively. ICC was excellent for version but only good for inclination. ICC was highest among Walch A glenoids for both version (near excellent) and inclination (good), and lowest among Walch D for version (near poor) and Walch B for inclination (moderate). For version, VIP had the highest concordance with radiologists' measurements; Blueprint had the lowest. For inclination, Blueprint had the highest concordance while ExactechGPS had the lowest.

CLINICAL RELEVANCE/APPLICATION

Glenoid deformity had a strong influence on both version and inclination measurement reliability of the four software packages investigated. Further research is needed to understand how this variability should be accounted for during shoulder arthroplasty preoperative planning.

SSMK04-5   Physeal Stress Injuries Vs.Salter-harris Fractures:The Role Of The Perichondrium

Participants
Simukayi Mutasa, MD, Newport Beach, California (*Presenter*) Nothing to Disclose

PURPOSE

Differentiating physeal stress injuries (PSI) with Salter-Harris fractures (SHF) can sometimes be difficult. We propose that the perichondrium is an under-utilized differentiating marker and aim to determine whether or not it violated in SHFs versus PSIs.*Methods and Materials A retrospective study of MRI scans in patients with SHFs and PSIs was performed. 54 MRI scans were obtained in patients diagnosed with PSI (Top 3: 18 shoulders, 8 ankles, 8 elbows) and 35 in patients diagnosed with SHF (11 Knee, 10 Ankle, 3 wrist/elbow). 27 studies were excluded. After training on 20 examinations with a pediatric MSK specialist radiologist, the remaining cases were evaluated for discontinuity of the perichondrium by a PGY-VI Musculoskeletal radiology fellow (SM). Technical exclusion criteria included missing proton density, DESS, and/or T2 FSE sequences, or excessive motion artifact. Non-technical exclusion criteria involved no evidence of initial injury on subsequent second review by a pediatric MSK attending, imaging after physeal closure, and an imaging time period greater than 6 weeks after the inciting injury. Fisher exact test was used to calculate correlations between age, sex, and fracture class.*Results 0 of 35 remaining PSIs had evidence of perichondrial injury on imaging. 22 of 27 (82%) remaining SHFs had perichondrial breaks (Fisher's test p-value 0.00001). Of the SHFs age, sex, and Salter-Harris class were not significant predictors of the development of a perichondrial break (p = 0.16 In this study, the presence of perichondrium disruption is specific for the presence of a Salter-Harris fracture mechanism if a patient with an open physis at the joint of interest is imaged within 6 weeks. Conversely, an intact perichondrium on imaging does not preclude a Salter-Harris fracture mechanism. , 1.0, and 0.14 respectively).*Conclusions •Perichondrial disruption = specific for Salter-Harris fracture •Intact perichondrium does not preclude fracture. •Violation of the perichondrium may be used as a diagnostic criterion for differentiating Salter-Harris fractures from physeal stress injuries.*Clinical Relevance/Application Violation of the perichondrium may be used as a diagnostic criterion for differentiating Salter-Harris fractures from physeal stress injuries.

RESULTS

0 of 35 remaining PSIs had evidence of perichondrial injury on imaging. 22 of 27 (82%) remaining SHFs had perichondrial breaks (Fisher's test p-value 0.00001). Of the SHFs age, sex, and Salter-Harris class were not significant predictors of the development of a perichondrial break (p = 0.16 In this study, the presence of perichondrium disruption is specific for the presence of a Salter-Harris fracture mechanism if a patient with an open physis at the joint of interest is imaged within 6 weeks. Conversely, an intact perichondrium on imaging does not preclude a Salter-Harris fracture mechanism. , 1.0, and 0.14 respectively).

CLINICAL RELEVANCE/APPLICATION

Violation of the perichondrium may be used as a diagnostic criterion for differentiating Salter-Harris fractures from physeal stress injuries.

SSMK04-6   Articular Drop-down Lesions: Imaging Findings, And Ominous And Non-ominous Mimics

Participants
Alessandra Sax, MD, Philadelphia, Pennsylvania (*Presenter*) Nothing to Disclose

PURPOSE

Proximal humeral lesions are common, with benign subchondral and subentheseal processes predominating. However, occasionally lesions in this location are malignant, presenting a management challenge. We hypothesize that benign "articular drop-down" (ADD) lesions mimicking malignancy may represent imbibition of joint fluid into the humerus, with adjacent reactive change. Here, we delineated the imaging findings of such lesions and correlated them with pathology in order to provide guidance for this commonly encountered diagnostic dilemma.*Methods and Materials We retrospectively mined our PACS database for shoulder MRIs referred by the orthopedic oncology service for second-opinion interpretation of proximal humeral lesions. Images were reviewed by at least

two fellowship-trained musculoskeletal radiologists. Imaging features were documented (location, size, signal characteristics). We conducted a chart review for patient demographics and pathology results.*Results 20 MRI exams were reviewed in which ADD was offered as a leading diagnosis (average age 51; 9 female, 11 male). 80% of lesions were subarticular. 100% of the subarticular lesions were T2-hyperintense, T1-hypointense, with 80% showing adjacent curving fat (curved fat sign). 85% of the subarticular lesions were associated with arthritis or trauma. 16% of the subarticular lesions received direct MR arthrograms, with intra-osseous contrast extravasation from the joint into the lesion. 35% of patients received intravenous contrast, with varying degrees of enhancement. 35% of patients underwent needle biopsy. 25% of patients had a total shoulder replacement (for osteoarthritis). 86% of biopsy/resection specimens demonstrated trabeculated bone with reactive changes. None of the lesions in the subarticular location were malignant after biopsy/resection. 75% of non-subarticular lesions had completely non-aggressive imaging features and no biopsy was performed. One had imaging features of an aggressive chondroid lesion, and was subsequently a biopsy-proven chondrosarcoma that was resected.*Conclusions ADD lesions are common. We hypothesize this represents imbibition of synovial joint fluid into the proximal humerus, with reactive changes sometimes mimicking malignancy. We found that typical imaging features of these benign lesions include subarticular location with communication to the joint, T2-signal hyperintensity with varying degrees of enhancement, and the 'curved fat sign'. Our study provides clarification for the differential diagnosis and management of such lesions.*Clinical Relevance/Application By delineating the imaging findings of ADD lesions in the proximal humerus, we provide clarification to a commonly encountered diagnostic dilemma.

RESULTS

20 MRI exams were reviewed in which ADD was offered as a leading diagnosis (average age 51; 9 female, 11 male). 80% of lesions were subarticular. 100% of the subarticular lesions were T2-hyperintense, T1-hypointense, with 80% showing adjacent curving fat (curved fat sign). 85% of the subarticular lesions were associated with arthritis or trauma. 16% of the subarticular lesions received direct MR arthrograms, with intra-osseous contrast extravasation from the joint into the lesion. 35% of patients received intravenous contrast, with varying degrees of enhancement. 35% of patients underwent needle biopsy. 25% of patients had a total shoulder replacement (for osteoarthritis). 86% of biopsy/resection specimens demonstrated trabeculated bone with reactive changes. None of the lesions in the subarticular location were malignant after biopsy/resection. 75% of non-subarticular lesions had completely non-aggressive imaging features and no biopsy was performed. One had imaging features of an aggressive chondroid lesion, and was subsequently a biopsy-proven chondrosarcoma that was resected.

CLINICAL RELEVANCE/APPLICATION

By delineating the imaging findings of ADD lesions in the proximal humerus, we provide clarification to a commonly encountered diagnostic dilemma.

SPR-GU-1 **Using AI To Improve Image Processing Workflows For Clinical Practice Integration - Establishment Of An Automated CT Renal Donor Evaluation Protocol**

Participants
Timothy L. Kline, PhD, Rochester, Minnesota (*Presenter*) Nothing to Disclose

PURPOSE

The goal of this study was to implement and evaluate an efficient method to facilitate the development of an automated workflow for renal donor evaluation from contrast-enhanced CT images.*Methods and Materials A total of 374 historical contrast-enhanced CT images and corresponding segmentation masks were curated. This data was used to train a deep learning convolutional neural network architecture to automatically segment the kidneys and relevant vasculature structures. The data was split into training (80%), validation (10%), and a hold-out test set (10%). Model architectures including 2D, 2D slab (multi-slice), multi-orientation (i.e. axial, coronal, sagittal), and 3D models were tested. Visual (i.e. qualitative), and quantitative assessment was performed to optimize and finalize the model. After model development of the automated tool, a validation study was performed to assess workflow improvement and Radiologist qualitative assessments comparing the previous manual workflow with the automated workflow.*Results Excellent visual renderings were generated by the final model. The max, median, mean, and min Dice similarity were 0.95, 0.92, 0.91, and 0.63, respectively. The case with the lowest Dice had an error in the manual segmentation (only the enhanced cortex region was segmented, and thus was properly segmented by the automated approach). The next lowest Dice was 0.85. In the validation study, all cases evaluated were accepted as properly segmenting the kidneys and all relevant vascular structures. In the limited roll-out phase, the automated workflow significantly reduced the overall workflow process - original 11.8±2.0 min, AI 1.1±1.0 min. The two radiologist readers that were surveyed to perform a visual inspection of both segmentations did not report a significant difference between the original and AI-corrected workflows.*Conclusions The automated workflow reduced image analysis processing time from 10-20 min, to 1-2 min per case. Radiologist review did not show any significant differences between renderings and the workflow process was significantly favored for the automated approach.*Clinical Relevance/Application This study completed the full scope of an automated workflow - from data curation, model prototyping, and ultimately a clinical simulation. With ~1000 donor evaluations forecasted for the coming year at our institution alone; a time-savings of 250 technologist/Radiologist labor hours could come from this one analytic. Based on this success, this study will form the foundation for future studies evaluating the integration of automated workflows into the clinical practice.

RESULTS

Excellent visual renderings were generated by the final model. The max, median, mean, and min Dice similarity were 0.95, 0.92, 0.91, and 0.63, respectively. The case with the lowest Dice had an error in the manual segmentation (only the enhanced cortex region was segmented, and thus was properly segmented by the automated approach). The next lowest Dice was 0.85. In the validation study, all cases evaluated were accepted as properly segmenting the kidneys and all relevant vascular structures. In the limited roll-out phase, the automated workflow significantly reduced the overall workflow process - original 11.8±2.0 min, AI 1.1±1.0 min. The two radiologist readers that were surveyed to perform a visual inspection of both segmentations did not report a significant difference between the original and AI-corrected workflows.

CLINICAL RELEVANCE/APPLICATION

This study completed the full scope of an automated workflow - from data curation, model prototyping, and ultimately a clinical simulation. With ~1000 donor evaluations forecasted for the coming year at our institution alone; a time-savings of 250 technologist/Radiologist labor hours could come from this one analytic. Based on this success, this study will form the foundation for future studies evaluating the integration of automated workflows into the clinical practice.

SPR-GU-10 **Combination Of Quantitative Parameters And Vesical Imaging- Report And Data System In Predicting Muscle Invasion Of Bladder Cancer**

Participants
Hongyu Yin, Tai Zhou, China (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the applicantion value of quantitative MRI parameters combined with Vesical Imaging-Reporting and Data System (VI-RADS) in predicting muscle-invasive bladder cancer(MIBC).*Methods and Materials Seventy-four patients with pathologically proven bladder cancer in our hospital between May 2015 and May 2021(57 cases with non-muscle-invasive bladder cancer(NMIBC) and 17 cases with MIBC) were retrospectively analyzed. All patients who underwent multiparametric magnetic resonance imaging(mp-MRI)before transurethral resection of bladder tumor(TURBT) or radical cystectomy. According to the VI-RADS criteria,two radiologists,with 2 and 15 years of clinic experience,scored all mp-MRI examinations. The quantitative parameters of mp-MRI, including the tumor contact length(TCL) , maximum tumor diameter(Dmax) and TCL/Dmax were measured and calculated independently. Interobserver agreement was assessed by the weighted-kappa coefficient, intraclass correlation coefficient(ICC)and Bland Altman analysis. LASSO regression was used to select the quantitative parameters that were significant for distinguishing MIBC.Logistics regression analysis was used to determine the ability of VI-RADS,quantitative parameters,and VI-RADS combined

with quantitative parameter to predict MIBC.The receiver operating characteristic(ROC) analysis was applied to evaluate the diagnostic performance.*Results Interobserver agreement was strong for VI-RADS scores (K=0.780), and almost perfect in the measurement of quantitative parameters (ICC:0.806-0.960). LASSO regression was used to extract VI-RADS and TCL/Dmax that were most significant for predicting MIBC.ROC analysis showed that VI-RADS score 4 was found to be the best cut-off level in predicting MIBC (AUC=0.890 and 0.904),with the sensitivity of 64.71% and 76.47%, the specificity of 98.15% and 96.30%, respectively. TCL/Dmax=1.027 was found to be the best cut-off level,with the AUC of 0.835,the sensitivity of 94.12%,the specificity of 71.93%.The AUC of VI-RADS combined with TCL/Dmax was 0.979, with the sensitivity of 100.00% and the specificity of 92.98%,which was higher than that of VI-RADS or TCL/Dmax alone. The difference was statistically significant(P<0.05).For the patients with VI-RADS 3, when TCL/Dmax is applied in addition to VI-RADS, the accuracy increases from 80.0% to 92.0%.*Conclusions VI-RADS has good diagnostic performance and interobserver agreement, and the combination of quantitative parameters and VI-RADS performed decently in distinguishing MIBC.*Clinical Relevance/Application VI-RADS can be encouraged to be used in daily practice, and the combined use of VI-RADS with TCL/Dmax may be a better method for detecting MIBC, especially for patient with VI-RADS 3.

RESULTS

Interobserver agreement was strong for VI-RADS scores (K=0.780), and almost perfect in the measurement of quantitative parameters (ICC:0.806-0.960). LASSO regression was used to extract VI-RADS and TCL/Dmax that were most significant for predicting MIBC.ROC analysis showed that VI-RADS score 4 was found to be the best cut-off level in predicting MIBC (AUC=0.890 and 0.904),with the sensitivity of 64.71% and 76.47%, the specificity of 98.15% and 96.30%, respectively. TCL/Dmax=1.027 was found to be the best cut-off level,with the AUC of 0.835,the sensitivity of 94.12%,the specificity of 71.93%.The AUC of VI-RADS combined with TCL/Dmax was 0.979, with the sensitivity of 100.00% and the specificity of 92.98%,which was higher than that of VI-RADS or TCL/Dmax alone. The difference was statistically significant(P<0.05).For the patients with VI-RADS 3, when TCL/Dmax is applied in addition to VI-RADS, the accuracy increases from 80.0% to 92.0%.

CLINICAL RELEVANCE/APPLICATION

VI-RADS can be encouraged to be used in daily practice, and the combined use of VI-RADS with TCL/Dmax may be a better method for detecting MIBC, especially for patient with VI-RADS 3.

SPR-GU-11 Multi-center Evaluation Of The Multi-parametric MRI Clear Cell Renal Cell Carcinoma Likelihood Score (CCLS) For Assessment Of Clinical T1a (<4cm) Solid Renal Masses

Participants
Nicola Schieda, MD, Ottawa, Ontario (*Presenter*) Nothing to Disclose

PURPOSE

Small renal masses (SRMs, <4 cm) are common and represent a diverse group of benign and malignant tumors. Clear cell renal cell carcinoma (ccRCC) represents the most common and aggressive subtype. A ccRCC Likelihood Score (ccLS) system to diagnose ccRCC on multi-parametric magnetic resonance imaging (mpMRI) has been proposed but lacks external validation. We evaluated the diagnostic performance and inter-observer agreement of the ccLS system to diagnose ccRCC in solid SRMs at 5 academic medical centers.*Methods and Materials This IRB-approved, retrospective, multi-center, cross-sectional study included 241 patients with 250 consecutive solid (=25% volume enhances) SRMs examined with mpMRI at 5 academic medical centers. All masses were histologically confirmed by nephrectomy (N=177) or 18-gauge needle biopsy (N=73). Masses with macroscopic fat were excluded. After a 1.5-hour training session, two radiologists at each center, blinded to histologic diagnosis, independently applied the ccLS system to 50 masses. Diagnostic performance was calculated for diagnosis of ccRCC using random effects logistic regression modeling, and distribution of ccRCC by ccLS was tabulated. Inter-observer agreement for ccLS was evaluated with Fleiss Kappa.*Results Mean size was 25±8 mm (range 10-39 mm). ccRCC was found in 48% (119/250) and other histologies in 52% (131/250). Sensitivity, specificity and positive predictive value for diagnosis of ccRCC (95% confidence interval [CI]) when ccLS=4 were: 75% (68%, 81%), 78% (72%, 84%), and 76% (69%, 81%), respectively. Negative predictive value of ccLS=2 was 88% (81%, 93%). The proportion of ccRCC in each of the five ccLS scores (95% CI) were 6% (2%, 13%), 38% (18%, 62%), 32% (24%, 40%), 71% (72%, 79%), and 81% (73%, 88%). Average inter-observer agreement for ccLS scoring across sites was moderate (Kappa=0.58 [0.42, 0.75]).*Conclusions The clear cell likelihood scoring (ccLS) system applied to mpMRI has moderate inter-observer agreement, differentiates ccRCC from other solid renal masses with moderate sensitivity and specificity, and has a good negative predictive value for ccRCC.*Clinical Relevance/Application This study establishes the reproducibility of the ccLS system, which provides a framework for a standardized approach to the characterization of small renal masses with multiparametric magnetic resonance imaging.

RESULTS

Mean size was 25±8 mm (range 10-39 mm). ccRCC was found in 48% (119/250) and other histologies in 52% (131/250). Sensitivity, specificity and positive predictive value for diagnosis of ccRCC (95% confidence interval [CI]) when ccLS=4 were: 75% (68%, 81%), 78% (72%, 84%), and 76% (69%, 81%), respectively. Negative predictive value of ccLS=2 was 88% (81%, 93%). The proportion of ccRCC in each of the five ccLS scores (95% CI) were 6% (2%, 13%), 38% (18%, 62%), 32% (24%, 40%), 71% (72%, 79%), and 81% (73%, 88%). Average inter-observer agreement for ccLS scoring across sites was moderate (Kappa=0.58 [0.42, 0.75]).

CLINICAL RELEVANCE/APPLICATION

This study establishes the reproducibility of the ccLS system, which provides a framework for a standardized approach to the characterization of small renal masses with multiparametric magnetic resonance imaging.

SPR-GU-14 Application Value Of Individualized Tube Voltage Selection In Renal Computed Tomography Angiography Imaging Based On Body Mass Index With Low Iodine Intake

Participants
Junjun Li, Xi'an, China (*Presenter*) Nothing to Disclose

PURPOSE

To explore the application value of individualized kVp selection in Renal CTA based on body mass index (BMI) in reducing radiation dose and contrast medium (CM) dose.*Methods and Materials Totally 100 patients (BMI=30kg/m2) who underwent renal CTA were divided into individualized kVp group (group A, n=50) and conventional 100kVp group (group B, n=50), both with automatic tube current modulation (ATCM). Group A used a personalized protocol: 70kVp, ATCM for noise index (NI) setting of 18 ASIR-V at 80%

strength, and CM dose rate of 17mgI/kg/s for 10s for BMI<25kg/m2 patients; 80kVp, ATCM for NI of 17 ASIR-V at 70% strength, and CM dose rate of 19mgI/kg/s for 10s for 25kg/m2=BMI=30kg/m2 patients. Group B used the standard protocol: 100kVp, 50ml of 350 mgI/ml CM at the flow rate of 4.5 ml/s. The CT values and SD values of the right renal artery and left renal artery were measured to calculate the signal-to-noise ratio (SNR) and contrast-to-noise ratio (CNR). The image quality was subjectively scored by two experienced radiologists blindly using a five-point criterion. The CM dose and effective radiation dose in both groups were calculated and compared. Image quality between the two groups was also compared.*Results There was no significant difference in patient characteristics between the two groups (P>0.05). Compared to group B, group A significantly reduced effective radiation dose (in mSv) by 28.4% (2.07±0.92 vs. 2.89±0.62), CM dose by 27.2% (12.75g±2.19gI vs. 17.5gI), and injection rate (in ml/s) by 22.7% (3.48±0.64 vs. 4.5) (all P<0.001). The two groups had similar SD values in erector spinae (P>0.05). Group A had significantly higher CT values, SNR and CNR values of the renal arteries than group B (all P<0.001). The two radiologists had excellent agreement (Kappa value >0.8, P<0.05) in the subjective scores and there was no statistically significant difference in the subjective scores of renal CTA images between the two groups (4.57±0.42 vs. 4.41±0.49) (P>0.05).*Conclusions BMI-based individualized kVp selection protocol in renal CTA imaging significantly reduces radiation dose and total iodine intake while maintaining diagnostic image quality.*Clinical Relevance/Application BMI-based individualized kVp selection protocol in renal CTA imaging significantly reduces radiation dose and total iodine intake while maintaining diagnostic image quality and reduce the risk of contrast-induced nephropathy

RESULTS

There was no significant difference in patient characteristics between the two groups (P>0.05). Compared to group B, group A significantly reduced effective radiation dose (in mSv) by 28.4% (2.07±0.92 vs. 2.89±0.62), CM dose by 27.2% (12.75g±2.19gI vs. 17.5gI), and injection rate (in ml/s) by 22.7% (3.48±0.64 vs. 4.5) (all P<0.001). The two groups had similar SD values in erector spinae (P>0.05). Group A had significantly higher CT values, SNR and CNR values of the renal arteries than group B (all P<0.001). The two radiologists had excellent agreement (Kappa value >0.8, P<0.05) in the subjective scores and there was no statistically significant difference in the subjective scores of renal CTA images between the two groups (4.57±0.42 vs. 4.41±0.49) (P>0.05).

CLINICAL RELEVANCE/APPLICATION

BMI-based individualized kVp selection protocol in renal CTA imaging significantly reduces radiation dose and total iodine intake while maintaining diagnostic image quality and reduce the risk of contrast-induced nephropathy

SPR-GU-16 Primary Renal Sarcomas - Imaging Features And Discrimination From Non-sarcoma Renal Tumors

Participants
Johannes Uhlig, Goettingen, Germany (*Presenter*) Speaker, Bayer AG

PURPOSE

Primary renal sarcomas are rare renal malignancies carrying a dismal prognosis. This study assessed imaging features of primary renal sarcomas to discriminate this rare malignancy from more common non-sarcoma renal tumors.*Methods and Materials Adult patients diagnosed with primary renal sarcomas from 1995-2018 on cross-sectional imaging studies were included from 11 European centers. The non-sarcoma renal tumor cohort was randomly selected from one center and sized 4:1 compared to renal sarcomas. For both renal sarcomas and non-sarcoma renal tumors, CT and MRI studies were assessed using 21 predefined imaging features. For discrimination of renal sarcomas vs. non-sarcoma renal tumors, a random forest algorithm was trained based on demographics and imaging features. Diagnostic performance was evaluated using a 10-fold cross-validation approach.*Results n=34 renal sarcomas were included and compared to n=136 non-sarcoma renal tumors. Renal sarcomas manifested in younger patients (median 55 vs. 67 years, p<0.01) and were more complex (high RENAL score complexity 79.4% vs. 25.7%, p<0.01). Renal sarcomas were larger (median diameter 108 vs. 43mm, p<0.01) with irregular shape and ill-defined margins, and more frequently demonstrated invasion of the renal vein or inferior vena cava, tumor necrosis, direct invasion of adjacent organs, and contact to renal artery or vein, compared to non-sarcoma renal tumors (p<0.05, each). The random forest algorithm yielded a median area-under-the ROC curve AUC=93.8% to predict renal sarcoma histology, with sensitivity=90.4%, specificity=76.5%, and positive predictive value=93.9%.*Conclusions Renal sarcomas are rare tumors manifesting as large masses in young patients. A random forest algorithm using demographics and standardized imaging features shows excellent diagnostic accuracy for discrimination of renal sarcomas from non-sarcoma renal tumors and might aid in clinical decision making.*Clinical Relevance/Application Primary renal sarcomas present with specific imaging features, which can be used to discriminate them from non-sarcoma renal tumors. Given the dismal prognosis of renal sarcomas, a timely and accurate diagnosis could optimize treatment.

RESULTS

n=34 renal sarcomas were included and compared to n=136 non-sarcoma renal tumors. Renal sarcomas manifested in younger patients (median 55 vs. 67 years, p<0.01) and were more complex (high RENAL score complexity 79.4% vs. 25.7%, p<0.01). Renal sarcomas were larger (median diameter 108 vs. 43mm, p<0.01) with irregular shape and ill-defined margins, and more frequently demonstrated invasion of the renal vein or inferior vena cava, tumor necrosis, direct invasion of adjacent organs, and contact to renal artery or vein, compared to non-sarcoma renal tumors (p<0.05, each). The random forest algorithm yielded a median area-under-the ROC curve AUC=93.8% to predict renal sarcoma histology, with sensitivity=90.4%, specificity=76.5%, and positive predictive value=93.9%.

CLINICAL RELEVANCE/APPLICATION

Primary renal sarcomas present with specific imaging features, which can be used to discriminate them from non-sarcoma renal tumors. Given the dismal prognosis of renal sarcomas, a timely and accurate diagnosis could optimize treatment.

SPR-GU-17 Proportion Of Prostate Cancers Diagnosed By Systematic Template Biopsy After Negative Multiparametric MRI And Predictive Clinical Factors Which May Influence Detection

Participants
Mohammad Haroon, MD, Ottawa, Ontario (*Presenter*) Nothing to Disclose

PURPOSE

Biopsy deferral in men with a negative multiparametric MRI (mpMRI) is gaining popularity in clinical practice; however, prostate cancer (PCa) may be diagnosed at subsequent template biopsy in this population. This study evaluated the proportion of men with PCa diagnosis at template biopsy following a negative mpMRI.*Methods and Materials This IRB-approved, retrospective, single center, cross-sectional study identified 201 consecutive men with negative mpMRI (PI-RADS score 1 or 2) performed before TRUS-guided systematic template biopsy. Clinical indication for mpMRI was active surveillance (AS; 52.7% [106/201] or pre-biopsy for

elevated PSA/abnormal DRE (biopsy naïve 15.9% [32/201] and previous negative template biopsy 31.3% [63/201]). Proportion of men with clinically significant (CS) PCa (ISUP grade group =2) diagnosed at subsequent template biopsy were recorded. PSA and PSA density (PSAD) were compared between groups to derive clinically predictive factors of PCa.*Results Overall, 16.4% (33/201) men had CS-PCa diagnosed at template biopsy; 22.6% (24/106) in the AS group and 9.5% (9/95) in the pre-biopsy group (p=0.009). In the AS group, both PSA (p=0.96) and PSAD (p=0.92) did not differ between men with or without CS-PCa diagnosed at subsequent template biopsy. In the pre-biopsy group, PSA (p<0.01) and PSAD (p<0.01) were higher in men with eventual CS-PCa diagnosed at template biopsy, but otherwise did not differ in men with or without a preceding negative template biopsy (p=0.62). Area under the ROC curve for diagnosis of CS-PCa in the pre-biopsy group using PSA and PSAD were: 0.60 (95% CI 0.39,0.82) and 0.72 (0.53,0.92). The optimal cutpoint for PSAD derived by the method of Youden was =0.21 with sensitivity and specificity of 67% and 71% respectively. Using a published cutpoint of =0.15 yielded sensitivity and specificity of 78% and 45% respectively.*Conclusions Clinically significant prostate cancer detection rates in men with negative mpMRI differs by clinical indication and in our study was approximately 25% in men undergoing active surveillance and 10% in men with pre-biopsy MRI. PSAD was not useful to predict eventual CS-PCa diagnosis in the AS group but was useful in the pre-biopsy group, with an optimal cutpoint of 0.21 yielding moderate accuracy for diagnosis of CS-PCa at subsequent template biopsy.*Clinical Relevance/Application Biopsy deferral after negative mpMRI should be considered separately for men referred for pre-biopsy evaluation versus active surveillance. PSAD may be a useful clinical metric to determine which men with negative pre-biopsy MRI should undergo template biopsy.

RESULTS

Overall, 16.4% (33/201) men had CS-PCa diagnosed at template biopsy; 22.6% (24/106) in the AS group and 9.5% (9/95) in the pre-biopsy group (p=0.009). In the AS group, both PSA (p=0.96) and PSAD (p=0.92) did not differ between men with or without CS-PCa diagnosed at subsequent template biopsy. In the pre-biopsy group, PSA (p<0.01) and PSAD (p<0.01) were higher in men with eventual CS-PCa diagnosed at template biopsy, but otherwise did not differ in men with or without a preceding negative template biopsy (p=0.62). Area under the ROC curve for diagnosis of CS-PCa in the pre-biopsy group using PSA and PSAD were: 0.60 (95% CI 0.39,0.82) and 0.72 (0.53,0.92). The optimal cutpoint for PSAD derived by the method of Youden was =0.21 with sensitivity and specificity of 67% and 71% respectively. Using a published cutpoint of =0.15 yielded sensitivity and specificity of 78% and 45% respectively.

CLINICAL RELEVANCE/APPLICATION

Biopsy deferral after negative mpMRI should be considered separately for men referred for pre-biopsy evaluation versus active surveillance. PSAD may be a useful clinical metric to determine which men with negative pre-biopsy MRI should undergo template biopsy.

SPR-GU-18 Computer-aided Diagnosis Of Prostate Cancer: External Validation Study Of Deep Learning Using Convolutional Neural Networks

Participants
Sung Bin Park, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

The accurate detection of prostate cancer is an interesting but still challenging task. Multiparametric MRI is the essential method for diagnosing prostate cancer. Over the past two decades, computer-aided diagnosis (CAD) has been a rapidly growing and active area of research. The purpose of this study is to evaluate the performance of a CAD algorithm for identifying prostate cancer in multiparametric MRI.*Methods and Materials The prototype CAD algorithm using convolutional neural network has been developed with 1,500 cases data set for training and test with 5-fold cross validation method (4 training and 1 validation sequentially). This CAD algorithm performed auto segmentation of prostate gland and detection of prostate cancer. Then it merged to show result visualization as probability map for prostate cancer. The diagnostic performance of CAD algorithm for identifying prostate cancer from MRI was performed. 352 external validated multiparametric MRIs (T2-weighted, diffusion-weighted and apparent diffusion coefficient images, b value of 0, and 1000 s/mm2) at two institutions were enrolled for this study. All data were acquired on 3T MRI scanners with pelvic phased-array coils. Using pathologic diagnosis after radical prostatectomy whole mount specimen as gold standard or ground truth, the diagnostic performance of CAD algorithm using convolutional neural network for prostate cancer was evaluated. The prostate gland was arbitrary divided into three levels such as apex, mid gland and base. Each level was also divided into 4 areas (two peripheral zones and two transitional zones). In total, 4,224 areas in 352 patients were compared with pathology in a point-by-point manner.*Results The diagnostic performance of all prostate gland was a sensitivity of 71.1%, specificity of 82.1%, positive predictive value of 73.1%, negative predictive value of 80.6%, and accuracy of 77.7%. *Conclusions CAD algorithm in multiparametric prostate MRI using convolutional neural network can have compatible diagnostic performance for prostate cancer. Comprehensive further studies for different experienced radiologists to evaluate the performance with/without CAD algorithm are needed.*Clinical Relevance/Application In view of its compatible performance, we believe CAD algorithm in multiparametric MRI using convolutional neural network can be used as a useful supplementary tool in patients with suspicious of prostate cancer.

RESULTS

The diagnostic performance of all prostate gland was a sensitivity of 71.1%, specificity of 82.1%, positive predictive value of 73.1%, negative predictive value of 80.6%, and accuracy of 77.7%.

CLINICAL RELEVANCE/APPLICATION

In view of its compatible performance, we believe CAD algorithm in multiparametric MRI using convolutional neural network can be used as a useful supplementary tool in patients with suspicious of prostate cancer.

SPR-GU-19 Bladder Pressure Estimation Using Subharmonic Signal Scattered By Ultrasound Contrast Agents

Participants
Kourosh Kalayeh, PhD, Ann Arbor, Michigan (*Presenter*) Equipment Support, GE Healthcare

PURPOSE

Cystometrograms (CMG) evaluate the functionality of the bladder. The CMG catheter is inserted into the bladder through the urethra and fills the bladder with saline while recording its pressure. The presence of the catheter partially or completely occludes the urethra resulting in an increase in flow resistance and falsely elevated bladder pressures. This highlights the need for catheter-free bladder pressure measurements, specifically during voiding. The purpose of this study is, therefore, to use pressure sensitive

subharmonic signal scattered by ultrasound contrast agents (UCAs) to estimate benchtop bladder phantom (BBP) pressures-a method known as subharmonic aided pressure estimation (SHAPE).*Methods and Materials A bladder phantom is designed and built, capable of simulating clinically relevant bladder pressure tracings of variable compliance and non-voiding contractions. Definity® (Lantheus Medical Imaging, Billerica, MA, USA) commercial UCA is diluted in 0.9 % normal saline at an optimized concentration of 0.06 % v/v and infused using CMG equipment (30 ml/min). Simultaneously, UCA scattered subharmonic signal is acquired with a GE Logiq E10 ultrasound scanner equipped with SHAPE mode using a C2-9 probe. The ultrasound transmit output is set at a calibrated mechanical index (MI) for maximum ambient pressure sensitivity. The UCA concentration had been optimized to compensate for bubble destruction due the infusion system. All experiments are done in a water tank at room temperature. A TPX sheet (2 mm thickness) is used as an acoustic window as it has an acoustic impedance close to water and minimal attenuation.*Results The subharmonic signal shows an inverse relationship with BBP pressure, as the pressure increases the subharmonic signal amplitude decreases. The change in subharmonic signal varies linearly with BBP pressure with correlation factor of -0.057 dB/cmH2O (n=30, R2=0.73, RMSE=1.017 dB).*Conclusions A strong correlation is found to exist between UCA scattered subharmonic signal and BBP pressure. These findings provide the support to evaluate this method in vivo and take the next step towards developing a catheter-free voiding bladder pressure measurement using SHAPE.*Clinical Relevance/Application This work aims at developing a methodology for catheter-free voiding bladder pressure measurement. By doing so, bladder voiding pressure can be estimated more accurately under more natural conditions which in turn results in better assessment of bladder functionality.

RESULTS

The subharmonic signal shows an inverse relationship with BBP pressure, as the pressure increases the subharmonic signal amplitude decreases. The change in subharmonic signal varies linearly with BBP pressure with correlation factor of -0.057 dB/cmH2O (n=30, R2=0.73, RMSE=1.017 dB).

CLINICAL RELEVANCE/APPLICATION

This work aims at developing a methodology for catheter-free voiding bladder pressure measurement. By doing so, bladder voiding pressure can be estimated more accurately under more natural conditions which in turn results in better assessment of bladder functionality.

SPR-GU-2   Defining Diagnostic Criteria For Ductal Adenocarcinoma Of Prostate On Multi-parametric Magnetic Resonance Imaging

Participants
Weranja Ranasinghe, Houston, Texas (*Presenter*) Nothing to Disclose

PURPOSE

To develop mpMRI criteria to define DACs and assess its diagnostic performance.*Methods and Materials Men with histologically proven DAC who had mpMRIs before radical prostatectomy (RP) were retrospectively identified from 2011-18. mpMRI diagnostic criteria were defined and used to compare men with =1cm in the peripheral zone DAC with the International Society of Urological Pathology (ISUP) grade group (GG) 4-5 PAC on biopsy, who underwent RP during the same time period and were matched 1:1 on tumor size on MRI and tumor location. Four radiologists, blinded to the diagnoses, separately scored the mpMRIs in consensus. STARD criteria were used to report diagnostic performance. Chi-Squared, T-tests, Mann-Whitney-U tests, Cohen's Kappa, and sensitivity analyses were performed.*Results Fifty-nine men with DAC (median age 63 (IQR 56,67) and 59 matched men with PAC (median age 64 (IQR 59,69) were compared to determine the presence of predefined mpMRI criteria: 1) intermediate T2 signal, 2) well-defined margin 3) lobulations and 4) hypointense rim.On the consensus read, =3 mpMRI features were detected in a higher proportion of DACs compared with PACs (76% vs. 12%, p<.001).If =3 features were present, then the features demonstrated 76% sensitivity, 88% specificity, 87% positive predictive value (PPV), and 79% negative predictive value (NPV) in diagnosing PCa with a DAC component and 100% sensitivity, 88% specificity, 65% PPV and 100% NPV in pure DAC.All DACs had restricted diffusion and contrast enhancement (p=1) but no differences in absolute or relative T2 signal intensity (p=.09) or ADC values compared with PACs (p=.73).*Conclusions DAC can be differentiated from PAC using =3 characteristic features with restricted diffusion and contrast enhancement on prostatic mpMRI.*Clinical Relevance/Application Ductal prostate adenocarcinoma (DAC) is an aggressive histologic variant of prostate cancer (PCa). However, DACs are often underappreciated on clinical exam, not detected on prostate biopsy, and currently cannot be characterized on multiparametric (MP) MRI. Based on our results, ductal prostate cancers can be characterized on MRI by the presence of =3 features (intermediate T2 signal, well-defined margin, lobulations, and intermittent, hypointense peripheral rim) with restricted diffusion and contrast enhancement.

RESULTS

Fifty-nine men with DAC (median age 63 (IQR 56,67) and 59 matched men with PAC (median age 64 (IQR 59,69) were compared to determine the presence of predefined mpMRI criteria: 1) intermediate T2 signal, 2) well-defined margin 3) lobulations and 4) hypointense rim.On the consensus read, =3 mpMRI features were detected in a higher proportion of DACs compared with PACs (76% vs. 12%, p<.001).If =3 features were present, then the features demonstrated 76% sensitivity, 88% specificity, 87% positive predictive value (PPV), and 79% negative predictive value (NPV) in diagnosing PCa with a DAC component and 100% sensitivity, 88% specificity, 65% PPV and 100% NPV in pure DAC.All DACs had restricted diffusion and contrast enhancement (p=1) but no differences in absolute or relative T2 signal intensity (p=.09) or ADC values compared with PACs (p=.73).

CLINICAL RELEVANCE/APPLICATION

Ductal prostate adenocarcinoma (DAC) is an aggressive histologic variant of prostate cancer (PCa). However, DACs are often underappreciated on clinical exam, not detected on prostate biopsy, and currently cannot be characterized on multiparametric (MP) MRI. Based on our results, ductal prostate cancers can be characterized on MRI by the presence of =3 features (intermediate T2 signal, well-defined margin, lobulations, and intermittent, hypointense peripheral rim) with restricted diffusion and contrast enhancement.

SPR-GU-20   Teaching A Machine To Find Adrenal Glands: Novel Machine Learning Model For Adrenal Gland Segmentation And Mass Classification On CT

Participants
Cory Robinson Weiss, MD, Boston, Massachusetts (*Presenter*) Nothing to Disclose

PURPOSE

To develop a fully-automated machine learning model that can reliably segment and classify normal adrenal glands and adrenal masses on abdominal CT.*Methods and Materials The cohort consisted of 265 contrast-enhanced CT exams containing 421 normal

adrenal glands and 109 adrenal masses (63 left and 46 right). Of the 109 adrenal masses, 67 (61%) measured 1-2 cm, 32 (29%) measured 2-4 cm, and 10 (9%) measured >4 cm. There were 127 males and 138 females with mean age 60 years (range 21-93 years). All exams were reviewed by one of five radiologists and adrenal glands were classified as normal or containing a mass. Adrenal glands were manually outlined utilizing commercially available software (Visage Imaging, Berlin, Germany) to create labeled segmentations serving as the "ground truth." Ten randomly selected exams were reviewed by all 5 radiologists to determine interobserver variability. The cohort was divided into an initial training set of 214 exams with the subsequent validation and testing sets of 26 and 25 exams respectively. A two-stage machine-learning based pipeline was developed and validated. The first stage performed segmentation of the adrenal glands in the full portal venous phase contrast enhanced abdominal CT series using an ensemble of 3D UNet convolutional neural networks (CNN). In the second stage, volumetric regions of interest around each of the two adrenal glands were extracted and classified by an ensemble of 3D DenseNet CNNs as adrenal masses or normal glands. Primary outcome was the classification of adrenal masses based on radiologists' annotations. Segmentation and classification performance was evaluated by the Dice similarity coefficient which compares the degree of overlap between the radiologist's ground truth manual segmentation and model predicted segmentation.*Results In 45 of 49 (92%) of adrenal glands in the test set, the model was able to accurately outline the adrenal glands and correctly classify the adrenal as normal or containing a mass. Median radiologist inter-observer Dice scores were .884 and .890 for normal and adrenal masses respectively. Median model Dice scores on the same dataset were .806 and .845, showing close to expert segmentation performance.*Conclusions A novel machine learning-based model successfully (92%) segmented adrenal glands and classified them as normal or containing a mass on abdominal CT with performance comparable to radiologists.*Clinical Relevance/Application A machine learning tool can help identify adrenal masses which are present in 5-7% of the adult population. This can facilitate radiologist exam interpretation and potentially decrease interobserver variability.

RESULTS

In 45 of 49 (92%) of adrenal glands in the test set, the model was able to accurately outline the adrenal glands and correctly classify the adrenal as normal or containing a mass. Median radiologist inter-observer Dice scores were .884 and .890 for normal and adrenal masses respectively. Median model Dice scores on the same dataset were .806 and .845, showing close to expert segmentation performance.

CLINICAL RELEVANCE/APPLICATION

A machine learning tool can help identify adrenal masses which are present in 5-7% of the adult population. This can facilitate radiologist exam interpretation and potentially decrease interobserver variability.

SPR-GU-3   Clinical Utility Of Renal Ultrasound In COVID-19 Patients With Acute Kidney Injury - Worth The Risk? An Evaluation Of 108 Consecutive Inpatients

Participants
Hanisha Patel, MD, New York, New York (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the clinical utility of renal ultrasound (US) in hospitalized COVID-19 patients with acute kidney injury and absence of other clinical symptoms of urinary obstruction.*Methods and Materials Keyword search of the electronic imaging database was performed for all adult patients with renal US between 12/1/2020 - 2/28/2021. Inclusion criteria included inpatient status, active COVID-19 infection at the time of imaging, acute kidney injury (=50% creatinine increase from baseline (if available), GFR decrease by =25%, and/or urine output below 0.5 mL/kg/hr for > 6 hours), and absence of other genitourinary symptoms (hematuria, flank pain, etc) that may prompt renal imaging. Patient demographics, medical history, clinical course, and renal US findings were recorded.*Results Keyword search resulted in a total of 661 patients, with the final cohort consisting of 108 consecutive inpatients (64M, 44F, mean age 68.1 ± 15.1 years) with 117 renal US meeting inclusion criteria. Renal US were performed on day 1 to day 38 (median 4 days, mean 7.5 ± 7.3 days) of hospitalization. Average serum creatinine at imaging was 2.90 ± 1.95 mg/dL, with baseline of 1.56 ± 1.08 mg/dL. Findings included echogenic parenchyma in 35.9% (42/117) of studies, renal atrophy in 6% (7/117), and renal stones in 4.3% (5/117). Hydronephrosis was seen in 5.1% (6/117), chronic in 3 cases, resolved in 2 cases with no intervention, and improved with Foley catheter flushing in one case. No patients required emergent stent placement. One renal biopsy was performed for nephrotic range proteinuria, with pathology of focal segmental glomerulosclerosis. There were no significant differences in demographics, medical history, or renal US findings in deceased patients (44/108, 40.7%) vs. patients that were discharged from the hospital (64/108, 59.3%). Deceased patients were significantly more likely to be in the ICU (p=<.001), intubated (p=<.007), and require dialysis (p=<.001). Mean serum creatinine at the time of renal US was higher for decreased patients compared to patients discharged from the hospital, though it was not significant (3.18 mg/dL vs. 2.67 mg/dL, p=.137).*Conclusions No emergent urological intervention was required in this cohort of inpatients hospitalized with active COVID-19 infection, AKI, and no other genitourinary signs or symptoms undergoing renal US. Given the low yield/clinical utility of renal US in this patient population, it should be reconsidered unless other genitourinary symptoms exist.*Clinical Relevance/Application Routine renal US in COVID-19 patients with AKI (but no other genitourinary signs or symptoms) should be reconsidered, as it may risk additional staff exposure (US technologists) to COVID-19 while adding little to no clinical utility.

RESULTS

Keyword search resulted in a total of 661 patients, with the final cohort consisting of 108 consecutive inpatients (64M, 44F, mean age 68.1 ± 15.1 years) with 117 renal US meeting inclusion criteria. Renal US were performed on day 1 to day 38 (median 4 days, mean 7.5 ± 7.3 days) of hospitalization. Average serum creatinine at imaging was 2.90 ± 1.95 mg/dL, with baseline of 1.56 ± 1.08 mg/dL. Findings included echogenic parenchyma in 35.9% (42/117) of studies, renal atrophy in 6% (7/117), and renal stones in 4.3% (5/117). Hydronephrosis was seen in 5.1% (6/117), chronic in 3 cases, resolved in 2 cases with no intervention, and improved with Foley catheter flushing in one case. No patients required emergent stent placement. One renal biopsy was performed for nephrotic range proteinuria, with pathology of focal segmental glomerulosclerosis. There were no significant differences in demographics, medical history, or renal US findings in deceased patients (44/108, 40.7%) vs. patients that were discharged from the hospital (64/108, 59.3%). Deceased patients were significantly more likely to be in the ICU (p=<.001), intubated (p=<.007), and require dialysis (p=<.001). Mean serum creatinine at the time of renal US was higher for decreased patients compared to patients discharged from the hospital, though it was not significant (3.18 mg/dL vs. 2.67 mg/dL, p=.137).

CLINICAL RELEVANCE/APPLICATION

Routine renal US in COVID-19 patients with AKI (but no other genitourinary signs or symptoms) should be reconsidered, as it may risk additional staff exposure (US technologists) to COVID-19 while adding little to no clinical utility.

SPR-GU-5   Assessment Of Elastographic Q-analysis Score Combined With PI-RADS Based On TRUS/MP-MRI

Fusion-guided Biopsy In Differentiating Benign And Malignant Prostate

Participants
Hongtian Tian, Shenzhen, China (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate Elastographic Q-Analysis Score(EQS) combined with PI-RADS based on rectal ultrasound (TRUS)/multiparametric MRI fusion biopsy in differentiating benign and malignant prostate lesions.*Methods and Materials A total of 296 patients with 318 prostate lesions who underwent TRUS/MP-MRI fusion biopsy between October 2017 and October 2019 at our hospital were retrospectively analyzed. The performance of the EQS was evaluated on the sites of the suspicious areas of MP-MRI.The cut-off value of EQS was obtained according to ROC curve, which was used to upgrade and downgrade the PI-RADS scores. The diagnostic efficacy of new PI-RADS was calculated based on pathological results and chi-square test.*Results In total, 318 MP-MRI suspicious prostate lesions, 94 lesions were confirmed as prostate cancer, and the rest were benign prostate lesions. The diagnostic coincidence rate of PIRADS was increased from 0.667 to 0.874 by using elastic ultrasound, among which the diagnostic rate of prostate cancer was increased from 0.557 to 0.806, and the diagnostic rate of non-prostate cancer was increased from 0.775 to 0.967.*Conclusions The TRUS/MP-MRI fusion-based combination of the EQS and the PI-RADS could improve the efficiency of differentiating malignant and benign prostate lesions.*Clinical Relevance/Application The combination of the PI-RADS and the EQS with TRUS/MP-MRI fusion can not only improve the accuracy of PCa diagnosis and the detection rate of clinically significant cancer but also reduce unnecessary biopsy procedures and prevent overdiagnosis.

RESULTS

In total, 318 MP-MRI suspicious prostate lesions, 94 lesions were confirmed as prostate cancer, and the rest were benign prostate lesions. The diagnostic coincidence rate of PIRADS was increased from 0.667 to 0.874 by using elastic ultrasound, among which the diagnostic rate of prostate cancer was increased from 0.557 to 0.806, and the diagnostic rate of non-prostate cancer was increased from 0.775 to 0.967.

CLINICAL RELEVANCE/APPLICATION

The combination of the PI-RADS and the EQS with TRUS/MP-MRI fusion can not only improve the accuracy of PCa diagnosis and the detection rate of clinically significant cancer but also reduce unnecessary biopsy procedures and prevent overdiagnosis.

SPR-GU-6   Diagnostic Performance Of Prostate 3t-multiparametric Magnetic Resonance Imaging In Different Race: Based On Pi-radsv2.1 And Using Whole-mount Histopathology Reference

Participants
Qi Miao, MD, Shenyang, China (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the relative performance of 3T-multiparametric Magnetic Resonance Imaging (3T-mpMRI) for the detection of clinically significant prostate cancer (csPCa) foci in African-, Asian- and European- American men with whole-mount histopathology (WMHP) reference.*Methods and Materials This IRB approved, HIPAA compliant observational study cohort comprised 556 patients, who underwent 3T-mpMRI prior to prostatectomy from July 2010 to December 2020. Patients were categorized into 3 different subcohorts stratified by race (African-, Asian- and European-American). The sub-analysis was performed using a propensity score caliper matching algorithm to match Asian to White and African to White in a 1:2 ratio using the variables age and PSA. The prostate cancer detection rate (CDR) and positive predicted value (PPV) of PCa, csPCa were compared in groups using Chi-square test or Fisher's Exact test.*Results Of the 556 men, 41 (7%), 40 (7%) and 475 (86%) were African-, Asian- and European- origin men, respectively. In unmatched analysis, the CDR csPCa of African, Asian and European subgroups were 66%, 73% and 71% (p=0.767). In matched analysis, CDRcsPCa of African, and European- origin subcohorts were 66% and 77%, (p=0.162) and CDRcsPCa of Asian and European subcohorts was 73% and 64%, (p=0.280). In matched analysis, PPVscsPCa of African and European-origin were 67% and 87% (p=0.324). The PPVscsPCa of Asian and European-origin subgroup were 79% and 71% (p=0.325).*Conclusions 3T mpMRI has good performance for the detection of csPCa among African, Asian and European-origin subgroups, but the CDR csPCa and PPV csPCa of African origin subcohort were lower than the Asian and European subcohorts.*Clinical Relevance/Application For African origin men the performance of 3TmpMRI for clinically suspected csPCa, may require additional modifications to improve performance.

RESULTS

Of the 556 men, 41 (7%), 40 (7%) and 475 (86%) were African-, Asian- and European- origin men, respectively. In unmatched analysis, the CDR csPCa of African, Asian and European subgroups were 66%, 73% and 71% (p=0.767). In matched analysis, CDRcsPCa of African, and European- origin subcohorts were 66% and 77%, (p=0.162) and CDRcsPCa of Asian and European subcohorts was 73% and 64%, (p=0.280). In matched analysis, PPVscsPCa of African and European-origin were 67% and 87% (p=0.324). The PPVscsPCa of Asian and European-origin subgroup were 79% and 71% (p=0.325).

CLINICAL RELEVANCE/APPLICATION

For African origin men the performance of 3TmpMRI for clinically suspected csPCa, may require additional modifications to improve performance.

SPR-GU-8   Augmenting AI With Automated Segmentation Of Report Findings Applied To Prostate Cancer Detection In Biparametric MRI

Participants
Joeran Bosma, BSC, Nijmegen, Netherlands (*Presenter*) Nothing to Disclose

PURPOSE

To improve risk stratification of clinically significant prostate cancer (csPCa) with a 3D deep learning detection model, by augmenting the largest prostate MRI dataset reported in literature to date.*Methods and Materials This retrospective study included 6,866 prostate bpMRI studies (axial T2-weighted, high b-value (= 1400) and apparent diffusion coefficient scans) from 5,646 consecutive patients, with elevated PSA or clinical suspicion of PCa, between 2014-2020 for training. All studies were evaluated by experienced radiologists during clinical routine. The findings in 2,659 studies were manually segmented.We propose a hybrid framework to augment our detection model with more training data. After training with expert csPCa segmentations, we

generate automatic cancer segmentations by masking our model predictions with the number of csPCa lesions automatically extracted from radiology reports. An augmented detection model is then trained jointly on manual and automatically generated csPCa segmentations.Models trained on expert or augmented cancer segmentations are evaluated on 296 visits of 296 consecutive men with elevated PSA or clinical suspicion of prostate cancer from an independent, external, centre. Ground truth is provided by MR-guided and TRUS-guided biopsies, and radical prostatectomy when available. Studies are considered positive if they have at least one Gleason grade group = 2 lesion (csPCa).We trained our models on expert and augmented segmentations with 5-fold cross-validation and 5 restarts. Diagnostic performance was evaluated using the Area under the Receiver Operating Characteristic curve (AUROC). We performed a permutation test to obtain the statistical significance level.*Results Augmenting the training set with automatic csPCa segmentations guided by report findings, significantly improves the case-level risk stratification of csPCa. For the external test set, the AUROC increased from 85.7±2.5% to 89.0±1.2% (P < 0.0001).On the external test set, experienced radiologists had a sensitivity of 91.4±2.7% at 78.3±2.4% specificity. At the same sensitivity, adding automatic segmentations improved the model's specificity from 46.8±12.8% to 62.0±7.1% (P < 0.0001).*Conclusions Augmenting training with automatic report driven segmentations of prostate cancer in bpMRI significantly improved the risk-stratification of the deep learning prostate cancer detection model.*Clinical Relevance/Application Risk stratification for clinically significant prostate cancer using prostate MRI is instrumental to reduce over-treatment. Deep learning can assist, but requires expensive expert segmentations.

RESULTS

Augmenting the training set with automatic csPCa segmentations guided by report findings, significantly improves the case-level risk stratification of csPCa. For the external test set, the AUROC increased from 85.7±2.5% to 89.0±1.2% (P < 0.0001).On the external test set, experienced radiologists had a sensitivity of 91.4±2.7% at 78.3±2.4% specificity. At the same sensitivity, adding automatic segmentations improved the model's specificity from 46.8±12.8% to 62.0±7.1% (P < 0.0001).

CLINICAL RELEVANCE/APPLICATION

Risk stratification for clinically significant prostate cancer using prostate MRI is instrumental to reduce over-treatment. Deep learning can assist, but requires expensive expert segmentations.

SPR-NMMI-12   **Evaluation Of Baseline Tumor Burden As Response Predictor For Lymphoma Patients Undergoing CAR T-Cell Therapy**

Participants
Michael Winkelmann, Munich, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Chimeric antigen receptor (CAR) T-cell therapy with patient-derived T cells against tumor cells are approved for relapsed or refractory (r/r) diffuse large B-cell lymphoma (DLBCL). In some of the clinical trials for FDA approval, extensive tumor burden was associated with poor survival. We re-assessed the impact of tumor burden before transfusion on response at 3 months, progression-free (PFS) and overall survival (OS).*Methods and Materials Consecutive r/r DLBCL patients with CT imaging at baseline (BL) and CT or PET/CT at 3 months (follow-up; FU) after CAR T-cell transfusion were selected. For all patients, up to 6 target lesions were 3D-segmented using MintLesion at both time points. The sum of target lesion volume (STLV) was used to represent tumor burden (TB). Moreover, SUVmax and Deauville score were calculated for patients with FU PET/CT imaging. The prognostic value of BL-TB was evaluated for complete metabolic response (CMR)/ Deauville Score in FU PET/CT and for stratification of PFS and OS.*Results 28 patients were included (median age: 64 years, 57% male) with median baseline STLV of 88.3 ml and mean baseline STLV of 189 ml. Both median and mean STLV at baseline did not significantly stratify PFS (Figure 1A+B) or OS (Figure 1C+D). For 23 patients with FU PET/CT imaging, PET parameters were analyzed with a median SUVmax of 4.3. 14 patients showed CMR (Deauville score 1-3) and 9 patients had no CMR (Deauville score 4+5). There was no significant difference in distribution of BL-TB and Deauville score at FU (Figure 2). BL-TB showed no significant correlation with FU-TB (Figure 3A; r=0.21, p=0.29) or FU-SUVmax (Figure 3B; r=-0.08, p=0.73).*Conclusions In this post-marketing study, tumor burden at baseline had only limited prognostic value regarding response at 3 months, PFS or OS. Our data indicate that clinical patient selection for CAR T cell treatment should therefore not exclude patients solely based on extensive tumor burden. Future studies should explore the prognostic value of other baseline imaging markers.*Clinical Relevance/Application CAR T-cell therapy has emerged as a new effective antigen-driven cell-based immunotherapy to treat patients with DLBCL. Identifying prognostic parameters at baseline is crucial for patient selection.

RESULTS

28 patients were included (median age: 64 years, 57% male) with median baseline STLV of 88.3 ml and mean baseline STLV of 189 ml. Both median and mean STLV at baseline did not significantly stratify PFS (Figure 1A+B) or OS (Figure 1C+D). For 23 patients with FU PET/CT imaging, PET parameters were analyzed with a median SUVmax of 4.3. 14 patients showed CMR (Deauville score 1-3) and 9 patients had no CMR (Deauville score 4+5). There was no significant difference in distribution of BL-TB and Deauville score at FU (Figure 2). BL-TB showed no significant correlation with FU-TB (Figure 3A; r=0.21, p=0.29) or FU-SUVmax (Figure 3B; r=-0.08, p=0.73).

CLINICAL RELEVANCE/APPLICATION

CAR T-cell therapy has emerged as a new effective antigen-driven cell-based immunotherapy to treat patients with DLBCL. Identifying prognostic parameters at baseline is crucial for patient selection.

SPR-NMMI-13   **Ga-68 FAPI Imaging Versus FDG-PET Imaging In Hepatocellular Carcinoma**

Participants
Vineel Inampudi I, MD, Vijayawada, India (*Presenter*) Nothing to Disclose

PURPOSE

This study aims to assess the diagnostic accuracy of FDG PET-CT assessment of Hepatocellular Carcinoma and the benefit of using Ga-68 Fibroblast Activation Protein Inhibitor (FAPI) instead of FDG in the PET assessment of the same.*Methods and Materials This study is a prospective study that has been carried out at our institution on 850 patients between January 2015 to January 2021 who were diagnosed to have HCCs on PET-CT assessment with confirmation on either biopsy or AFP assessment. The SUVmax of these tumors using both FDG and Ga-68 FAPI were studied and compared.*Results 850 patients, had both FDG and Ga-68 FAPI assessment 1 day apart. 581 patients had lesions where the largest dimension was more than 5 cm while 269 patients had a largest lesion dimension of less than 5 cm. 443 patients had background cirrhosis and 407 patients did not have chronic liver disease. Out of the total 850 patients who underwent FDG PET-CT, 781 lesions were FDG avid and 69 lesions did not show FDG uptake while all 850 patients who underwent Ga-68 FAPI imaging showed lesion avidity. The mean SUVmax of HCCs among the 850 patients who underwent both imaging modalities 1 day apart was 4.39 + 2.1 for FDG and 12.29 + 6.86 for Ga-68 FAPI with a p value < 0.05 (significant). The sensitivity of FDG in detection of HCC was 92% and that of Ga-68 FAPI was 100%.*Conclusions Ga-68 FAPI PET assessment for Hepatocellular carcinomas is a useful imaging tool in terms of definitive assessment of malignancy and scores higher than FDG-PET in accuracy for diagnosing HCC and can possibly replace FDG in the future.*Clinical Relevance/Application Hepatocellular carcinoma is one of the most common malignancies in our country and is encountered across various age groups. Apart from a few clinical parameters, imaging forms a major part of the assessment of these malignancies which present as hepatic masses and the core question to be answered in every case is whether the mass is benign or malignant and if malignant, then

whether it is hepatocellular carcinoma or another malignancy such as Cholangiocarcinoma. The use of multiple imaging characteristics on contrast enhanced CT scans has formed the basis of diagnosis however PET-CT assessment with FDG has been less accurate owing to the variable uptake by HCCs.

RESULTS

850 patients, had both FDG and Ga-68 FAPI assessment 1 day apart. 581 patients had lesions where the largest dimension was more than 5 cm while 269 patients had a largest lesion dimension of less than 5 cm. 443 patients had background cirrhosis and 407 patients did not have chronic liver disease. Out of the total 850 patients who underwent FDG PET-CT, 781 lesions were FDG avid and 69 lesions did not show FDG uptake while all 850 patients who underwent Ga-68 FAPI imaging showed lesion avidity. The mean SUVmax of HCCs among the 850 patients who underwent both imaging modalities 1 day apart was 4.39 + 2.1 for FDG and 12.29 + 6.86 for Ga-68 FAPI with a p value < 0.05 (significant). The sensitivity of FDG in detection of HCC was 92% and that of Ga-68 FAPI was 100%.

CLINICAL RELEVANCE/APPLICATION

Hepatocellular carcinoma is one of the most common malignancies in our country and is encountered across various age groups. Apart from a few clinical parameters, imaging forms a major part of the assessment of these malignancies which present as hepatic masses and the core question to be answered in every case is whether the mass is benign or malignant and if malignant, then whether it is hepatocellular carcinoma or another malignancy such as Cholangiocarcinoma. The use of multiple imaging characteristics on contrast enhanced CT scans has formed the basis of diagnosis however PET-CT assessment with FDG has been less accurate owing to the variable uptake by HCCs.

SPR-NMMI-14   A Novel Approach To Targeting Bacterial Infection - D-[11C]methionine PET/MRI In Humans

Participants
Ilona Polvoy, MD, San Fransisco, California (*Presenter*) Nothing to Disclose

PURPOSE

This ongoing trial investigates the biodistribution, dosimetry and diagnostic performance of D-[11C]methionine ([11C]D-Met), a novel bacteria-specific PET radiotracer. Current clinical imaging of infection is not specific, unable to distinguish infection from mimics such as tumors or inflammation. [11C]D-Met, based on a 'mirror-image' amino acid, is rapidly incorporated into peptidoglycan, part of the bacterial cell wall. We recently developed a reliable radiosynthesis that was successfully tested in animal infection models. Now, we report human dosimetry as well as initial results in patients with suspected prosthetic joint infection (PJI).*Methods and Materials 370-740 MBq [11C]D-Met was synthesized by automated in-loop radiosynthesis followed by injection of asingle bolus into 6 HVs (3 males, 3 female) and 3 patients with suspected PJI. HVs underwent 6 whole-body PET/MRI scans for purposes of dosimetry. Time-activity curves were used to calculate residence time for each source organ. Absorbed doses to each organ and body effective dose were calculated using OLINDA/EXM 1.1 with ICRP60 tissue weighting factors. Patients with suspected PJI received dynamic PET for 30 minutes targeted at the site of infection followed by a whole body PET/MRI.*Results Effective dose was estimated at 0.0040 mSv/MBq with highest activity in the urinary and hepatobiliary systems. [11C]D-Met showed clearance from both hepatobiliary (slow) and urinary (rapid) pathways. Early background uptake was observed in the liver, pancreas and kidneys with minimal background uptake in other organs. Importantly, minimal uptake was observed in the GI tract or lungs, despite potential concerns regarding the uptake within the human microbiomes. Additionally, minimal background uptake was observed in the spine, CNS or musculoskeletal system. In 2/3 patients with suspected PJI, [11C]D-Met showed increased focal uptake in the area of interest in both early focused scans and delayed whole-body scans.*Conclusions [11C]D-Met was well tolerated by both HVs and infected patients. No adverse effects were reported. Furthermore, the agent showed increased focal uptake in an area of suspected chronic infection, making this a promising agent for infection imaging.*Clinical Relevance/Application [11C]D-Met PET/MR imaging is a novel imaging technique with modest radiation dose, minimal background, and no observed adverse effects. Targeted imaging of bacteria could have an important impact on the diagnosis and management of infections.

RESULTS

Effective dose was estimated at 0.0040 mSv/MBq with highest activity in the urinary and hepatobiliary systems. [11C]D-Met showed clearance from both hepatobiliary (slow) and urinary (rapid) pathways. Early background uptake was observed in the liver, pancreas and kidneys with minimal background uptake in other organs. Importantly, minimal uptake was observed in the GI tract or lungs, despite potential concerns regarding the uptake within the human microbiomes. Additionally, minimal background uptake was observed in the spine, CNS or musculoskeletal system. In 2/3 patients with suspected PJI, [11C]D-Met showed increased focal uptake in the area of interest in both early focused scans and delayed whole-body scans.

CLINICAL RELEVANCE/APPLICATION

[11C]D-Met PET/MR imaging is a novel imaging technique with modest radiation dose, minimal background, and no observed adverse effects. Targeted imaging of bacteria could have an important impact on the diagnosis and management of infections.

SPR-NMMI-17   Intravesicular Radionuclide Therapy Against Superficial Bladder Cancer

Participants
Akiva Mintz, MD, PhD, New York, New York (*Presenter*) Consultant, Regeneron Pharmaceuticals, Inc

PURPOSE

Our long-term goal is to develop an effective minimally invasive therapy that can reach below the urothelium of the bladder to attack tumor cells. External beam radiation of the bladder is used for advancing or refractory disease, but the risk of injury to the bladder and adjacent organs make this option suboptimal. Therefore, goal is to locally administer [90Y]Biotin-Avidin to deliver short range (3-7mm) radiation that penetrates the bladder urothelium and reaches throughout the bladder wall (3-5mm) which cannot be accomplished by other locoregional bladder therapies. [90Y]Biotin-Avidin presents an optimal vehicle due to its easy radiolabeling using DOTA-Biotin precursor and its highly negative charge that is pulled toward the positively charged urothelial and cancer cell membranes.*Methods and Materials For biodistribution, rats were injected intravesicularly with [68Ga]Biotin-Avidin for a 4 hour period, after which the bladder was washed 3 times with saline. During and after the scan, rats were imaged with microPET to visualize the systemic biodistribution, followed by post necropsy organ counting to confirm PET findings. For therapy, mice were implanted orthotopically with luciferase-expressing MB49 mouse bladder cancer cells. At 3 days post implantation, when tumor cells were confirmed below the urothelial surface, we infused mice intravesicularly for 2 hours with 250µCi of [90Y]Biotin-Avidin and subsequently washed with saline. Mice were imaged at days 10 after tumor implantation to quantitate biologic activity of [90Y]Biotin-Avidin.*Results Biodistribution of [68Ga]Biotin-Avidin did not demonstrate any significant systemic distribution outside

the bladder (all organs reading at or near baseline defined <0.1% ID/g) and the bladder measuring 0.15% ID/g. For the therapeutic experiments in our orthotopoic model of invasive bladder cancer, we did not observe any toxicity from intravesicular [90Y]Biotin-Avidin treatment. Bioluminescent imaging demonstrated significantly decreased tumor burden in [90Y]Biotin-Avidin treated mice (n=8) compared to control injected mice.*Conclusions Our results demonstrate potential safety and efficacy of intravesicular radionuclide therapy with [90Y]Biotin-Avidin against bladder cancer.*Clinical Relevance/Application Superficial transitional bladder carcinoma is responsible for 16,000 deaths per year. 70 percent of patients present with superficial non-muscle invasive disease, 50% of whom progress to devastating total cystectomy or to incurable metastatic disease. Given its reach below the urothelial surface, intravesicular radionuclide therapy against bladder cancer has the potential to eradicate early invasive disease in conjunction with standard-of-care local therapy.

RESULTS

Biodistribution of [68Ga]Biotin-Avidin did not demonstrate any significant systemic distribution outside the bladder (all organs reading at or near baseline defined <0.1% ID/g) and the bladder measuring 0.15% ID/g. For the therapeutic experiments in our orthotopoic model of invasive bladder cancer, we did not observe any toxicity from intravesicular [90Y]Biotin-Avidin treatment. Bioluminescent imaging demonstrated significantly decreased tumor burden in [90Y]Biotin-Avidin treated mice (n=8) compared to control injected mice.

CLINICAL RELEVANCE/APPLICATION

Superficial transitional bladder carcinoma is responsible for 16,000 deaths per year. 70 percent of patients present with superficial non-muscle invasive disease, 50% of whom progress to devastating total cystectomy or to incurable metastatic disease. Given its reach below the urothelial surface, intravesicular radionuclide therapy against bladder cancer has the potential to eradicate early invasive disease in conjunction with standard-of-care local therapy.

SPR-NMMI-5 18F-Florbetaben PET/CT Clinical Interpretation: Visual Assessment And Semiquantitative Analysis

Participants
David Petrover, MD, New Hyde Park, New York (*Presenter*) Nothing to Disclose

PURPOSE

Amyloid PET plays a vital role in in vivo detection of ß-Amyloid (Aß) accumulation in Alzheimer's disease. Increasingly, neuroradiologic trainees and infrequent readers are relying on semiquantitative analyses to support clinical diagnostic efforts. However, there is limited data assessing correspondence between visual assessment and semiquantitative analysis in the evaluation of cortical amyloid burden.*Methods and Materials We conducted a retrospective review of [18F]-florbetaben PET/CT studies acquired at our institution from June 2016-May 2018 (N=167). Visual interpretation to determine Aß+ status was conducted by two independent readers blinded to each other's interpretation. After reads were completed, scans were post-processed utilizing MIMneuro software, which generated regional-based semiquantitative Z-scores indicating cortical amyloid burden following industry standards including using the whole cerebellum as the reference region.*Results 167 [18F]-florbetaben PET/CTs were obtained (83 F, 84 M; mean age 76.1 ± 6.8 y). 92/167 (reader 1) and 101/167 scans (reader 2) scans were considered positive for amyloid deposition (agreement = 92.2%, ?=0.84). An additional 9 scans were identified as possible amyloid-positive based solely on semiquantitative analyses. The largest semiquantitative differences were identified in the left frontal lobe (Z = 7.74 in Aß+ versus 0.50 in Aß- subjects). All unilateral regions showed large statistically significant differences in Aß burden (P=2.08E-28 in all cases). Semiquantitative scores were highly sensitive to Aß+ status and highly accurate in their ability to identify amyloid-positive patients, defined as positive scan by both readers (AUC = 0.90 [0.79-1.00]). Spread analyses suggested that amyloid deposition was most severe in left posterior cingulate gyrus, where amyloid-positive individuals were most likely to cross standard cutoffs. The largest differences between negative and positive individuals were in left frontal lobe, and analyses using region-specific cutoffs indicated that presence of amyloid in the temporal and anterior cingulate cortex, while exhibiting relatively low Z-scores, were the more common.*Conclusions Visual assessment and semiquantitative analysis provide highly congruent results, thereby enhancing reader confidence and improving scan interpretation. This is particularly relevant given recent advances in development of amyloid-targeting disease modifying therapeutics, allowing for accurate patient selection for clinical trials and assessment of target engagement and treatment efficacy.*Clinical Relevance/Application Qualitative assessment of amyloid PET scans may be facilitated by relying on results from semiquantitative analysis.

RESULTS

167 [18F]-florbetaben PET/CTs were obtained (83 F, 84 M; mean age 76.1 ± 6.8 y). 92/167 (reader 1) and 101/167 scans (reader 2) scans were considered positive for amyloid deposition (agreement = 92.2%, ?=0.84). An additional 9 scans were identified as possible amyloid-positive based solely on semiquantitative analyses. The largest semiquantitative differences were identified in the left frontal lobe (Z = 7.74 in Aß+ versus 0.50 in Aß- subjects). All unilateral regions showed large statistically significant differences in Aß burden (P=2.08E-28 in all cases). Semiquantitative scores were highly sensitive to Aß+ status and highly accurate in their ability to identify amyloid-positive patients, defined as positive scan by both readers (AUC = 0.90 [0.79-1.00]). Spread analyses suggested that amyloid deposition was most severe in left posterior cingulate gyrus, where amyloid-positive individuals were most likely to cross standard cutoffs. The largest differences between negative and positive individuals were in left frontal lobe, and analyses using region-specific cutoffs indicated that presence of amyloid in the temporal and anterior cingulate cortex, while exhibiting relatively low Z-scores, were the more common.

CLINICAL RELEVANCE/APPLICATION

Qualitative assessment of amyloid PET scans may be facilitated by relying on results from semiquantitative analysis.

SPR-NMMI-6 "Theranostics" - Molecular Imaging and Radionuclide Therapy for Metastatic Colorectal Cancer Targeting CSCP1

Participants
Tahleesa Cuda, Brisbane, Australia (*Presenter*) Nothing to Disclose

PURPOSE

The five-year survival for patients with metastatic colorectal cancer (CRC) is less than 12%. Theranostics is a novel imaging and therapy modality consisting of molecular imaging and radionuclide therapy. Molecular imaging and radionuclide therapy use radionuclides conjugated to antigen-specific ligands to specifically image and treat metastatic cancers.10D7 is a monoclonal antibody which targets CDCP1, a transmembrane glycoprotein overexpressed on a range of malignancies including CRC. This study sought to assess whether CDCP1 is a suitable molecular imaging and radionuclide therapy target for CRC in a range of preclinical

models.*Methods and Materials We assessed the avidity during positron emission tomography (PET) imaging of Zirconium-89 (89Zr)-10D7 in detecting CRC in a range of mouse models.In a therapeutic phase, tumour response of mice bearing CRC treated with the radioligand Lutetium-177 (177Lu)-10D7 was assessed.*Results During PET imaging, 89Zr-10D7 demonstrated significantly higher avidity than control radioligands demonstrating high specificity for CRC. 177Lu-10D7 was significantly more effective than conventional chemotherapy at reducing CRC tumour growth. 177Lu-10D7 also improved the efficacy of conventional chemotherapy.*Conclusions Molecular imaging targeting CDCP1 has high specificity for CRC in preclinical models. Radionuclide therapy targeting CDCP1 may have a role as a standalone therapy agent or synchronous agent for use with existing therapies to achieve a synergistic effect. Theranostics targeting CDCP1 may offer a new therapy for patients with metastatic CRC. Further progression towards humanisation and clinical trial should be sought.

RESULTS

During PET imaging, 89Zr-10D7 demonstrated significantly higher avidity than control radioligands demonstrating high specificity for CRC. 177Lu-10D7 was significantly more effective than conventional chemotherapy at reducing CRC tumour growth. 177Lu-10D7 also improved the efficacy of conventional chemotherapy.

SPR-NMMI-7 Clinical Activity Of Yttrium-90-labeled Ibritumomab Tiuxetan For Treatment Of Relapsed Or Refractory B Cell Non-Hodgkin Lymphoma

Participants
Kaoru Maruyama, Osaka, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the efficacy of yttrium-90-labeled ibritumomab tiuxetan radioimmunotherapy (90Y-IT) in patients with relapsed or refractory non-Hodgkin lymphoma (NHL).*Methods and Materials This is a retrospective study of 68 NHL patients received 90Y-IT between October 2012 and December 2017. Patient characteristics included a mean age of 68 years (range, 45 to 87 years old); 50% men; 60% stage III/IV; 90% three or more prior therapies before baseline. NHL included 47 Follicular lymphoma (FL), 15 Mucosa associated lymphoid tissue lymphoma (MALT), and 6 Mantle cell lymphoma (MCL). Response was evaluated at 3 months after 90Y-IT using 18F-fluorodeoxyglucose positron emission tomography/computed tomography, etc. By using Kaplan-Meier method overall survival (OS), progression-free survival (PFS), and duration of response in responders (complete response, CR; partial response, PR) were analyzed (Table 1).*Results An overall response rate (ORR) of 87% (a 63% CR and a 24% PR rate) was observed (Table 2). Age had no impact on response (less than 60 years vs. more than 60 years, Fisher's exact test p=ns). The duration of follow-up between 90Y-IT and the latest clinical record ranged from 0.9 to 101 months. Kaplan-Meier estimated OS and PFS rate in all patients was 88% and 53% at 50 months after 90Y-IT, respectively. Among histological subgroups, OS rate in MCL was 50% at 11 months. In the MCL group, the rapid progression in the non-responders lowered the median OS. All responses were durable, lasting from 4 to 96 months. At 5 years after 90Y-IT, eight patients remained in CR.*Conclusions Radioimmunotherapy with 90Y-labeled ibritumomab tiuxetan is a very active agent in treatment of relapsed or refractory B-cell NHL, especially FL and MALT. The observation suggested that patients with MCL may require more aggressive management.*Clinical Relevance/Application 90Y-labeled ibritumomab tiuxetan is an effective treatment option for patients with B cell NHL who had failed prior chemotherapy, including patients of aged over 60 years old.

RESULTS

An overall response rate (ORR) of 87% (a 63% CR and a 24% PR rate) was observed (Table 2). Age had no impact on response (less than 60 years vs. more than 60 years, Fisher's exact test p=ns). The duration of follow-up between 90Y-IT and the latest clinical record ranged from 0.9 to 101 months. Kaplan-Meier estimated OS and PFS rate in all patients was 88% and 53% at 50 months after 90Y-IT, respectively. Among histological subgroups, OS rate in MCL was 50% at 11 months. In the MCL group, the rapid progression in the non-responders lowered the median OS. All responses were durable, lasting from 4 to 96 months. At 5 years after 90Y-IT, eight patients remained in CR.

CLINICAL RELEVANCE/APPLICATION

90Y-labeled ibritumomab tiuxetan is an effective treatment option for patients with B cell NHL who had failed prior chemotherapy, including patients of aged over 60 years old.

SSBR05-5   Impact On Risk Categorization With Inclusion Of Mammographic Density In The Tyrer-cuzick Model

Participants
Stamatia Destounis, MD, Rochester, New York (*Presenter*) Medical Advisory Committee, Hologic, Inc;Medical Advisory Board, iCAD, Inc

PURPOSE

To understand the impact of mammographic density (MD) measures on clinically actionable breast cancer risk estimates reported by the Tyrer-Cuzick (TC) model, and differential impacts on subgroups of our population.*Methods and Materials We identified 59,257 women who underwent full-risk assessment using TC version 7 (TCv7) at the time of screening at a specialized breast imaging clinic, between 7 July 2019 and 31 January 2020. Using thresholds of low (<15%), intermediate (15-20%) and high (=20%) lifetime risk, we determined which women would have experienced a change in clinical management following the addition of volumetric breast density (VBD) or BI-RADS to TC version 8 (TCv8). To determine whether MD is differentially affecting specific subsets of women, analysis was conducted in R using the epitools package.*Results Overall, we found that compared to the 8.3% of women classified as high-risk using the TC (v7) model with no density input, there were significantly higher proportions of high-risk women when using TCv8 with VBD (11.4%; p<0.001) versus lower proportion using BI-RADS (6.9%; p<0.001). When considering a change in risk category in either direction by including density, women under age 55 had an odds ratio (OR) of 2.8 when using VBD and 3.5 using BIRADS (p < 0.001). Premenopausal women had an OR of 2.6 when using VBD and 2.9 using BIRADS (p < 0.001). Of 896 (1.5%) women who became low risk by adding density using the VBD, there were 144 (16%) with a family history of a first degree relative with breast cancer under the age 45. Of women at low or intermediate risk using TCv8, 36% had dense breasts.*Conclusions Younger, pre-menopausal women are more affected by the addition of MD to the TC risk model. A substantial number of women who fall into low or intermediate risk categories have dense breasts (36%) and may still benefit from supplemental imaging. Many women with a family history whose lifetime risk fall below 20% when using breast density will meet criteria for genetic testing.*Clinical Relevance/Application Clinics wanting to establish high-risk screening programs should understand that different MD measures incorporated into risk models can differentially impact patient management.

RESULTS

Overall, we found that compared to the 8.3% of women classified as high-risk using the TC (v7) model with no density input, there were significantly higher proportions of high-risk women when using TCv8 with VBD (11.4%; p<0.001) versus lower proportion using BI-RADS (6.9%; p<0.001). When considering a change in risk category in either direction by including density, women under age 55 had an odds ratio (OR) of 2.8 when using VBD and 3.5 using BIRADS (p < 0.001). Premenopausal women had an OR of 2.6 when using VBD and 2.9 using BIRADS (p < 0.001). Of 896 (1.5%) women who became low risk by adding density using the VBD, there were 144 (16%) with a family history of a first degree relative with breast cancer under the age 45. Of women at low or intermediate risk using TCv8, 36% had dense breasts.

CLINICAL RELEVANCE/APPLICATION

Clinics wanting to establish high-risk screening programs should understand that different MD measures incorporated into risk models can differentially impact patient management.

SSBR05-6   Denser Or Just Thinner? Mammographic Breast Density Characterization Around The World

Participants
Ioannis Sechopoulos, PhD, Nijmegen, Netherlands (*Presenter*) Research Grant, Siemens AG;Speakers Bureau, Siemens AG;Research Grant, Canon Medical Systems Corporation;Scientific Advisory Board, Fischer Medical;Research Grant, Sectra AB;Research Grant, ScreenPoint Medical BV;Research Grant, Volpara Health Technologies Limited

PURPOSE

To determine if the distributions of volumetric breast density (VBD) across screening populations around the world are consistent when compared at equal compressed breast thicknesses.*Methods and Materials Six digital mammography screening datasets from different countries were collected. Each dataset consisted of the VBD estimates (Volpara Health Ltd.), compressed breast thickness, view (cranio-caudal (CC) or medio-lateral oblique (MLO)), side, and an anonymized exam ID. In total, data from 780,648

screened women =50 years old (USA: 189,859; Netherlands: 32,757; Norway: 547,614; Brazil: 6,402; Malaysia: 2,121; Greece: 1,895) were included. The distribution of VBD within each of 10 different compressed breast thickness bins (15-25 mm, 26-35 mm, etc.) was analyzed separately per view, to estimate the 5th, 10th, 25th, 50th, 75th, 90th and 95th percentile density for each thickness bin and their corresponding 95% CI. Differences between the mean VBD across datasets and the corresponding VBD for the same percentiles in each dataset were compared.*Results The difference in the VBDs for the same percentile density and breast thickness across the screening programs had a range of CC: -4.4% - +5.0% and MLO: -5.8% - +6.3% from the worldwide means. The majority (516/686=75%) of these differences were statistically significant. For example, for a 56-65 mm thick CC-view breast, the 5th, 50th, and 95th percentile VBDs across the six datasets ranges are 2.4% - 3.3%, 4.2% - 6.5%, and 10.7% - 16.6%, respectively (5/6, 3/6, and 4/6 statistically different from the mean VBDs of 2.8%, 5.3%, and 13.4%).*Conclusions Descriptive statistics on breast characteristics are required in some settings, such as for dosimetry or estimation of cancer development risk, but international variations in the prevalence of dense breasts suggests that a single model may not be broadly representative. However, this quantitative analysis of data from six countries demonstrates that breasts of comparable thickness actually have similar VBD distributions across populations, with the differences being statistically, but probably not clinically, significant. This suggests that, in the absence of patient-specific VBD estimates, a single population-based model of VBD as a function of breast thickness may be appropriate for worldwide use for many applications.*Clinical Relevance/Application If the breast thickness is also considered, the same criteria for categorizing breast density based on VBD can be used worldwide, for applications such as radiation dose estimates or risk modeling.

RESULTS

The difference in the VBDs for the same percentile density and breast thickness across the screening programs had a range of CC: -4.4% - +5.0% and MLO: -5.8% - +6.3% from the worldwide means. The majority (516/686=75%) of these differences were statistically significant. For example, for a 56-65 mm thick CC-view breast, the 5th, 50th, and 95th percentile VBDs across the six datasets ranges are 2.4% - 3.3%, 4.2% - 6.5%, and 10.7% - 16.6%, respectively (5/6, 3/6, and 4/6 statistically different from the mean VBDs of 2.8%, 5.3%, and 13.4%).

CLINICAL RELEVANCE/APPLICATION

If the breast thickness is also considered, the same criteria for categorizing breast density based on VBD can be used worldwide, for applications such as radiation dose estimates or risk modeling.

SSCH01-1   The Role Of Chest CT In Phenotyping High Risk COVID-19 Patients

Participants
Fatemeh Darvizeh, MD, Milan, Italy (*Presenter*) Nothing to Disclose

PURPOSE

The aim of the present study was to investigate the role of chest CT in risk stratification of COVID-19 patients, measuring quantitative biomarkers of cardiovascular risk (calcium score), fragility (sarcopenia) and dysmetabolism (fatty liver, osteoporosis).*Methods and Materials This study is a retrospective multicenter observational study. 1845 consecutive COVID-19 patients from 15 hospitals in Northen Italy underwent chest CT within 72 hours from hospital admission were enrolled. All clinical data including demographics, comorbidities, and lab tests were collected from electronic medical records as well as oxygen therapy, access to ICU and in-hospital death. All chest CT were analyzed in a single core-lab and the following parameters were extracted: well-aereted lung volume, percentage of pneumonia involvement, coronary artery calcium (CAC) scoring, paraverterbral muscle density (D12) as marker of sarcopenia, bone density (D12) as marker of osteoporosis and liver density as marker of liver steatosis. Uni/multivariate analyses were performed using Logistic regression models.*Results The final cohort consisted of 1669 patients (1104 men) with median age of 67 years old. The mortality rate was found higher in men (28%) compared to women (19%, p <0.001).COVID-19 was found more lethal in elderly (75.39±10.21 vs. 56.42±14.76 y.o p <0.001) with higher CAC score (547.96±1067.14 vs. 243.01±813.03, p <0.001), higher degree of sarcopenia (32.43±19.56 vs. 43.83±12.64 HU, p <0.001), liver steatosis (41.77±16.49 vs. 50.85±12.78 HU, p <0.001) and lower bone density (111.54±45.26 vs. 164.30±51.05 HU, p <0.001). All these CT parameters were predictors of unfavorable outcome at univariate analysis. At multivariate analysis, sarcopenia was a CT predictor of death (p=0.005) independent from gender (p=0.017 for men and p=0.02 for women), together with fatty liver in men (p=0.004). Sarcopenia was associated to severe pneumonia (>50% of lung involvement) at multivariable model (p=0.002), together with older age, male sex, higher BMI, lower SatO2, higher LDH and CRP.*Conclusions Sarcopenia and fatty liver at chest CT are associated to pneumonia severity and outcome in COVID-19.*Clinical Relevance/Application In COVID-19 patients, Chest CT provides information about patient's fragility and metabolic alterations affecting disease severity and outcome.

RESULTS

The final cohort consisted of 1669 patients (1104 men) with median age of 67 years old. The mortality rate was found higher in men (28%) compared to women (19%, p <0.001).COVID-19 was found more lethal in elderly (75.39±10.21 vs. 56.42±14.76 y.o p <0.001) with higher CAC score (547.96±1067.14 vs. 243.01±813.03, p <0.001), higher degree of sarcopenia (32.43±19.56 vs. 43.83±12.64 HU, p <0.001), liver steatosis (41.77±16.49 vs. 50.85±12.78 HU, p <0.001) and lower bone density (111.54±45.26 vs. 164.30±51.05 HU, p <0.001). All these CT parameters were predictors of unfavorable outcome at univariate analysis. At multivariate analysis, sarcopenia was a CT predictor of death (p=0.005) independent from gender (p=0.017 for men and p=0.02 for women), together with fatty liver in men (p=0.004). Sarcopenia was associated to severe pneumonia (>50% of lung involvement) at multivariable model (p=0.002), together with older age, male sex, higher BMI, lower SatO2, higher LDH and CRP.

CLINICAL RELEVANCE/APPLICATION

In COVID-19 patients, Chest CT provides information about patient's fragility and metabolic alterations affecting disease severity and outcome.

SSCH01-2   Quantitative Chest CT Combined With Plasma Cytokines Predicts Outcomes In COVID-19 Patients

Participants
Emma Klein, MS, New York, New York (*Presenter*) Nothing to Disclose

PURPOSE

To assess the power of 1) chest CT qualitative score, 2) chest CT quantitative measurements, 3) soluble cytokines in plasma independently and 4) in combination for predicting death during hospitalization and maximum severity degree in COVID-19 patients.*Methods and Materials 152 COVID-19 patients admitted to a single institution, with plasma cytokine assessment and a chest CT within 5 days from admission were included. Demographics, clinical, and laboratory variables, including plasma cytokines (IL-6, IL-8, and TNF-a) were collected. A CT qualitative score based on the extent of lung involvement (score 0-20), was obtained by two independent radiologists; and a CT quantitative analysis was performed using a segmentation software supervised by one reader, to calculate total lung volume (ml), aerated lung volume (ml), ground-glass opacities (GGO) volume (ml), consolidation volume (ml), and GGO to aerated lung ratio. We used spearman correlations, fisher exact test and cox proportional hazard models to test the relationships between variables and endpoints. Next, we used elastic net regression strategy to evaluate predictive power of five scenarios: 1) Cytokines, 2) CT qualitative, 3) CT quantitative, 4) Combined cytokines + CT and, 5) A feature

optimized model, to predict hospital death and maximum severity degree (WHO score). We validated the performance of our models using a combination of training/testing splits and cross-fold validation followed by ROC analysis. Finally, we built a nomogram for risk of death during hospitalization using the variables from our optimized model.*Results The mortality rate was 17.1% (n=26). The maximum severity degree achieved was mild (n= 78, 51.3%) or severe (n=74, 47.3%). Prediction power was fair to good, with AUCs for hospital death and maximum severity degree, as follows: 1) Cytokine model 0.70 (CI: 65-75%) and 0.70 (CI: 66-75%); 2) CT qualitative model 0.60 (CI: 57-62%) and 0.74 (CI: 70-78%); 3) CT quantitative model 0.66 (CI: 60-70%) and 0.81 (CI: 77-86%), 4) combined model 0.75 (CI: 69-80%) and 0.84 (CI: 80-88%); and 5) optimized model 0.78 (CI: 72-84%) and 0.82 (CI: 76-86%). Clinical variables such as O2 and demographics were not predictive and filtered during coefficient selection except for age.*Conclusions Chest-CT assessment in combination with plasma cytokines may represent a useful non-invasive tool to predict death and maximum severity degree in COVID-19 patients.*Clinical Relevance/Application Chest-CT assessment in combination with plasma cytokines may be helpful in triaging COVID-19 patients and managing future outbreaks.

RESULTS

The mortality rate was 17.1% (n=26). The maximum severity degree achieved was mild (n= 78, 51.3%) or severe (n=74, 47.3%). Prediction power was fair to good, with AUCs for hospital death and maximum severity degree, as follows: 1) Cytokine model 0.70 (CI: 65-75%) and 0.70 (CI: 66-75%); 2) CT qualitative model 0.60 (CI: 57-62%) and 0.74 (CI: 70-78%); 3) CT quantitative model 0.66 (CI: 60-70%) and 0.81 (CI: 77-86%), 4) combined model 0.75 (CI: 69-80%) and 0.84 (CI: 80-88%); and 5) optimized model 0.78 (CI: 72-84%) and 0.82 (CI: 76-86%). Clinical variables such as O2 and demographics were not predictive and filtered during coefficient selection except for age.

CLINICAL RELEVANCE/APPLICATION

Chest-CT assessment in combination with plasma cytokines may be helpful in triaging COVID-19 patients and managing future outbreaks.

SSCH01-3   Chest-CT Derived Pulmonary Hypertension At The Admission Predicts Overall Survival In COVID-19 Patients: Insight From 1461 Consecutive Patients In Italy

Participants
Anna Palmisano, MD, Milan, Italy (*Presenter*) Nothing to Disclose

PURPOSE

In non-COVID-19 setting, enlarged main pulmonary artery diameter (MPAD) resulted associated to pulmonary hypertension and mortality. Aim was to investigate and validate the association between MPAD enlargement and overall survival in COVID-19 patients.*Methods and Materials This is a cohort study on 1469 consecutive COVID-19 patients submitted to chest-CT within 72 hours from admission in seven tertiary level hospitals in Northern Italy, between March 1st to April 20th, 2020. Derivation cohort (n=761) included patients from the first three participating hospitals, validation cohort (n=633) included patients from the remaining hospitals. CT images were centrally analyzed in a core-lab blinded to clinical data. Prognostic value of MPAD on overall survival was evaluated at adjusted and multivariable Cox's regression analysis and final multivariable model tested on a validation cohort.*Results In the derivation cohort, the median age was 69 [IQR, 58-77] years and 537 (70.6%) were male. In the validation cohort, the median age was 69 [IQR, 59-77] years with 421 (66.5%) males. Enlarged MPAD (=31mm) was a predictor of mortality at adjusted (hazard ratio, HR [95% CI]: 1.741 [1.253-2.418], P<0.001) and multivariable regression analysis (HR [95% CI]: 1.592 [1.154-2.196], P=0.005), together with male gender, old age, high creatinine, low well-aerated lung volume and high pneumonia extension (c-index [95% CI]=0.826 [0.796-0.851]). Model discrimination was confirmed on the validation cohort (c-index [95% CI]=0.789 [0.758-0.823]), also using CT measurement from a second reader (c-index [95% CI]=0.790 [0.753;0.825]).*Conclusions Enlarged MPAD (=31 mm) at admitting chest-CT is independent predictor of mortality in COVID-19.*Clinical Relevance/Application Enlargement of main pulmonary artery diameter at chest-CT performed within 72 hours from the admission was associated to a higher rate of in-hospital mortality in COVID-19 patients.

RESULTS

In the derivation cohort, the median age was 69 [IQR, 58-77] years and 537 (70.6%) were male. In the validation cohort, the median age was 69 [IQR, 59-77] years with 421 (66.5%) males. Enlarged MPAD (=31mm) was a predictor of mortality at adjusted (hazard ratio, HR [95% CI]: 1.741 [1.253-2.418], P<0.001) and multivariable regression analysis (HR [95% CI]: 1.592 [1.154-2.196], P=0.005), together with male gender, old age, high creatinine, low well-aerated lung volume and high pneumonia extension (c-index [95% CI]=0.826 [0.796-0.851]). Model discrimination was confirmed on the validation cohort (c-index [95% CI]=0.789 [0.758-0.823]), also using CT measurement from a second reader (c-index [95% CI]=0.790 [0.753;0.825]).

CLINICAL RELEVANCE/APPLICATION

Enlargement of main pulmonary artery diameter at chest-CT performed within 72 hours from the admission was associated to a higher rate of in-hospital mortality in COVID-19 patients.

SSNMMI01-2   18F-Fluoroestradiol PET/CT Imaging Of Invasive Lobular Carcinoma

Participants
Matthew Covington, MD, Salt Lake City, Utah (*Presenter*) Consultant, inviCRO, LLC

PURPOSE

Invasive lobular carcinoma (ILC), the second-most common breast cancer subtype, is often difficult to detect on physical examination and standard imaging to include mammography, ultrasound, CT, and FDG-PET/CT. Given that ILC has high rates of estrogen receptor (ER) positivity (around 95% of ILC's are ER positive), imaging of ERs using 18F-Fluoroestradiol-PET/CT (FES-PET/CT) may advance ILC detection. The primary purpose of this study is to establish the positive detection rate of histologically proven ILC on FES-PET/CT. A higher proportion of tumors are expected to have positive uptake by FES-PET/CT compared to FDG-PET/CT.*Methods and Materials This study has IND and IRB approval. 24 patients with biopsy proven ILC from any body site will be recruited and enrolled. FES-PET/CT will be performed with a 6 mCi dose and 60 minute uptake time. An optional FDG-PET/CT scan is also offered if not already performed within 4 weeks of enrollment. Positive uptake at site of biopsy proven ILC will be documented on FES-PET/CT and, if available, FDG-PET/CT, as defined by focal uptake above background and, for FES, SUVmax >1.5.*Results 9 female patients, average age of 61.7 years (range 41 to 82 years) with 14 sites of biopsy proven ILC (13 breast, 1 axilla) have been enrolled over 4 months of accrual. All patients have ILC diagnosed on biopsy within 12 weeks of imaging. Of the 14 sites of biopsy proven ILC, 12 of 13 are ER+ and one is triple negative. All 14 demonstrated positive uptake on FES-PET/CT (average SUVmax of 4.7 (range 1.5 to 12.7)). FDG-PET/CT was performed on 6 patients with 10 lesions. On FDG-PET/CT, 9 of 10 lesions (90%) demonstrated positive uptake.*Conclusions Preliminary analysis shows positive FES-PET/CT at all sites of ILC. One case of ER+ ILC showed abnormal uptake on FES-PET/CT that was not evident on FDG-PET/CT. One case of triple negative ILC on biopsy did show abnormal FES uptake, suggesting possible tumoral heterogeneity with some ER+ disease.*Clinical Relevance/Application This is the first prospective study to evaluate the performance of FES-PET/CT in a dedicated population of histologically proven ILC cases. The study results may be of particular importance to ILC patients for whom conventional imaging is frequently inaccurate.

RESULTS

9 female patients, average age of 61.7 years (range 41 to 82 years) with 14 sites of biopsy proven ILC (13 breast, 1 axilla) have been enrolled over 4 months of accrual. All patients have ILC diagnosed on biopsy within 12 weeks of imaging. Of the 14 sites of biopsy proven ILC, 12 of 13 are ER+ and one is triple negative. All 14 demonstrated positive uptake on FES-PET/CT (average SUVmax of 4.7 (range 1.5 to 12.7)). FDG-PET/CT was performed on 6 patients with 10 lesions. On FDG-PET/CT, 9 of 10 lesions (90%) demonstrated positive uptake.

CLINICAL RELEVANCE/APPLICATION

This is the first prospective study to evaluate the performance of FES-PET/CT in a dedicated population of histologically proven ILC cases. The study results may be of particular importance to ILC patients for whom conventional imaging is frequently inaccurate.

SSNMMI01-3   Simultaneous 18F-FDG PET/MRI Radiomics And Machine Learning Analysis For The Prediction Of Axillary Lymph Node Status In Breast Cancer

Participants
Valeria Romeo, Naples, Italy (*Presenter*) Nothing to Disclose

PURPOSE

To investigate whether radiomics and machine learning (ML) applied to simultaneous 18F-FDG PET/MRI allow prediction of the axillary lymph node (LN) status in breast cancer (BC) patients through the assessment of intratumor heterogeneity.*Methods and Materials In this IRB-approved prospective, single institution study, 74 patients with 82 histologically proven BC lesions and axillary LN (negative LN=31, positive LN=51) were included and underwent simultaneous breast 18F-FDG PET/MRI. Images were analyzed to extract quantitative parameters from dynamic contrast-enhanced (DCE) (tumor Mean Transit Time, Volume Distribution, Plasma

Flow), diffusion-weighted imaging (DWI) (tumor ADCmean and contralateral breast parenchyma), and PET (tumor SUVmax, mean and minimum, SUVmean of ipsi- and contralateral breast parenchyma) images. Whole-lesion manual segmentation was then performed on DCE, T2-w, DWI and PET images to extract handcrafted first-, second- and higher-order radiomics features. Different ML models were developed using a fine gaussian support vector machine (SVM) classifier with a 5-fold cross validation and different combinations of quantitative parameters and radiomics features to obtain the highest accuracy for prediction of axillary LN status, in terms of absence/presence of LN metastasis.*Results Eight radiomics models were developed. Among these, the model employing radiomics features extracted from DCE, ADC and PET images obtained the highest accuracy (AUROC 0.784, 95% CI 0.697 - 0.871) for prediction of LN status, with sensitivity, specificity, PPV and NPV of 75.5%, 66.8%, 68.8%, and 73.9%, respectively.*Conclusions A ML-based radiomics model using handcrafted 18F-FDG PET/MRI radiomics features extracted from BC allows prediction of axillary LN status through the assessment of intratumor heterogeneity.*Clinical Relevance/Application Radiomics and ML applied to 18F-FDG PET/MRI show promise for a non-invasive assessment of nodal status and treatment planning of breast cancer patients.

RESULTS

Eight radiomics models were developed. Among these, the model employing radiomics features extracted from DCE, ADC and PET images obtained the highest accuracy (AUROC 0.784, 95% CI 0.697 - 0.871) for prediction of LN status, with sensitivity, specificity, PPV and NPV of 75.5%, 66.8%, 68.8%, and 73.9%, respectively.

CLINICAL RELEVANCE/APPLICATION

Radiomics and ML applied to 18F-FDG PET/MRI show promise for a non-invasive assessment of nodal status and treatment planning of breast cancer patients.

SSNMMI01-4 Comparison Of Nodal Staging Between CT, MRI And 18F-FDG PET/MRI In Patients With Newly Diagnosed Breast Cancer

Participants
Janna Morawitz, MD, Dusseldorf, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To compare CT, MRI and 18F-fluorodeoxyglucose positron emission tomography (18F-FDG PET/MRI) for nodal status, regarding quantity and location of metastatic locoregional lymph nodes in patients with newly diagnosed breast cancer.*Methods and Materials 182 patients (mean age 52.7 ± 11.9 years) were included in this prospective double-center study. Patients underwent dedicated contrast enhanced chest/abdomen/pelvis computed tomography (CT) and whole-body (18F-FDG PET/) magnet resonance imaging (MRI). Thoracal datasets were evaluated separately regarding quantity, lymph node station (axillary level I-III, supraclavicular, internal mammary chain) and lesion character (benign vs. malign). Histopathology served as reference standard for patient-based analysis. Patient-based and lesion-based analyses were compared by a Mc Nemar test. Sensitivity, specificity, positive and negative predictive value as well as accuracy were assessed for all three imaging modalities.*Results On a patient-based analysis, PET/MRI correctly detected significantly more nodal positive patients than MRI (p<0.0001) and CT (p<0.0001). No statistically signifigant difference was seen between CT and MRI. PET/MRI detected 193 lesions in 75 patients (41.2 %), while MRI detected 123 lesions in 56 patients (30.8 %) and CT detected 104 lesions in 50 patients (27.5 %), respectively. Differences were statistically significant on a lesion-based analysis (PET/MRI vs. MRI, p<0.0001; PET/MRI vs. CT, p<0.0001; MRI vs. CT, p=0.015). Subgroup analysis for different lymph node stations showed that PET/MRI detected significantly more lymph node metastases than MRI and CT in each location (axillary level I-III, supraclavicular, mammary internal chain). MRI was superior to CT only in axillary level I (p=0.0291).*Conclusions 18F-FDG PET/MRI outperforms CT or MRI in detecting nodal involvement on a patient-based and on a lesion-based analysis. Furthermore PET/MRI was superior to CT or MRI in detecting lymph node metastases in all lymph node stations. Of all tested imaging modalities, PET/MRI showed the highest sensitivity, whereas CT showed the lowest sensitivity, but was most specific.*Clinical Relevance/Application PET/MRI localizes lymph node metastases with a higher detection rate and accuracy than MRI and CT and it can reliably be used for nodal staging in primary breast cancer patients.

RESULTS

On a patient-based analysis, PET/MRI correctly detected significantly more nodal positive patients than MRI (p<0.0001) and CT (p<0.0001). No statistically signifigant difference was seen between CT and MRI. PET/MRI detected 193 lesions in 75 patients (41.2 %), while MRI detected 123 lesions in 56 patients (30.8 %) and CT detected 104 lesions in 50 patients (27.5 %), respectively. Differences were statistically significant on a lesion-based analysis (PET/MRI vs. MRI, p<0.0001; PET/MRI vs. CT, p<0.0001; MRI vs. CT, p=0.015). Subgroup analysis for different lymph node stations showed that PET/MRI detected significantly more lymph node metastases than MRI and CT in each location (axillary level I-III, supraclavicular, mammary internal chain). MRI was superior to CT only in axillary level I (p=0.0291).

CLINICAL RELEVANCE/APPLICATION

PET/MRI localizes lymph node metastases with a higher detection rate and accuracy than MRI and CT and it can reliably be used for nodal staging in primary breast cancer patients.

SSNMMI01-5 A Pilot Study Of 68Ga-PSMA11 And68Ga-RM2 PET/MRI For Evaluation Of Prostate Cancer Response To High Intensity Focused Ultrasound (HIFU) Therapy

Participants
Heying Duan, MD, Stanford, California (*Presenter*) Nothing to Disclose

PURPOSE

Prostate specific membrane antigen (PSMA) and gastrin-releasing peptide receptors (GRPR) are both overexpressed in prostate cancer (PC). The degree of their expression at various stages of PC is not yet well understood. In this study, we evaluated a novel approach combining both 68Ga-RM2 and 68Ga-PSMA11 PET/MRI within each PC patient before and after treatment with high intensity focused ultrasound (HIFU) to assess accuracy of localization and response to treatment.*Methods and Materials Nine men, aged 63.7±8.8 years, with newly diagnosed PC were prospectively enrolled. Pre HIFU, patients underwent prostate biopsy, prostate multiparametric MRI (mpMRI), 68Ga-PSMA11 and 68Ga-RM2 PET/MRI. Response to HIFU treatment was assessed with 68Ga-PSMA11 and 68Ga-RM2 PET/MRI. For localization, the prostate was contoured and divided into 12 segments (apex lateral, apex medial, base lateral, base medial, mid lateral, mid medial, left and right, respectively) using PET/MRI data. Maximum standardized uptake values (SUVmax) of PC lesions, and background in each segment were collected.*Results Pre HIFU biopsy revealed 16 lesions of which 12 were clinically significant with a Gleason score (GS) =7 and *mpMRI showed 10 lesions with 9 being

=PIRADS 4. 68Ga-PSMA11 and 68Ga-RM2 PET/MRI demonstrated 20 and 19 positive lesions, respectively, with 17 congruent in 9 patients and 6 incongruent lesions in 4 patients. HIFU treated 21 zones whereas 20 were identified with both radiotracers and one was negative in 68Ga-RM2, but positive in 68Ga-PSMA11. In this patient, pre HIFU biopsy showed GS 4+3 and mpMRI PIRADS 4. For treatment evaluation, 68Ga-PSMA11 and 68Ga-RM2 PET/MRI were performed 8.59±4.23 and 9.21±2.45 months, respectively, after HIFU. In all patients, PET/MRI was negative for the respective treated area. Pre-treatment PSA prostate specific antigen (PSA) and PSA density were 9.04±3.59 ng/mL and 0.21±0.09 ng/ml2, respectively, and decreased significantly after HIFU to 3.93±2.62 ng/mL (P=0.00) and 0.10±0.07 ng/ml2 (P=0.02), respectively. Concordantly, pre-treatment SUVmax decreased significantly for both tracers (68Ga-PSMA11: 13.80±10.72 vs 3.45±3.58 [P=0.03] and 68Ga-RM2 12.09±9.95 vs 3.70±4.10 [P=0.02] before and after HIFU respectively).*Conclusions Our results show that 68Ga-PSMA11 and 68Ga-RM2 PET/MRI identified the dominant lesion for HIFU in 100% and 88.9%, respectively. Both radiotracers accurately verified response to treatment in all patients. The 6 incongruent lesions suggest different expression patterns of PSMA and GRPR in PC. Larger studies are needed to shed light on that.*Clinical Relevance/Application 68Ga-PSMA11 and 68Ga-RM2 PET/MRI are useful in identifying the dominant lesion for HIFU and treatment verification.

RESULTS

Pre HIFU biopsy revealed 16 lesions of which 12 were clinically significant with a Gleason score (GS) =7 and mpMRI showed 10 lesions with 9 being =PIRADS 4. 68Ga-PSMA11 and 68Ga-RM2 PET/MRI demonstrated 20 and 19 positive lesions, respectively, with 17 congruent in 9 patients and 6 incongruent lesions in 4 patients. HIFU treated 21 zones whereas 20 were identified with both radiotracers and one was negative in 68Ga-RM2, but positive in 68Ga-PSMA11. In this patient, pre HIFU biopsy showed GS 4+3 and mpMRI PIRADS 4. For treatment evaluation, 68Ga-PSMA11 and 68Ga-RM2 PET/MRI were performed 8.59±4.23 and 9.21±2.45 months, respectively, after HIFU. In all patients, PET/MRI was negative for the respective treated area. Pre-treatment PSA prostate specific antigen (PSA) and PSA density were 9.04±3.59 ng/mL and 0.21±0.09 ng/ml2, respectively, and decreased significantly after HIFU to 3.93±2.62 ng/mL (P=0.00) and 0.10±0.07 ng/ml2 (P=0.02), respectively. Concordantly, pre-treatment SUVmax decreased significantly for both tracers (68Ga-PSMA11: 13.80±10.72 vs 3.45±3.58 [P=0.03] and 68Ga-RM2 12.09±9.95 vs 3.70±4.10 [P=0.02] before and after HIFU respectively).

CLINICAL RELEVANCE/APPLICATION

68Ga-PSMA11 and 68Ga-RM2 PET/MRI are useful in identifying the dominant lesion for HIFU and treatment verification.

SSNMMI01-6 PSMA Expression In Hepatocellular Carcinoma (HCC): Immunohistochemistry And Imaging With 68Ga-PSMA PET Using Cyclotron-produced 68Ga

Participants
Garima Suman, MD,MBBS, Rochester, Minnesota (*Presenter*) Nothing to Disclose

PURPOSE

To determine the protein expression and localization of PSMA in surgically resected HCC and to prospectively evaluate 68Ga-PSMA PET imaging using cyclotron-produced 68Ga in patients with HCC.*Methods and Materials In phase I, PSMA immunohistochemistry on tissue microarrays of surgically resected HCCs (n=148) was scored for PSMA expression (0 = none, 0.5 = < 5%, 1 = 5-30%, 2=31-60%, 3=61-100%) and findings were correlated to histopathology and clinical variables using multivariate logistic regression. Overall survival following surgical resection for HCC was estimated using Kaplan-Meier analysis stratified by HCC PSMA expression. In phase II, 68Ga-PSMA PET/CT (n=15) or PET/MRI (n=5) was performed in 20 patients (23 lesions) with treatment-naïve HCC after written informed consent. PSMA uptake in lesions was graded qualitatively in reference to liver and spleen, and semi-quantitatively including tumor-to-liver background ratio (TBR). Cross-sectional imaging features were compared between lesions with high vs. low PSMA uptake.*Results PSMA was expressed in 91% of HCCs (n=134) and predominantly localized to the neovasculature. 75% (n=113) of HCCs showed PSMA expression greater than 30% and 40% (n=58) of HCCs showed PSMA expression greater than 60%. Higher HCC tumor grade was associated with positive PSMA expression (p=0.012). No association between positive HCC PSMA expression and tumor size (p=0.14), fibrosis (p=0.35), cirrhosis (p=0.74), HBV (p=0.31) or HCV (p=0.15). There was a trend toward improved survival among HCCs without PSMA expression compared to those with PSMA expression (median OS: 4.2 v. 1.9 years post-surgery; p=0.273). Image quality was excellent in all PET studies. On qualitative evaluation, 61% (n=14) lesions had high PSMA uptake (higher than liver or spleen). Patients with high PSMA uptake had SUVmax [median (range)] 10.6 (4.9-26.5), SUVmean 5 (2.6-12.7), and TBR 2 (1.1-8.0). Two patients had PSMA-avid portal vein tumor thrombus and one patient had PSMA-avid metastatic gastrohepatic lymph node. Lesions with high PSMA uptake had higher relative frequency of background cirrhosis (p=0.02) (14/14; 100%) vs. lesions with low PSMA uptake (6/9; 67%) but other imaging features including size were not different.*Conclusions PSMA is expressed on the neovasculature of a high proportion of HCCs. Its ex vivo expression translates to tumor avidity on 68Ga-PSMA PET imaging, which suggests that PSMA has the potential to be an imaging biomarker in patients with HCC.*Clinical Relevance/Application The high avidity of HCC lesions on PSMA PET opens the prospect for investigation of PSMA-targeted radionuclide therapy as a novel therapeutic option in patients with progressive/advanced PSMA-avid HCC after failure of other systemic options.

RESULTS

PSMA was expressed in 91% of HCCs (n=134) and predominantly localized to the neovasculature. 75% (n=113) of HCCs showed PSMA expression greater than 30% and 40% (n=58) of HCCs showed PSMA expression greater than 60%. Higher HCC tumor grade was associated with positive PSMA expression (p=0.012). No association between positive HCC PSMA expression and tumor size (p=0.14), fibrosis (p=0.35), cirrhosis (p=0.74), HBV (p=0.31) or HCV (p=0.15). There was a trend toward improved survival among HCCs without PSMA expression compared to those with PSMA expression (median OS: 4.2 v. 1.9 years post-surgery; p=0.273). Image quality was excellent in all PET studies. On qualitative evaluation, 61% (n=14) lesions had high PSMA uptake (higher than liver or spleen). Patients with high PSMA uptake had SUVmax [median (range)] 10.6 (4.9-26.5), SUVmean 5 (2.6-12.7), and TBR 2 (1.1-8.0). Two patients had PSMA-avid portal vein tumor thrombus and one patient had PSMA-avid metastatic gastrohepatic lymph node. Lesions with high PSMA uptake had higher relative frequency of background cirrhosis (p=0.02) (14/14; 100%) vs. lesions with low PSMA uptake (6/9; 67%) but other imaging features including size were not different.

CLINICAL RELEVANCE/APPLICATION

The high avidity of HCC lesions on PSMA PET opens the prospect for investigation of PSMA-targeted radionuclide therapy as a novel therapeutic option in patients with progressive/advanced PSMA-avid HCC after failure of other systemic options.

SSPH05-1   Single Image Local Variance Estimator: Deep Learning Framework For CT Noise Quantification

Participants
Nathan Huber, Rochester, Minnesota (*Presenter*) Nothing to Disclose

PURPOSE

Noise quantification is fundamental to CT image quality assessment and protocol optimization; however, methods to measure noise level in patient exams are limited. This study demonstrates Single Image Local Variance EstimatoR (SILVER), a widely accessible deep learning-based framework for estimating CT noise level directly based on patient images.*Methods and Materials SILVER was implemented using a convolutional neural network (CNN) trained with anthropomorphic phantom data. A torso phantom was scanned with 100 repetitions using a sequential whole-body-low-dose (WBLD) protocol (120 kV, 70 mAs, CTDIvol = 4.71 mGy) and reconstructed using FBP with a medium sharp kernel (Br64). Linear noise scaling data augmentation was used to improve generalizability to different noise levels. The noise map was calculated as the pixel-wise standard deviation of repeated scans. Phantom data was split into patches for training; training input was a single CT image and the training label was the corresponding noise map based on 100 repeated scans. A modified U-Net architecture was trained with mean-squared-error loss. Following training, SILVER was tested on two independently acquired phantoms (pelvis and head) and compared to noise maps calculated from 100 repeated scans. Additionally, SILVER was tested on ten patient WBLD-CT exams and accuracy assessed at uniform regions of interest (ROI).*Results When tested on two independent phantoms, the SILVER noise map closely matched the target noise map calculated based on repeated scans (RMSE: 6.7 HU). Within ten patient exams, SILVER noise map accuracy was verified with respect to noise measurements at several uniform ROI, including: aorta (95% agreement), brain (94% agreement), liver (93% agreement), and airways (91% agreement).*Conclusions The SILVER framework enabled accurate pixel-wise noise level estimate directly based on patient images. This method is widely accessible since it operates in the image domain and requires only phantom data for training.*Clinical Relevance/Application Patient CT noise estimate is beneficial for image quality assessment, protocol optimization, and adaptive image processing. The SILVER framework is easy to implement and can accurately estimate noise map based on patient CT images.

RESULTS

When tested on two independent phantoms, the SILVER noise map closely matched the target noise map calculated based on repeated scans (RMSE: 6.7 HU). Within ten patient exams, SILVER noise map accuracy was verified with respect to noise measurements at several uniform ROI, including: aorta (95% agreement), brain (94% agreement), liver (93% agreement), and airways (91% agreement).

CLINICAL RELEVANCE/APPLICATION

Patient CT noise estimate is beneficial for image quality assessment, protocol optimization, and adaptive image processing. The SILVER framework is easy to implement and can accurately estimate noise map based on patient CT images.

SSPH05-2   Validation Of Deep Transfer Learning On CT Scans For Informing Steroid Treatment Of 864 COVID-19 Patients

Participants
Jordan Fuhrman, Chicago, Illinois (*Presenter*) Nothing to Disclose

PURPOSE

The primary treatment for severe COVID-19 patients is corticosteroid administration. The authors previously developed a deep learning system to evaluate COVID-19 patient CT scans to predict if a patient would require steroids during their course of treatment. The previous study had a limited dataset of 41 patients; thus, the purpose of this study was to validate the deep learning system on a substantially larger patient cohort of 916 patients.*Methods and Materials In this retrospective study, a cascaded deep transfer learning approach was used to extract features from a VGG-19 convolutional neural network architecture pre-trained for emphysema detection on CT scans. The feature space dimension was reduced using principal component analysis and a support vector machine was trained for steroid treatment-related predictions. The initial study utilized 41 scans while the new independent cohort consisted of 864 scans. The new data were divided into subsets based on image acquisition parameters including scanner manufacturer (GE, Siemens, Philips, United, FMI) to determine its effect on performance. Classification performance of the full dataset and each subset was characterized through the area under the ROC curve (AUC) with statistical comparison.*Results Classifier performance (AUC) for the task of predicting use of steroids demonstrated a statistically significant reduction from 0.85 +/- 0.10 to 0.68 +/- 0.04 (p=0.02), but both were found statistically significantly different from AUC=0.5 (p=0.002, p=0.0001). Initial performance varied based on scanner manufacturer ranging from AUC of 0.52 to 0.64.*Conclusions While the performance was reduced on the expanded dataset, this may be attributed to limited training data and increased variety

of scanner manufacturers. Classification performances showed statistically significant performance, indicating strong potential for quantitative CT in informing steroid treatments with performance varying across scanner manufacturers.*Clinical Relevance/Application Clinical decisions for management and treatment of severe COVID-19 patients via steroid administrations can be supported by deep learning on a large, diverse dataset.

RESULTS

Classifier performance (AUC) for the task of predicting use of steroids demonstrated a statistically significant reduction from 0.85 +/- 0.10 to 0.68 +/- 0.04 (p=0.02), but both were found statistically significantly different from AUC=0.5 (p=0.002, p=0.0001). Initial performance varied based on scanner manufacturer ranging from AUC of 0.52 to 0.64.

CLINICAL RELEVANCE/APPLICATION

Clinical decisions for management and treatment of severe COVID-19 patients via steroid administrations can be supported by deep learning on a large, diverse dataset.

SSPH05-3   A Deep Learning Approach For The Estimation Of Partially Exposed Organs In CT

Participants
John E. Damilakis, PHD, Iraklion, Greece (*Presenter*) Nothing to Disclose

PURPOSE

Patient-specific Monte Carlo (MC) organ dose estimation using patient's CT images is limited to the scanning length and does not allow dose estimation for partially exposed organs or organs located outside the imaged region. The aim of this study was to train and evaluate a deep learning model for the prediction of liver dose in adult thorax CT examinations.*Methods and Materials The acquisition parameters and demographic data were recorded for a series of 200 patients of various sizes referred for thorax CT. All examinations were performed with a GE Revolution 64 scanner (GE Healthcare, Chicago, IL). Tube current modulation profile data were extracted from the DICOM header of each reconstructed CT image sequence. ?he water-equivalent diameter (WED) body size metric was calculated for each patient. Whole-body phantoms were developed using the extended Cardiac-Torso (XCAT) anatomical phantom framework to resemble the patients as much as possible. To obtain the 'ground truth' liver doses, thorax MC simulations were performed on each phantom with an equipment-specific and patient-specific MC code (ImpactMC, CT Imaging GmbH, Erlangen, Germany) using scan patient data for each exam. An Artificial Neural Network (ANN) was optimized and trained to predict liver doses. Thirty chest-abdomen CT exams were used for validation.*Results The root mean-squared error (RMSE) was 1.98 and 1.35 for the training and test set. The kV, tube load, scanning length, liver volume and WED were the most important features. A very good agreement was observed between liver doses estimated by the ANN algorithm and the MC simulation performed on the chest-abdomen CT exams used for validation (maximum difference in liver doses less than 10%).*Conclusions The current study demonstrated the feasibility of predicting liver dose using an ANN model. The method can be further expanded to include other partially exposed organs or organs outside the CT image volume. Further work is required to assess the robustness of the AI algorithm for larger patient sets.This project has received funding from the Euratom research and training programme 2014-2018 under grant agreement No755523.*Clinical Relevance/Application Machine learning can be used for accurate CT organ dose estimates outside the scan volume. A dose calculation algorithm with both high accuracy and high efficiency is much desired in today's medical imaging clinic.

RESULTS

The root mean-squared error (RMSE) was 1.98 and 1.35 for the training and test set. The kV, tube load, scanning length, liver volume and WED were the most important features. A very good agreement was observed between liver doses estimated by the ANN algorithm and the MC simulation performed on the chest-abdomen CT exams used for validation (maximum difference in liver doses less than 10%).

CLINICAL RELEVANCE/APPLICATION

Machine learning can be used for accurate CT organ dose estimates outside the scan volume. A dose calculation algorithm with both high accuracy and high efficiency is much desired in today's medical imaging clinic.

SSPH05-4   Deep Learning-based Coronary Artery Motion Estimation And Compensation For Iterative Cardiac CT Reconstructions

Participants
Joscha Maier, Heidelberg, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Cardiac motion may lead to reconstruction artifacts that degrade the diagnostic quality of cardiac CT and impair the assessment of coronary arteries. Therefore, we recently proposed the so-called deep partial-angle based motion compensation (Deep PAMoCo) that uses a neural network to estimate and compensate for coronary artery motion. While first results were restricted to analytic reconstructions, we here combine the Deep PAMoCo with an iterative reconstruction to further improve image quality.*Methods and Materials The Deep PAMoCo algorithm is based on the concept of partial-angle reconstructions (PARs). It divides the 180° scan range into several consecutive angular segments and reconstructs them separately. Due to the small angular coverage, these PARs have a high temporal resolution and represent a certain subphase of the cardiac cycle with virtually no motion artifacts. By applying a motion vector field (MVF), the PARs can be deformed to represent the same motion state. The sum of the deformed PARs yields the final motion-compensated reconstruction. In this process, the Deep PAMoCo uses a neural network that is trained to predict the MVF based on the set of input PARs and that applies this MVF internally. Here, the network was trained on 100,000 simulated datasets containing different coronary artery shapes and motion patterns. Finally, it was tested on 25 clinical cases that were reconstructed using an iterative algorithm (SAFIRE, Siemens Healthineers). Results were compared against a conventional MoCo approach and an analytic reconstruction.*Results For all 25 test cases, the Deep PAMoCo was able to remove motion artifacts regardless of the contrast, the radius and the motion amplitude of the coronary artery. Here, the Deep PAMoCo clearly outperformed the conventional approach in terms of image quality and processing time. Compared to an analytic reconstruction, the combination of the Deep PAMoCo with the iterative approach could reduce noise by 35 % on average, which corresponds to a potential dose reduction of 57 %.*Conclusions Combining the Deep PAMoCo with an iterative reconstruction provides an efficient approach to reduce motion artifacts in cardiac CT while enabling low dose protocols.*Clinical Relevance/Application Combining the Deep PAMoCo with an iterative reconstruction provides an efficient approach to reduce motion artifacts in cardiac CT while enabling low dose protocols.

RESULTS

For all 25 test cases, the Deep PAMoCo was able to remove motion artifacts regardless of the contrast, the radius and the motion amplitude of the coronary artery. Here, the Deep PAMoCo clearly outperformed the conventional approach in terms of image quality and processing time. Compared to an analytic reconstruction, the combination of the Deep PAMoCo with the iterative approach could reduce noise by 35 % on average, which corresponds to a potential dose reduction of 57 %.

CLINICAL RELEVANCE/APPLICATION

Combining the Deep PAMoCo with an iterative reconstruction provides an efficient approach to reduce motion artifacts in cardiac CT while enabling low dose protocols.

SSPH05-5   Generalizability Of Deep Convolutional-Neural-Network-Based Metal-Artifact-Reduction In CT-Guided Interventional Oncology Procedures

Participants
Liqiang Ren, PhD, Rochester, Minnesota (*Presenter*) Nothing to Disclose

PURPOSE

To assess the generalizability of deep convolutional neural networks (CNN) trained to reduce metal artifacts introduced by metallic probes in CT-guided interventional percutaneous kidney cryoablation procedures.*Methods and Materials Image and projection data were exported from the planning scan of ten CT-guided kidney cryoablation cases (Siemens SOMATOM Edge). CNN training images were created from these data by artificially inserting a cryoablation probe (Boston Scientific IceForce) in both projection space (images with artifacts, inputs) and image space (artifacts-free images, targets) at matching locations. The process was repeated at multiple positions/orientations for each case. Images were reconstructed using manufacturer-provided reconstruction software and clinical reconstruction parameters. With these data, two CNN models were trained to identify and remove the probe-induced artifacts from the input images. One model was trained on input data containing a single probe; whereas the second model was trained on data containing up to 4 probes intersecting a single plane. The two models were subsequently applied to previously unseen patient images from treatment monitoring scans during kidney cryoablations. Generalizability of the two models was tested on CT images with different slice thickness, reconstruction field-of-view (rFOV), reconstruction kernel, or number of intersecting probes. The optimal model was further tested on CT images for which the model was not trained, containing differences including metallic probe type, procedure location, or CT scanner model. Each variation was tested on 3 independent cases.*Results The single-probe model effectively reduced metal artifacts in patient images matching the training data parameters. Its performance slightly degraded with different rFOVs and was ineffective for different slice thickness, reconstruction kernel, or number of probes. The multi-probe model was effective for soft-tissue ablation procedures regardless of the number or type of probes and was generalizable to CT images from different CT scanner models. Its performance, however, degraded when applied to images from ablation procedures performed in different anatomical regions such as the chest or the spine.*Conclusions The multi-probe model outperformed the single-probe model by incorporating training data containing multiple intersecting probes and was generalizable to soft-tissue ablation procedures regardless of the number/type of probes, or CT scanner models.*Clinical Relevance/Application Generalizability of metal artifact reduction algorithms applied to CT-guided procedures is clinically important, as it is common to have different number and type of probes within the same CT image.

RESULTS

The single-probe model effectively reduced metal artifacts in patient images matching the training data parameters. Its performance slightly degraded with different rFOVs and was ineffective for different slice thickness, reconstruction kernel, or number of probes. The multi-probe model was effective for soft-tissue ablation procedures regardless of the number or type of probes and was generalizable to CT images from different CT scanner models. Its performance, however, degraded when applied to images from ablation procedures performed in different anatomical regions such as the chest or the spine.

CLINICAL RELEVANCE/APPLICATION

Generalizability of metal artifact reduction algorithms applied to CT-guided procedures is clinically important, as it is common to have different number and type of probes within the same CT image.

SSPH05-6   Scalable And Generalizable Small ROI Imaging Using Backprojection And Deep Learning

Participants
Chengzhu Zhang, BS, Madison, Wisconsin (*Presenter*) Nothing to Disclose

PURPOSE

To reduce radiation dose as well as scatter in cone beam CT imaging, the scanning field of view (FOV) is often reduced. However, this reduction of FOV inevitably leads to the notoriously difficult interior tomography problem. In this work, a new method was developed to enable scalable and generalizable small ROI imaging with high quantitative accuracy.*Methods and Materials The method consists of two steps: the acquired fully truncated projection data was weighted to account for data redundancy and then backprojected to form an initial image. This initial image turns out to be the blurred version of the true image with a specific 1/r blurring kernel. In the second step, a deep learning method was developed to reconstruct the true image. To train the deblurring model, 5,409 clinical MDCT images from head, chest and abdomen were curated. To test the performance of the new reconstruction method, 1,067 simulated clinical cases and 376 experimental clinical cases were used. The objective image quality assessment metric SSIM was used to evaluate the image quality. To test the generalizability of the developed method, additional experimental data were acquired using head phantom data acquired from our benchtop cone beam CT system.*Results 1) The method reconstructed artifact-free 5 cm FOV ROIs regardless of their locations. The reconstructed ROIs maintained all detailed structures with almost identical visualization as non-truncated FBP at the same ROI location. 2) The statistical SSIM of the trained model was reported as 0.985±0.018 evaluated on all simulated test data and 0.940 ± 0.025 evaluated on all experimental data test data. 3) The method was shown to be generalizable to phantom data acquired from the benchtop system.*Conclusions A scalable and generalizable small ROI image reconstruction method was developed to enable small ROI imaging with 5 cm diameter at arbitrary location.*Clinical Relevance/Application A low dose, low scatter artifact imaging method was developed for use in image-guided interventions and image-guided therapy with x-ray beams being collimated to illuminate a small ROI.

RESULTS

1) The method reconstructed artifact-free 5 cm FOV ROIs regardless of their locations. The reconstructed ROIs maintained all detailed structures with almost identical visualization as non-truncated FBP at the same ROI location. 2) The statistical SSIM of the

trained model was reported as 0.985±0.018 evaluated on all simulated test data and 0.940 ± 0.025 evaluated on all experimental data test data. 3) The method was shown to be generalizable to phantom data acquired from the benchtop system.

CLINICAL RELEVANCE/APPLICATION

A low dose, low scatter artifact imaging method was developed for use in image-guided interventions and image-guided therapy with x-ray beams being collimated to illuminate a small ROI.

SSNPM03-4 Magnetic Resonance Spectroscopy For The Differentiation Of Recurrent Glioma From Radiation Necrosis: A Cost Effectiveness Analysis

Participants
Huijun Liao, BS, Boston, Massachusetts (*Presenter*) Nothing to Disclose

PURPOSE

In the US, Magnetic Resonance Spectroscopy (MRS) has been difficult to reimbursed due to the 1994 national noncoverage determination by the Center for Medicare & Medicaid Services. However, the NCD was removed in 2020 leaving the coverage decisions to the state and local level. To support the need for MRS reimbursement, evidence of its cost-effectiveness is needed. The goal of this study was to determine the cost-effectiveness of MRS in its most widely used clinical application, the differentiation of recurrent glioma and radiation necrosis, utilizing a decision-analytic model.*Methods and Materials Model A decision-analytic model was based on the scenario provided by the BCBS TEC Assessment Report that compared the effectiveness of when MRS is performed and not performed for recurrent and necrosis differentiation. Analysis was performed over 5yr, 10yr and lifetime horizons. Input data were derived from systematic literature searches, meta-analyses, and medical fee book. Sensitivity Analysis: A probabilistic sensitivity analysis was performed on all study variables over a plausible range of values to recalculate model results in order to account for variability in factors such as test cost and local expertise and a Monte-Carlo simulation was used to create 1000 samples. All analysis and Monte Carlo simulations were performed by using a custom script using Microsoft® Excel.*Results In the deterministic model, the results showed that it cost less and had higher quality of life years (QALYs) over 5yr, 10yr and lifetime horizons respectively when a MRS exam was performed with incremental cost-effectiveness ratio (ICER) of -$98,978,-$50,666 and -$41,349 per QALY gained. All three ICER scatter plots of probabilistic sensitivity analysis for MRS versus no MRS performed (Fig. 1) had their summary points in Quadrant-D where MRS performed was more effective (incremental QALYs: 0.13,0.19,0.22) and less expensive (incremental Cost: -$12,678, -$10,233, -$8121). At a Willingness-to-Pay (WTP) threshold of $0 per QALY, MRS performed was already superior to no MRS performed in 73%, 62% and 62% of simulations for 5yr, 10yr and lifetime horizon respectively as shown in Fig 2. MRS performed was dominated in even 97%, 97% and 96% of simulations at WTP threshold of $50,000 (US-standard).*Conclusions Our results suggested that performing MRS was more effective and less costly compared with not performing MRS for recurrent glioma and necrosis differentiation. MRS should be considered reimbursable by policy makers in U.S.*Clinical Relevance/Application Our cost-effectiveness analysis showed that performing MRS was more cost-effective than not performing MRS for recurrent glioma and necrosis differentiation. MRS should be considered reimbursable by policy makers in U.S.

RESULTS

In the deterministic model, the results showed that it cost less and had higher quality of life years (QALYs) over 5yr, 10yr and lifetime horizons respectively when a MRS exam was performed with incremental cost-effectiveness ratio (ICER) of -$98,978,-$50,666 and -$41,349 per QALY gained. All three ICER scatter plots of probabilistic sensitivity analysis for MRS versus no MRS performed (Fig. 1) had their summary points in Quadrant-D where MRS performed was more effective (incremental QALYs: 0.13,0.19,0.22) and less expensive (incremental Cost: -$12,678, -$10,233, -$8121). At a Willingness-to-Pay (WTP) threshold of $0 per QALY, MRS performed was already superior to no MRS performed in 73%, 62% and 62% of simulations for 5yr, 10yr and lifetime horizon respectively as shown in Fig 2. MRS performed was dominated in even 97%, 97% and 96% of simulations at WTP threshold of $50,000 (US-standard).

CLINICAL RELEVANCE/APPLICATION

Our cost-effectiveness analysis showed that performing MRS was more cost-effective than not performing MRS for recurrent glioma and necrosis differentiation. MRS should be considered reimbursable by policy makers in U.S.

SSNPM03-6 Mismatch Between Supply Of Radiologists And Need For Imaging Services By US Geographic Region And State, From 2012-2018

Participants
Aditya Khurana, BS, Scottsdale, Arizona (*Presenter*) Nothing to Disclose

PURPOSE

Evaluate associated changes in the supply of radiologists and the need for imaging services in the aging United States population, by region and state.*Methods and Materials Supply of radiologists was estimated by the number of radiologists providing care to Medicare beneficiaries, by state and region, extracted from the CMS POSPUF (Physician and Other Supplier Public Use File) Database of Medicare Part B claims submitted. Demand for imaging services was estimated by the number of Medicare beneficiaries by state, obtained from the Kaiser Family Foundation. Overall, regional and state level rates of growth from 2012 to 2018 were

tabulated. The difference between the rate of growth of Medicare beneficiaries and the rate of growth of diagnostic radiologists was calculated for each region and state.*Results In 2012, 29,079 radiologists submitted claims to Medicare Part B, which increased to 30,354 in 2018 (+4.4%). Growth of radiologists was largest in the South (9,660, 10,290, 6.5%), followed by West (6,000, 6,340, 5.7%), Northeast (6,739, 6,910, 2.5%), and Midwest (6,680, 6,814, 2.0%). Growth of radiologists by state ranged from -19.6% (133, 107) in Maine to 21.5% (634, 770) in Minnesota.In 2012, there were 36,498,774 Medicare beneficiaries, which increased to 38,388,936 in 2018 (7.4%). Growth of Medicare beneficiaries was largest in the West (6,600,369, 7,642,302, 15.8%), followed by Northeast (6,858,841, 7,092,518, 3.4%), South (14,440,393, 14,895,104, 3.2%), and Midwest (8,599,171, 8,759,012, 1.9%). Growth of Medicare beneficiaries by state ranged from -10.8% (704,622, 628,709) in Alabama to 14.8% (125,943, 144,690) in Hawaii.Growth in beneficiaries outpaced growth in radiologists, with the mismatch in beneficiaries to radiologists being -3.0% overall, and by region -10.1% West, -0.9% Northeast, +0.1% Midwest, and 3.4% South. By state, the mismatch ranged from -26.7% in Hawaii to +28.5% in Minnesota.*Conclusions The overall growth in the Medicare population from 2012 to 2018 outpaced growth in the supply of radiologists. The mismatch of supply and demand for imaging services among the states differed by more than 50%. In some regions and states, such as the West, the growth of diagnostic radiologists may not be keeping up with the demand for imaging services. At the same time, the South and some states demonstrate the opposite trend in the supply demand mismatch, which could trend toward and overabundance of radiologists and potential limitations in radiologists' job prospects.*Clinical Relevance/Application Geographic variations in the mismatch of demand for imaging services and the supply of radiologists may result in widening variations in the availability of imaging services for Medicare patients and radiologists' job prospects.

RESULTS

In 2012, 29,079 radiologists submitted claims to Medicare Part B, which increased to 30,354 in 2018 (+4.4%). Growth of radiologists was largest in the South (9,660, 10,290, 6.5%), followed by West (6,000, 6,340, 5.7%), Northeast (6,739, 6,910, 2.5%), and Midwest (6,680, 6,814, 2.0%). Growth of radiologists by state ranged from -19.6% (133, 107) in Maine to 21.5% (634, 770) in Minnesota.In 2012, there were 36,498,774 Medicare beneficiaries, which increased to 38,388,936 in 2018 (7.4%). Growth of Medicare beneficiaries was largest in the West (6,600,369, 7,642,302, 15.8%), followed by Northeast (6,858,841, 7,092,518, 3.4%), South (14,440,393, 14,895,104, 3.2%), and Midwest (8,599,171, 8,759,012, 1.9%). SPR-IN-1   **Accurate Weakly-supervised Volumetric Universal Lesion Segmentation Using Large-scale Clinical RECIST Diameter Annotations And Regional Level Set Loss**

Participants
Youbao Tang, PhD, Bethesda, Maryland (*Presenter*) Nothing to Disclose

PURPOSE

Volumetric universal lesion segmentation (VULS) via computed tomography (CT) scans may be a clinically desirable means to precisely assess disease progression and therapy response. Radiologists usually do not perform volumetric lesion segmentation due to time constraints, even though it proves helpful. To reduce this manual burden, we design an Attention-enhanced High-Resolution Network (AHRNet) for accurate volumetric universal lesion segmentation using large-scale clinical RECIST (Response Evaluation Criteria in Solid Tumors) diameter annotations as weak supervisory signals and regional level set loss for optimizing the lesion boundary delineation.*Methods and Materials AHRNet provides advanced high-resolution deep image features by involving a decoder, dual-attention and scale attention mechanisms, which are crucial to performing accurate lesion segmentation. RLS can optimize the model reliably and effectively in a weakly-supervised fashion, forcing segmentation close to the lesion boundary. To make learning the model feasible, a pseudo mask is generated by fitting an ellipse from long- and short- axis diameters of each RECIST annotation. AHRNet was trained on the large-scale NIH DeepLesion dataset consisting of 32,735 lesions labeled with RECIST diameters from 10,594 studies of 4,459 patients. 1,000/200 lesions were randomly selected from 500/140 patients and manually annotated their 2D/3D masks as the validation/test set. The remaining patients' images served as the training set. A hold-out set containing 500 lesions with 3D masks from 160 patients was collected from another hospital for external real-life evaluation.*Results On the DeepLesion test dataset, AHRNet remarkably improved the VULS performance by increasing the 3D Dice score from 0.764±0.11 (the best previous result) to 0.866±0.068, demonstrating that AHRNet works significantly more accurately. Furthermore, AHRNet achieved a 3D Dice score of 0.858±0.045 on the external hold-out test set, indicating that AHRNet performs VULS stably and robustly.*Conclusions We proposed a powerful network and a novel loss for accurate volumetric universal lesion segmentation by reliably weakly-supervised learning from a large quantity of clinical RECIST diameter annotations. It brings in more robust and accurate volumetric lesion segmentation measurements for a variety of lesion classes covering all body sections.*Clinical Relevance/Application The proposed method is potentially of high importance for automated and large-scale tumor 3D volume measurement/management in the domain of precision quantitative radiology and oncology imaging. As such, it can help clinicians to achieve accurate tumor response measurements on CT in a large clinical scale.

RESULTS

On the DeepLesion test dataset, AHRNet remarkably improved the VULS performance by increasing the 3D Dice score from 0.764±0.11 (the best previous result) to 0.866±0.068, demonstrating that AHRNet works significantly more accurately. Furthermore, AHRNet achieved a 3D Dice score of 0.858±0.045 on the external hold-out test set, indicating that AHRNet performs VULS stably and robustly.

CLINICAL RELEVANCE/APPLICATION

The proposed method is potentially of high importance for automated and large-scale tumor 3D volume measurement/management in the domain of precision quantitative radiology and oncology imaging. As such, it can help clinicians to achieve accurate tumor response measurements on CT in a large clinical scale.

SPR-IN-10   **Explainable AI In Radiology: Side-by-side Comparison Of Two Contemporary Techniques**

Participants
Eduardo Farina, MD, Sao Paulo, Brazil (*Presenter*) Nothing to Disclose

PURPOSE

To compare whether Grad-CAM or SHAP gives better post-hoc explanations to the results produced by deep learning models in three different radiological scenarios.*Methods and Materials Three deep learning models (using the VGG16 architecture) were trained for three different tasks: detect brain hemorrhage, detect gadolinium in brain MRI, and differentiate an abdominal CT scan in portal phase from non-contrast. We then randomly selected 20 test images from each task and extracted their Grad-CAM (Gradient-weighted Class Activation Mapping) for the last layer and trained a SHAP (SHapley Additive exPlanations) Deep Explainer using 32 training images to get the SHAP values for the same selected images for which we have extracted Grad-CAM. Later, five radiologists (each with at least 4 years of experience) judged whether SHAP or Grad-CAM have produced more suitable explanations for the results produced by each model, or if both had given similarly good or bad explanations. For hypothesis testing, we used Wilcoxon Rank Test to compare whether SHAP or Grad-CAM have outperformed each other in each task and in the overall answers.*Results Our results showed that for each of the three different tasks, and for all the models together, SHAP gave a better explanation (visualization) of where the model is looking at for the prediction than Grad-CAM (for Hemorrhage Head-CT, Gadolinium Head MRI, Abdominal CT Portal phase, and combined answers' p-values were: 0.03, < 0.001, 0.01 and < 0.001, respectively).*Conclusions The explanations provided by using SHAP Deep Explainer outperformed Grad-CAM for model post-hoc explanation, showing that they might be more useful than Grad-CAM in different classification tasks.*Clinical Relevance/Application

The resistance to adopting AI in radiology due to the opaque nature of deep learning models can be alleviated by using post-hoc explanations of the models' predictions.

RESULTS

Our results showed that for each of the three different tasks, and for all the models together, SHAP gave a better explanation (visualization) of where the model is looking at for the prediction than Grad-CAM (for Hemorrhage Head-CT, Gadolinium Head MRI, Abdominal CT Portal phase, and combined answers' p-values were: 0.03, < 0.001, 0.01 and < 0.001, respectively).

CLINICAL RELEVANCE/APPLICATION

The resistance to adopting AI in radiology due to the opaque nature of deep learning models can be alleviated by using post-hoc explanations of the models' predictions.

SPR-IN-12 Deep Learning For Detecting Pulmonary Tuberculosis Via Chest Radiography: An International Study Across 10 Countries

Participants
Sahar Kazemzadeh, Mountain View, California (*Presenter*) Employee, Alphabet Inc;Stockholder, Alphabet Inc

PURPOSE

Tuberculosis (TB) is a top-10 cause of death worldwide. Though the WHO recommends chest radiographs (CXR) for TB screening, lack of access to expertise in CXR interpretation limits its use in many regions. To help with this problem, we developed a deep learning system (DLS) to detect active TB, evaluated it with retrospective data from multiple countries and settings, and compared its performance to radiologists from both endemic (India) and non-endemic (US) practice settings.*Methods and Materials We trained a DLS using over 100,000 de-identified CXR from 9 countries spanning Africa, Asia, and Europe. To improve generalization, we incorporated large-scale CXR pretraining, attention pooling, and semi-supervised learning via "noisy student". The DLS was evaluated on a combined test set of 1,262 images (1 per patient) from China, India, US, and Zambia, with TB confirmation via microbiology or molecular testing. Given WHO targets of 90% sensitivity and 70% specificity, the DLS's operating point was prespecified to favor sensitivity over specificity.*Results The DLS's receiver operating characteristic (ROC) curve was above all 9 India-based radiologists, with an area under the curve (AUC) of 0.90 (95%CI 0.87-0.92). At the prespecified operating point, the DLS's sensitivity (88%) was higher than the India-based radiologists (median sensitivity: 74%, range 69-87%, p<0.001 for superiority), and the DLS's specificity (79%) was non-inferior to these radiologists (median specificity: 86%, range 78-88%, p=0.004). Similar trends were observed within HIV positive and sputum smear positive sub-groups within these datasets. We additionally found that 5 US-based radiologists were more sensitive but less specific than the India-based radiologists. The DLS was similarly non-inferior to this second cohort of radiologists. Depending on the setting, use of the DLS as a prioritization tool could reduce the cost per positive TB case detected by 40-80% compared to the use of molecular testing alone.*Conclusions We developed a DLS to detect active pulmonary TB on CXR, that generalized to patient populations from 4 regions of the world, and merits prospective evaluation to assist cost-effective screening efforts in settings with scarce access to radiologists.*Clinical Relevance/Application Our AI detects pulmonary tuberculosis on chest x-rays with performance comparable to radiologists, and could be a cost-effective way to select patients for confirmatory workup and treatment.

RESULTS

The DLS's receiver operating characteristic (ROC) curve was above all 9 India-based radiologists, with an area under the curve (AUC) of 0.90 (95%CI 0.87-0.92). At the prespecified operating point, the DLS's sensitivity (88%) was higher than the India-based radiologists (median sensitivity: 74%, range 69-87%, p<0.001 for superiority), and the DLS's specificity (79%) was non-inferior to these radiologists (median specificity: 86%, range 78-88%, p=0.004). Similar trends were observed within HIV positive and sputum smear positive sub-groups within these datasets. We additionally found that 5 US-based radiologists were more sensitive but less specific than the India-based radiologists. The DLS was similarly non-inferior to this second cohort of radiologists. Depending on the setting, use of the DLS as a prioritization tool could reduce the cost per positive TB case detected by 40-80% compared to the use of molecular testing alone.

CLINICAL RELEVANCE/APPLICATION

Our AI detects pulmonary tuberculosis on chest x-rays with performance comparable to radiologists, and could be a cost-effective way to select patients for confirmatory workup and treatment.

SPR-IN-13 Commercial Artificial Intelligence Solutions For Radiology: A Market Update

Participants
Kicky van Leeuwen, MSc, Nijmegen, Netherlands (*Presenter*) Technical Expert, Scarlet NB

PURPOSE

Provide an overview of the current market of regulatory-cleared artificial intelligence (AI) software for radiology.*Methods and Materials An overview of CE marked AI products for clinical radiology is maintained online (https://www.AIforRadiology.com). Vendors were asked to verify and complete the product information. This overview allows for analysis of market trends. Characteristics of the market were based on the state of the database on the 1st of May 2021.*Results In May 2021 there were 161 CE marked AI products on the market, an increase of 36% compared with one year prior. The growth from 2019 to 2020 was 69% (from 70 to 118 products). The number of vendors offering AI products only grew with 13% from 61 in 2020 to 69 in 2021. The average number of products per company therefore increased from 1.9 to 2.3. The time from company founding to the first product on the market is on average 4 years and 1 month. Most prevalent are tools for neuro and chest imaging. With respect to modality, CT and MR covered 62% of all products. Half of the CE marked AI products (51%) have also been cleared by the FDA. To our knowledge, only four products were CE marked under the new Medical Device Regulations. Subscription or licensing are the most popular pricing models. The majority of products are offered with both the option of local and cloud-based installation.*Conclusions The growth of AI products new to the market is slowing down. This effect is even stronger for vendors. Existing vendors have been expanding their portfolios.*Clinical Relevance/Application The market of AI products for radiology is growing. Our research provides a transparent overview of the available products and their evidence.

RESULTS

In May 2021 there were 161 CE marked AI products on the market, an increase of 36% compared with one year prior. The growth from 2019 to 2020 was 69% (from 70 to 118 products). The number of vendors offering AI products only grew with 13% from 61 in

2020 to 69 in 2021. The average number of products per company therefore increased from 1.9 to 2.3. The time from company founding to the first product on the market is on average 4 years and 1 month. Most prevalent are tools for neuro and chest imaging. With respect to modality, CT and MR covered 62% of all products. Half of the CE marked AI products (51%) have also been cleared by the FDA. To our knowledge, only four products were CE marked under the new Medical Device Regulations. Subscription or licensing are the most popular pricing models. The majority of products are offered with both the option of local and cloud-based installation.

CLINICAL RELEVANCE/APPLICATION

The market of AI products for radiology is growing. Our research provides a transparent overview of the available products and their evidence.

SPR-IN-14 Leveraging Large-scale Weakly Labeled Data For Semi-supervised Mammogram Mass Detection

Participants
Yuxing Tang, Bethesda, Maryland (*Presenter*) Nothing to Disclose

PURPOSE

To develop a novel self-training-based semi-supervised learning framework for robust mass detection in mammograms, by leveraging the probabilistic image-level labels generated from the diagnostic report by a BERT-based natural language processing (NLP) model on a large-scale dataset.*Methods and Materials We collected a large-scale mammography dataset containing 134,520 images with diagnostic reports from 30,495 patients, among which 2,634 images have pixel-level mass masks labeled by radiologists. To fully leverage the diagnosis reports, we adopt a BERT-based NLP model to generate the probability of mass presence for the corresponding image, which is subsequently assigned as the image-level probabilistic label. We propose a novel semi-supervised learning framework to leverage a small number of fully labeled and large-scale weakly labeled images (with diagnostic reports) for mass detection. Starting with a fully supervised model trained on the data with pixel-level masks, the proposed framework iteratively refines the model itself using the entire weakly labeled data in a self-training fashion. A novel consistency-based sample selection strategy is proposed to identify those most informative samples for each iteration, based on the current model output and the soft labels of the weakly labeled data. A soft cross-entropy loss and a soft focal loss are also designed to serve as the image-level and pixel-level classification loss respectively.*Results A hold-out testing set of 689 mammography studies (2,756 images) manually labeled by radiologists was used to evaluate the performance of the proposed mass detection framework. Using all the fully and weakly labeled images, the sensitivities at 0.1, 0.2, 0.5, 1, and 2 false positive per image (FPPI) are 0.726, 0.778, 0.820, 0.850, and 0.962, respectively. Training using 25% (or 50%) of the fully labeled images together with the weakly labeled data, our semi-supervised model achieves performance on par ($p>0.05$) with training using 50% (or 100%) of the fully labeled images.*Conclusions The proposed semi-supervised learning model can effectively take advantage of soft labels generated by the NLP and pixel-level prediction, which models them as a means of uncertainties for weak data. It has a high sensitivity for mass detection. The performance of our self-training method can be persistently increased with more weakly labeled data available. It also demonstrates better mass detection accuracy than the supervised baseline and other comparing methods.*Clinical Relevance/Application The proposed framework enables large-scale self-training from weakly labeled data, which can reduce the effort of manual annotations from medical experts. It is unique and universally practical in medical image analysis.

RESULTS

A hold-out testing set of 689 mammography studies (2,756 images) manually labeled by radiologists was used to evaluate the performance of the proposed mass detection framework. Using all the fully and weakly labeled images, the sensitivities at 0.1, 0.2, 0.5, 1, and 2 false positive per image (FPPI) are 0.726, 0.778, 0.820, 0.850, and 0.962, respectively. Training using 25% (or 50%) of the fully labeled images together with the weakly labeled data, our semi-supervised model achieves performance on par ($p>0.05$) with training using 50% (or 100%) of the fully labeled images.

CLINICAL RELEVANCE/APPLICATION

The proposed framework enables large-scale self-training from weakly labeled data, which can reduce the effort of manual annotations from medical experts. It is unique and universally practical in medical image analysis.

SPR-IN-16 Prediction Of Radiography Study Volume And Turnaround Times

Participants
Akhil Dhamija, Lebanon, Ohio (*Presenter*) Nothing to Disclose

PURPOSE

Traditionally, radiologist schedules are constructed so that a predetermined, fixed number of radiologists cover a service. This process is inefficient as it does not account for variation in the daily study volume or the potential radiologist capacity. The purpose of this study was to determine if a machine learning (ML) algorithm could be used to predict study turnaround times (TAT = final report completion time - end exam time) based on the scheduled compliment of radiologists.*Methods and Materials A retrospective study was performed at a large academic children's hospital with a large pediatric radiology fellowship program. Data from all radiographs performed between 2017-2019 was extracted from multiple radiology information systems. Radiologist scores were calculated based on their mean and median TAT, shift type (day/night), and predicted volume per shift. Pearson correlation coefficients were determined between the predictor variables and the mean and median TAT. A ML pipeline with recursive feature selection using random forests and hyper parameter tuning using grid search for random forest and neural network models was used to find the best performing model on a test data spanning 3 months with training data from previous 33 months.*Results 397,806 radiographs were included in the data analysis. The mean TAT was weakly correlated ($R2 = \sim0.4$) with several variables. There was a noticeable increase in the rolling 7-day mean TAT from June to September each year thought to be due to the on-boarding of new fellows (Figure 1). Each day's mean TAT was weakly correlated with the same day's mean TAT from the prior week ($R2 = 0.43$). The modeling pipeline's prediction for daily study volume was strongly correlated with the actual study volume ($R2 = \sim 0.9$). However, there was little correlation between the predicted mean and median TAT and the actual values ($R2 = <0.32$) (Table 1). *Conclusions Optimizing radiologist scheduling using machine learning techniques is not feasible in its current iteration. Currently, we can only predict the study volume with a high-level of certainty.*Clinical Relevance/Application Prediction forecasts for shift turnaround times require further development and variable identification. Study volume can be predicted with a high level of accuracy.

RESULTS

397,806 radiographs were included in the data analysis. The mean TAT was weakly correlated ($R2 = \sim0.4$) with several variables.

There was a noticeable increase in the rolling 7-day mean TAT from June to September each year thought to be due to the on-boarding of new fellows (Figure 1). Each day's mean TAT was weakly correlated with the same day's mean TAT from the prior week (R2 = 0.43). The modeling pipeline's prediction for daily study volume was strongly correlated with the actual study volume (R2 = ~ 0.9). However, there was little correlation between the predicted mean and median TAT and the actual values (R2 = <0.32) (Table 1).

CLINICAL RELEVANCE/APPLICATION

Prediction forecasts for shift turnaround times require further development and variable identification. Study volume can be predicted with a high level of accuracy.

SPR-IN-2   Synthesis Of Discriminative Imaging Features Using Generative Adversarial Networks

Participants
Kyle Hasenstab, PhD, La Jolla, California (*Presenter*) Nothing to Disclose

PURPOSE

Convolutional neural networks (CNN) have been proposed to assist in radiological diagnosis, but current methods of providing CNN transparency are limited. We sought to assess the feasibility of a novel strategy using a generative adversarial network (GAN) to improve CNN explainability, through synthesis of images representative of CNN features.*Methods and Materials We previously developed two CNNs: one for regression of N-terminal pro-hormone brain natriuretic peptide (NT-proBNP) from chest radiographs, and a second for classification of intravenous contrast uptake adequacy on hepatobiliary phase MRI. With IRB approval and waiver of informed consent, we obtained 21,374 x-ray images and 826 hepatobiliary phase MRI volumes for algorithm development. Images were propagated through each CNN and features from the final fully-connected layer were extracted. Linear dimension reduction techniques were applied to reduce to a subset of principal features. A novel feature interpretation GAN (FIGAN) was then trained to synthesize images based on these principal features and structural segmentations. FIGAN-synthesized images were then reviewed by radiologists to determine the interpretations of these principal features for each CNN. FIGAN was also compared to conventional approaches for CNN explainability, including gradient-weighted class activation maps (Grad-CAMs) and saliency maps (SMs).*Results FIGAN-synthesized x-ray images showed that inference of NT-proBNP relied on size of the cardiomediastinal silhouette, body habitus, and perihilar pulmonary vasculature. FIGAN-synthesized MRI images showed that inference of hepatobiliary phase adequacy relied on differential enhancement of liver parenchyma and veins, textural nodularity, and hepatic venous opacification. Grad-CAM and SM results showed nonspecific and inconsistent CNN attention across the source images.*Conclusions FIGAN is effective and reliable for synthesizing visual representations of imaging features utilized by regression and classification CNNs to improve CNN explainability and is particularly beneficial for delineating both the location and visual characteristics of imaging features used by CNNs.*Clinical Relevance/Application The proposed algorithm can be used to visualize discriminative regional and diffuse imaging features used by CNNs and may help improve transparency of CNNs for medical imaging.

RESULTS

FIGAN-synthesized x-ray images showed that inference of NT-proBNP relied on size of the cardiomediastinal silhouette, body habitus, and perihilar pulmonary vasculature. FIGAN-synthesized MRI images showed that inference of hepatobiliary phase adequacy relied on differential enhancement of liver parenchyma and veins, textural nodularity, and hepatic venous opacification. Grad-CAM and SM results showed nonspecific and inconsistent CNN attention across the source images.

CLINICAL RELEVANCE/APPLICATION

The proposed algorithm can be used to visualize discriminative regional and diffuse imaging features used by CNNs and may help improve transparency of CNNs for medical imaging.

SPR-IN-4   Inpainting Of Anatomical Side (L/R) Mark For Enhancing Deep Learning Classifier In Chest Radiographs Of Multi-Center Trials

Participants
Ki Duk Kim, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To propose an L/R mark inpainting with deep learning to enhance a classifier between normal and abnormal, which could be used to overcome different protocols between centers of placing anatomical side markers in multicenter.*Methods and Materials 2,000 normal and 2,000 abnormal chest radiographs from two centers (A, B) were evenly enrolled. 200 randomly sampled radiographs from public National Institutes of Health (NIH) dataset were also used as an external validation. The anatomical side markers on chest radiographs from center-A can indicate normal or abnormal labels, while other centers do not have such bias. To evaluate the influence of the markers, inpainting these markers were performed for all centers with EfficientDet to first detect region of interest (ROI) of markers and InpaintingGAN to inpaint only the ROI by replacing it with relevant information. A ResNet50 based classifier were developed using center-A data with original and inpainted datasets. The center-A dataset was divided into training, tuning, and validation sets as 6:2:2. External validations on the center-B and the NIH datasets were performed with two models. The area under the curve (AUC), accuracy, sensitivity, and specificity were evaluated and compared. In addition, attention map which shows highlighted region for classification was also compared.*Results In center-B, AUC, accuracy, sensitivity, and specificity were 0.672, 0.501, 0.002, and 1.000, respectively for the original model and 0.738, 0.659, 0.744, and 0.573, respectively for the marker inpainted model. In NIH dataset, those were 0.618, 0.45, 0.216, and 0.924, respectively for the original model and 0.737, 0.685, 0.739, and 0.576, respectively for the marker inpainted model. Pairwise comparisons of receiver operating characteristics (ROC) curves showed difference between original model and marker inpainted model (P < 0.0001, P = 0.049 for center-B, NIH dataset, respectively). In addition, attention map shows highlighted region on L/R marker in the original model while anatomical regions in the marker inpainted model, which was confirmed by an thoracic expert radiologist with more than 20 years' experience.*Conclusions The L/R marker inpainted model significantly enhanced the classification performance of external datasets, which could be useful to develop a more robust and accurate deep learning classifier especially with dataset from multicenter.*Clinical Relevance/Application Our model is expected to improve the robustness and performance of computer aided detection with dataset from multicenter by inpainting anatomical side markers.

RESULTS

In center-B, AUC, accuracy, sensitivity, and specificity were 0.672, 0.501, 0.002, and 1.000, respectively for the original model and 0.738, 0.659, 0.744, and 0.573, respectively for the marker inpainted model. In NIH dataset, those were 0.618, 0.45, 0.216, and 0.924, respectively for the original model and 0.737, 0.685, 0.739, and 0.576, respectively for the marker inpainted model. Pairwise

comparisons of receiver operating characteristics (ROC) curves showed difference between original model and marker inpainted model (P < 0.0001, P = 0.049 for center-B, NIH dataset, respectively). In addition, attention map shows highlighted region on L/R marker in the original model while anatomical regions in the marker inpainted model, which was confirmed by an thoracic expert radiologist with more than 20 years' experience.

CLINICAL RELEVANCE/APPLICATION

Our model is expected to improve the robustness and performance of computer aided detection with dataset from multicenter by inpainting anatomical side markers.

SPR-IN-5 Classification Of Focal Liver Lesions In CT Images Using Uncertainty-aware Ensemble Of Radiomics And Deep Learning Classifiers

Participants
Hansang Lee, Daejeon, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To improve the classification efficiency of focal liver lesions (FLLs) in CT images, we propose an uncertainty-weighted ensemble method for integrating radiomics and deep learning classifiers using the uncertainty estimated from two classifiers.*Methods and Materials A dataset of 502 portal phase CT scans of 1,290 FLLs with 676 cysts, 130 hemangiomas, and 484 metastases, was used. First, we train a random forest (RF) on 67-dimensional radiomic texture and shape features and an AlexNet CNN on the training images. From two trained classifiers, we evaluate the aleatoric uncertainty through the test-time augmentation (TTA) method. In TTA, the affine-based augmentation is applied to each test data, and the uncertainty is computed by the entropy of the label distribution obtained from the classified labels of the augmented test data. In the integration of two classifiers, we propose an uncertainty-weighted ensemble to integrate the two classifiers while also maintaining the advantage of each classifier. In the uncertainty-weighted ensemble, the label distributions of two classifiers weighted by the inversed uncertainty are linearly combined to obtain the ensemble distribution. The uncertainty-weighted ensemble allows the classifier to significantly reflect the decision of one classifier with high certainty in its decision.*Results In experiments, we compared the results of the proposed method with those of a single RF, a single AlexNet, and a linear combination ensemble of two classifiers. The two single classifiers of RF and AlexNet achieved an accuracy of 82.7% and 78.8%, respectively, and both classifiers have a higher probability of misclassification in higher uncertainty cases. The linear combination ensemble of the two classifiers achieved an accuracy of 81.8%, showing lower performance than a single RF. The proposed method showed improved results than single classifiers and a linear combination ensemble through the uncertainty weighted ensemble. As a result, the proposed method achieved an accuracy of 85.0%, showing improvements of 2.3%p, 6.2%p, and 3.2%p compared to the single RF, single AlexNet, and the linear combination ensemble, respectively.*Conclusions The proposed uncertainty-weighted ensemble weighs each classifier's uncertainty in combining the two classifiers so that the classifier which is more certain in its own decision is further reflected. (This work was supported by the NRF grant funded by the MSIT No. 2020R1A2C1102140)*Clinical Relevance/Application Our method can be applied not only to tumor analysis problems in which radiomic feature learning is important but also to the overall tasks of integrating two learners with different characteristics.

RESULTS

In experiments, we compared the results of the proposed method with those of a single RF, a single AlexNet, and a linear combination ensemble of two classifiers. The two single classifiers of RF and AlexNet achieved an accuracy of 82.7% and 78.8%, respectively, and both classifiers have a higher probability of misclassification in higher uncertainty cases. The linear combination ensemble of the two classifiers achieved an accuracy of 81.8%, showing lower performance than a single RF. The proposed method showed improved results than single classifiers and a linear combination ensemble through the uncertainty weighted ensemble. As a result, the proposed method achieved an accuracy of 85.0%, showing improvements of 2.3%p, 6.2%p, and 3.2%p compared to the single RF, single AlexNet, and the linear combination ensemble, respectively.

CLINICAL RELEVANCE/APPLICATION

Our method can be applied not only to tumor analysis problems in which radiomic feature learning is important but also to the overall tasks of integrating two learners with different characteristics.

SPR-IN-6 A Prospective Controlled Study Of Distension Protocols In Bladder Mp-MRI

Participants
Juan Hu, Kunming, China (*Presenter*) Nothing to Disclose

PURPOSE

To compare the imaging quality of bladder mpMRI with different bladder distension protocols and explore the optimal patient preparation protocol for VI-RADS application.*Methods and Materials Patients who applied for pelvic mpMRI examination in our hospital from July 2020 to April 2021 were prospectively included with the approval of the hospital ethics committee, and were randomly divided into three groups after signing informed consent: Group 1 (urine holding alone: urine abstinence after urination 1~2 hours before scan), Group 2 (water drinking alone: drinking 500-1000 ml of water within 0.5~1 hour before scan), Group 3 (urine holding and water drinking: urination 1~2 hours before the examination + drinking 500~1000ml water before the scan). The pelvic mpMRI was performed on a 3.0T MR scanner, and the sequences included high-resolution T2WI (axial/coronal/sagittal), DWI/ADC (b-value=0/1000/1400 s/mm2), and DCE. A reviewer who was unaware of the preparation protocol performed separate quality scores for T2WI, DWI/ADC, and DCE(arterial phase) of bladder wall; motion artifacts affecting the bladder wall were evaluated; initial and final sequence bladder volumes (Vpre, Vpost) were measured using 3D Slicer, and volume changes(Vpost-pre) were calculated. Patients filled out the scale to collect height, weight, urination time, and water drink time, etc. Vpre, Vpost, and Vpost-pre in each group, the image quality and motion artifacts of each sequence in each group were compared by SPSS 21.0 software. Differences were considered statistically significant at P < 0.05.*Results The differences of Vpre, Vpost, and Vpost-pre were statistically significant(P=0.001, 0.000, 0.000) in group 1 (31 cases, 55.9±14.4 years), group 2 (31 cases, 56.2±12.9 years) and group 3 (30 cases,60.0±13.6 years). T2WI, DWI/ADC, DCE quality scores showed: Group 3 > Group 2 > Group 1, and the differences were statistically significant (F=9.989,9.844,13.068; P=0.000,0.000,0.000), while the differences in motion artifact scores between groups were not statistically significant (F=1.861; P=0.161).*Conclusions The combination of the urine holding and water drinking protocol has advantages over urine holding or water drinking alone protocol in bladder distension and image quality.*Clinical Relevance/Application The combination of the urine holding and water drinking protocol is recommended as the optimal bladder distension protocol for VI-RADS scoring of bladder mpMRI.

RESULTS

The differences of Vpre, Vpost, and Vpost-pre were statistically significant(P=0.001, 0.000, 0.000) in group 1 (31 cases, 55.9±14.4 years), group 2 (31 cases, 56.2±12.9 years) and group 3 (30 cases,60.0±13.6 years). T2WI, DWI/ADC, DCE quality scores showed: Group 3 > Group 2 > Group 1, and the differences were statistically significant (F=9.989,9.844,13.068; P=0.000,0.000,0.000), while the differences in motion artifact scores between groups were not statistically significant (F=1.861; P=0.161).

CLINICAL RELEVANCE/APPLICATION

The combination of the urine holding and water drinking protocol is recommended as the optimal bladder distension protocol for VI-RADS scoring of bladder mpMRI.

SPR-IN-8   FedNorm: Federated Learning With Modality-based Normalization

Participants
Shadi Albarqouni, PhD, Munchen, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Organ segmentation is an important task in medical image analysis, which can be performed by deep learning models to assist physicians with their diagnoses. However, labeling medical datasets for organ segmentation is expensive and requires expert knowledge. As a consequence, many hospitals cannot provide the required amount of data to train a deep learning model on their own. Typically, one would collect data from multiple hospitals and train a model in a centralized manner, but this is often not possible due to privacy regulations, especially in the medical sector. Therefore, it would be helpful to train a shared, decentralized model, where training data from different modalities and multiple hospitals contributes to the training process.*Methods and Materials In this work, we focus on multi-modal liver segmentation with CT and MRI data using federated learning. We present a novel federated learning algorithm, FedNorm, which uses a normalization technique based on the modalities of the data. Additionally, FedNorm learns a global model which can compute the liver segmentation mask for CT and MRI input scans. We compare FedNorm to other state-of-the-art federated learning algorithms, namely; FedAvg, FedAvgM, FedVC, FedBN, and SiloBN, in multiple settings, where different numbers of clients and modalities participate during training. Therefore, we validate our method on five publicly available datasets: LiTS17 (w/o 3D-IRCADb, 111 patients), 3D-IRCADb (20 patients), Multi-Atlas (30 patients), SLIVER07 (20 patients), CHAOS19 (20 CT and 100 MR scans). Furthermore, we evaluate the generalization performance of the shared global model on unseen multi-modal data.*Results We show that FedNorm outperforms other federated learning approaches on unseen data by a large margin. In one of our MRI generalization tests, FedNorm shows 8x higher global Dice score over SiloBN (0.076 to 0.752), which is the best performing algorithm among the others. In the per-patient evaluation, 9x higher Dice score over SiloBN (0.066 to 0.718) is achieved.*Conclusions Due to the great generalization performance of our trained global model, there is no need to train a separate model at each hospital. It is sufficient if only a few hospitals with different modalities contribute to the training process. Further, our method allows users to feed the model with either a CT or MR image and always get a liver segmentation.*Clinical Relevance/Application In general, FedNorm allows training accurate liver segmentation models, which can be used in a variety of applications. Examples of such applications would be the detection of liver cancer, which is preceded by liver enlargement as a physical sign, or the task of liver age prediction.

RESULTS

We show that FedNorm outperforms other federated learning approaches on unseen data by a large margin. In one of our MRI generalization tests, FedNorm shows 8x higher global Dice score over SiloBN (0.076 to 0.752), which is the best performing algorithm among the others. In the per-patient evaluation, 9x higher Dice score over SiloBN (0.066 to 0.718) is achieved.

CLINICAL RELEVANCE/APPLICATION

In general, FedNorm allows training accurate liver segmentation models, which can be used in a variety of applications. Examples of such applications would be the detection of liver cancer, which is preceded by liver enlargement as a physical sign, or the task of liver age prediction.

SPR-IN-9   Feddis: Disentangled Federated Learning For Unsupervised Brain Pathology Segmentation

Participants
Shadi Albarqouni, PhD, Munchen, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Collecting and labeling medical data is cumbersome and costly. Data is often scattered across multiple institutions, and privacy regulations make it difficult to access. In addition, medical images must be reviewed by specially trained physicians, which is time-consuming and expensive. The goal of this work is to collaboratively train an ML model to segment anomalies in brain MR scans without sharing local data and without requiring labeled images. Still, in such a distributed setup, data heterogeneity between institutes/datasets poses a major challenge.*Methods and Materials To mitigate this problem, we propose a novel federated method called Federated Disentanglement (FedDis), to disentangle the parameter space in shape and appearance and learn only a global shape model. Our method is based on the premise that the underlying anatomical structure in MR scans of the brain is similar across different institutions and scanners, and sharing shape information would be beneficial in detecting abnormalities.*Results In this work, we use healthy brain scans from 623 subjects from multiple institutions with real-world data (OASIS, ADNI) in a federated manner. We validated our method FedDis on real pathological databases with 109 subjects: two publicly available MS lesions (MSLUB, MSISBI) and an in-house database with MS and glioblastoma (MSI and GBI). Our method reached an average dice score of 0.38, outperforming the state-of-the-art (sota) Auto Encoder by 42% and the sota federated method by 11%.*Conclusions We have shown superior performance of our FedDis on a couple of publicly available databases of MR Braim pathologies; Multiple Sclerosis, and Glioblastoma. The code idea of our method of disentangling the parameter space in shape and appearance and learn only a global shape model has been shown its effectiveness.*Clinical Relevance/Application This work shows a scalable and efficient solution to brain anomaly detection that can be used to improve the radiological workflow efficiency by guiding clinicians to abnormalities that might otherwise go undetected.

RESULTS

In this work, we use healthy brain scans from 623 subjects from multiple institutions with real-world data (OASIS, ADNI) in a federated manner. We validated our method FedDis on real pathological databases with 109 subjects: two publicly available MS lesions (MSLUB, MSISBI) and an in-house database with MS and glioblastoma (MSI and GBI). Our method reached an average dice score of 0.38, outperforming the state-of-the-art (sota) Auto Encoder by 42% and the sota federated method by 11%.

CLINICAL RELEVANCE/APPLICATION

This work shows a scalable and efficient solution to brain anomaly detection that can be used to improve the radiological workflow efficiency by guiding clinicians to abnormalities that might otherwise go undetected.

SPR-RO-1   **Imaging And Treatment Of Primary And Metastatic Tumors Via Abscopal Immunotherapy Involving Reductions In Circulating Tumor Cells (CTCs), CTC Clusters, And Their Extravasation Using Targeted Antigen-capturing Nanoparticles Containing Ezrin Inhibitor And Ouabain Directed By Radiation.**

Participants
Satoshi G. Harada, MD, Shiwa, Japan (*Presenter*) Nothing to Disclose

PURPOSE

In vivo imaging and treatment of primary and metastasized tumors using microcapsules releasing antigen-capturing nanoparticles (AC-NPs) containing Ezrin inhibitor (NSC 668394) and Ouabain in two radiation sessions with programmed death-ligand 1 (PD-L1) blockade.*Methods and Materials For session 1, nanocapsules (NCs) generated by modifying iopamiron and 400 µg of anti-PD-L1 antibody (Ab) were mixed with 1.0 mL of 4% alginate, 3% hyaluronate, and 1 µg/mL of P-selectin solution and sprayed into 0.5 mmol/L of $FeCl_2$ supplemented with 1 µg/mL of anti-a4ß1 Ab. NCs were injected intravenously into BALB/c mice with primary K7M2 tumors in the left hind leg and lung metastases. After 9 h, primary tumors were exposed to 10 or 20 Gy of 60Co ?-rays. For session 2, 400 nM of Ouabain and 30 µM of NSC 668394 were encapsulated in poly(lactic-co-glycolic) acid (PLGA) AC-NPs via nanoprecipitation. The particles were mixed with the alginate-hyaluronate cocktail and sprayed into 0.5 mmol/L of $FeCl_2$ supplemented with 1 µg/mL of anti-P-selectin Ab. NCs (1×10^{10}) were injected intravenously. After 9 h, the tumors were irradiated, as in session 1.*Results In session 1, anti-a4ß1 NCs accumulating around primary and metastatic tumors were detected on computed tomography. NCs released P-selectin and anti-PD-L1 Ab on irradiation. In session 2, NCs accumulated around primary tumors via a P-selectin antigen (Ag)-Ab reaction and released PLGA AC-NPs containing Ouabain and NSC 668394. PLGA AC-NPs captured and transported tumor-derived protein Ag released by the second radiation dose to dendritic cells (DCs), which intensified DC-mediated cluster of differentiation (CD)8+ T-cell priming. The primed antitumor CD8+ T cells targeted primary and metastatic tumors, single circulating tumor cells (CTCs), and CTC clusters with PD-L1 blockade from session 1. Furthermore, Ouabain from PLGA AC-NPs dissociated CTC clusters. NSC 668394 then inhibited CTC extravasation and dissociated CTC clusters, reducing new metastasis seeding. These treatments conferred increased antitumor effects (enhancement factor 1.9) and reduced metastasis by 90.3%.*Conclusions Our NC improves tumor diagnosis and treatment.*Clinical Relevance/Application Targeted AC-NP-mediated immunotherapy with radiation-directed Ouabain and Ezrin inhibitor enhances the primary and metastatic antitumor effects of radiotherapy with PD-L1 blockade.

RESULTS

In session 1, anti-a4ß1 NCs accumulating around primary and metastatic tumors were detected on computed tomography. NCs released P-selectin and anti-PD-L1 Ab on irradiation. In session 2, NCs accumulated around primary tumors via a P-selectin antigen (Ag)-Ab reaction and released PLGA AC-NPs containing Ouabain and NSC 668394. PLGA AC-NPs captured and transported tumor-derived protein Ag released by the second radiation dose to dendritic cells (DCs), which intensified DC-mediated cluster of differentiation (CD)8+ T-cell priming. The primed antitumor CD8+ T cells targeted primary and metastatic tumors, single circulating tumor cells (CTCs), and CTC clusters with PD-L1 blockade from session 1. Furthermore, Ouabain from PLGA AC-NPs dissociated CTC clusters. NSC 668394 then inhibited CTC extravasation and dissociated CTC clusters, reducing new metastasis seeding. These treatments conferred increased antitumor effects (enhancement factor 1.9) and reduced metastasis by 90.3%.

CLINICAL RELEVANCE/APPLICATION

Targeted AC-NP-mediated immunotherapy with radiation-directed Ouabain and Ezrin inhibitor enhances the primary and metastatic antitumor effects of radiotherapy with PD-L1 blockade.

SPR-RO-2   **Comparison Of Longitudinal MRI Radiomic Texture Features Between Protons And Photon Radiation Therapy In Non-tumoral Regions Of Brain At The Same Dose Levels In Paediatric Patients With Brain Tumours - An Exploratory Study**

Participants
Priyanka Sakhavalkar, MSc, BDS, Nashik, India (*Presenter*) Nothing to Disclose

PURPOSE

To assess if there is any difference in T2 texture features between non-tumoral parts of brain in photon vs proton radiotherapy at the same dose levels.*Methods and Materials Longitudinal retrospective study was carried out in 51 paediatric patients diagnosed with primary brain tumours treated with photon (Ph;n=30) or proton (Pr;n=21) radiotherapy. T2 baseline and at each fixed time point from the date of surgery to two years following radiotherapy were selected for the textural analysis. Scans were bias corrected, registered with the CT dose maps and with baseline scan for each patient. Regions of interest (ROI) of fixed diameter were drawn in 11 predetermined non-tumoral regions of brain including in peri-tumoural region (PTV). ROIs were placed in homogenous white/grey matter. Radiation dose was calculated in each of these 11 ROIs and texture features were extracted using pyradiomics. Data were analysed using machine learning & statistical analysis and 16 primary texture features were compared between therapies across whole brain and in each ROI separately at the same dose levels (between 0-60 Gy)*Results 1.Whole brain: When all 11 ROIs were analysed together in 50 patients, mean of different longitudinal textural feature values showed

significant differences (p <0.005) between both therapies at each dose levels. Number of observations (N) were different at each dose group in each therapy due to difference in dose distribution. At dose group A(0-10.55Gy;N=Ph144,Pr 609)& C(20.56-30.55Gy;N=Ph172,Pr26) means of 15 longitudinal feature value showed significant difference; at B(10.56-20.55Gy;Ph58,Pr83) & E (40.56-50.55;GyN=Ph108,Pr42), significant difference was shown by mean of 1 feature , at dose D (30.56-40.55Gy;N=Ph196,Pr27) mean of 3 feature values showed difference and 11 features mean values showed significant difference at dose F(50.56-60.55Gy; N=Ph514,Pr128) 2.In each ROI: When similar ROI was selected and compared, significant difference (p<0.005) was seen in some mean values. Individual features showing significant difference vary as per dose group. Eg. Mean of total energy at dose E, at pons showed significant difference*Conclusions There is a significant difference in some primary textural feature values over non-tumoural brain parenchyma at the same dose levels between proton and photon therapy. Radiomic texture analysis is promising technique to understand these differences.*Clinical Relevance/Application This is a first radiomic study showing significant difference in some of the textural features between proton and photon therapy pointing to the possible difference in underlying biologic/structural brain changes after each therapy. This may imply different biologic effect of each therapy.

RESULTS

1.Whole brain: When all 11 ROIs were analysed together in 50 patients, mean of different longitudinal textural feature values showed significant differences (p <0.005) between both therapies at each dose levels. Number of observations (N) were different at each dose group in each therapy due to difference in dose distribution. At dose group A(0-10.55Gy;N=Ph144,Pr 609)& C(20.56-30.55Gy;N=Ph172,Pr26) means of 15 longitudinal feature value showed significant difference; at B(10.56-20.55Gy;Ph58,Pr83) & E (40.56-50.55;GyN=Ph108,Pr42), significant difference was shown by mean of 1 feature , at dose D (30.56-40.55Gy;N=Ph196,Pr27) mean of 3 feature values showed difference and 11 features mean values showed significant difference at dose F(50.56-60.55Gy; N=Ph514,Pr128) 2.In each ROI: When similar ROI was selected and compared, significant difference (p<0.005) was seen in some mean values. Individual features showing significant difference vary as per dose group. Eg. Mean of total energy at dose E, at pons showed significant difference

CLINICAL RELEVANCE/APPLICATION

This is a first radiomic study showing significant difference in some of the textural features between proton and photon therapy pointing to the possible difference in underlying biologic/structural brain changes after each therapy. This may imply different biologic effect of each therapy.

SPR-RO-3   Treatment Compliance To Linac-based Prostate SBRT Using Real-time Electromagnetic Tracking

Participants
RAFFAELLA LUCCHINI, MONZA, Italy (*Presenter*) Nothing to Disclose

PURPOSE

To investigate treatment compliance and early gastrointestinal (GI) and genitourinary (GU) side effects in patients with organ confined prostate cancer following linac-based Stereotactic Body Radiation Therapy (SBRT) using an electromagnetic (EM) tracking device for real-time intra-fraction organ motion.*Methods and Materials Ten consecutive patients with prostate cancer (cT2-T3N0M0) were treated with dose escalated prostate SBRT in 4 or 5 fractions, in a single week, for a total dose of 38 Gy or 40 Gy, respectively. A volumetric modulated arc therapy (VMAT) was delivered on VersaHD linac with two 6FFF or 10FFF arcs optimized to have the 95% isodose covering at least 95% of the PTV (2 mm isotropic expansion of the CTV). The EM tracking device consisted in an integrated Foley catheter with a transmitter in a dedicated lumen, which was placed before the first treatment fraction and removed after the last one. After the daily CBCT, the system monitored the transmitter position, and the beam delivery was interrupted whenever the displacement exceeded 2 mm. Organ motion mitigation was obtained by a rectal micro-enema and a 100 cc bladder filling. Acute toxicity was evaluated with Common Terminology Criteria for Adverse Events version 5 (CTCAE_v5) scale at baseline and during treatment.*Results Median age was 74 years (range 63-82). Intermediate and high risk prostate cancer accounted for 70% and 30% respectively. Median International Prostate Symptom Score (IPSS) score at baseline was 8 (range 2-14). Median PTV volume was 81.2 cc (range 48.9-128.5). Average total treatment time lasted 9.3 minutes (range 6-14), 5.8 minutes (range 3-9) for setup and 3.5 minutes (range 2-5) for beam delivery. In 41% of the monitored fractions, a new CBCT was mandated. The prostate was found within 1 mm from its initial position in 78.7% of the beam-on time, between 1 and 2 mm in 19.1%, and exceeds 2 mm only in 2.2%. All patients completed the treatment in the expected time and their compliance to the procedure was excellent. No clinically significant acute Grade 2 or higher GI (rectal) and GU toxicity was observed. Only one patient experienced acute Grade 1 GI toxicity, while acute Grade 1 GU toxicity occurred in five (50%) patients.*Conclusions Linac-based SBRT by means of VMAT-FFF technique coupled with daily image guidance including real-time EM tracking allowed dose-escalated treatment with negligible early side effects.*Clinical Relevance/Application The procedure was implemented rapidly and resulted well tolerated and less invasive than the surgically implanted transmitter.

RESULTS

Median age was 74 years (range 63-82). Intermediate and high risk prostate cancer accounted for 70% and 30% respectively. Median International Prostate Symptom Score (IPSS) score at baseline was 8 (range 2-14). Median PTV volume was 81.2 cc (range 48.9-128.5). Average total treatment time lasted 9.3 minutes (range 6-14), 5.8 minutes (range 3-9) for setup and 3.5 minutes (range 2-5) for beam delivery. In 41% of the monitored fractions, a new CBCT was mandated. The prostate was found within 1 mm from its initial position in 78.7% of the beam-on time, between 1 and 2 mm in 19.1%, and exceeds 2 mm only in 2.2%. All patients completed the treatment in the expected time and their compliance to the procedure was excellent. No clinically significant acute Grade 2 or higher GI (rectal) and GU toxicity was observed. Only one patient experienced acute Grade 1 GI toxicity, while acute Grade 1 GU toxicity occurred in five (50%) patients.

CLINICAL RELEVANCE/APPLICATION

The procedure was implemented rapidly and resulted well tolerated and less invasive than the surgically implanted transmitter.

SPR-RO-4   Combined Positron Emission Tomography-Computed Tomography And Magnetic Resonance Imaging For Response Evaluation In Patients With Squamous Cell Anal Carcinoma Treated With Curative-intent Chemoradiotherapy

Participants
Pratik Adusumilli, MBChB, Leeds, United Kingdom (*Presenter*) Nothing to Disclose

PURPOSE

The aim was to assess effectiveness of Fluorine-18 Fluorodeoxyglucose (FDG) positron emission tomography-computed tomography

(PET-CT) and magnetic resonance imaging (MRI) for response assessment post curative-intent chemoradiotherapy (CRT) in anal squamous cell carcinoma (ASCC) and evaluate their efficacy for risk stratification.*Methods and Materials Consecutive patients with ASCC treated with curative-intent CRT at a large tertiary referral centre between January 2018 and April 2020 were retrospectively identified. Patient demographics, treatment and follow-up information including progression free survival (PFS) and overall survival (OS) outcomes were collated. Imaging was evaluated by 3 Radiologists using qualitative response assessment criteria with consensus agreement. Two-proportion z-test was used to assess differences in diagnostic performance metrics (sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV), accuracy). Kaplan-Meier survival analysis (Mantel-Cox log-rank) was performed.*Results 75 patients with median follow-up of 17.8 months (range 5 - 32.6) were included. 52 (69.3%) female and 23 (30.7%) male, median age 62 years (range 35 - 85). 15/75 (20%) had persistent anorectal and/or nodal disease after CRT. 3 patients died, median time to death 6.2 months (range 5 - 18.3). MRI and PET-CT response assessment performance metrics were broadly similar. When considered in combination there were statistically significant improvements in performance (Accuracy 94.7%, PPV 78.9%, NPV 100%). Kaplan Meier analysis demonstrated significant differences in PFS between responders and non-responders at PET-CT (p=0.007), MRI (p=0.005) and consensus evaluation (p=0.000). Cox regression analysis of PFS demonstrated a lower hazard ratio (HR) and narrower 95% confidence intervals for consensus findings (HR=0.093, p=0.000).*Conclusions Combined PET-CT and MRI response assessment post CRT was a better predictor of subsequent outcome than either modality alone. This could have valuable clinical benefits by guiding personalized risk-adapted patient follow-up and warrants further evaluation in a prospective study.*Clinical Relevance/Application Combined imaging response assessment with PET-CT and MRI more effectively stratified patients and could have valuable clinical benefits by guiding personalized risk-adapted follow-up.

RESULTS

75 patients with median follow-up of 17.8 months (range 5 - 32.6) were included. 52 (69.3%) female and 23 (30.7%) male, median age 62 years (range 35 - 85). 15/75 (20%) had persistent anorectal and/or nodal disease after CRT. 3 patients died, median time to death 6.2 months (range 5 - 18.3). MRI and PET-CT response assessment performance metrics were broadly similar. When considered in combination there were statistically significant improvements in performance (Accuracy 94.7%, PPV 78.9%, NPV 100%). Kaplan Meier analysis demonstrated significant differences in PFS between responders and non-responders at PET-CT (p=0.007), MRI (p=0.005) and consensus evaluation (p=0.000). Cox regression analysis of PFS demonstrated a lower hazard ratio (HR) and narrower 95% confidence intervals for consensus findings (HR=0.093, p=0.000).

CLINICAL RELEVANCE/APPLICATION

Combined imaging response assessment with PET-CT and MRI more effectively stratified patients and could have valuable clinical benefits by guiding personalized risk-adapted follow-up.

SPR-RO-6   **Patterns Of Failure In Immunosuppressed Patients With Cutaneous Squamous Cell Carcinomas Of The Head And Neck Undergoing Adjuvant Radiotherapy**

Participants
Teresa Easwaran, MD,MS, Minneapolis, Minnesota (*Presenter*) Nothing to Disclose

PURPOSE

Chronically immunosuppressed patients are at higher risk for both the development and recurrence of cutaneous malignancies, which are associated with a more aggressive disease phenotype. Prior retrospective studies have demonstrated that cutaneous squamous cell carcinomas of the head and neck (cSCC-HN) in immunosuppressed patients have a 3-4 fold greater risk of locoregional disease recurrence compared to immunocompetent patients. In this study, we retrospectively examined a cohort of immunosuppressed patients with cSCC-HN, assessing patterns of recurrence based on treatment modalities.*Methods and Materials We retrospectively reviewed patients with cSCC-HN who had undergone either bone marrow transplant (BMT) or solid organ transplant (SOT) at the University of Minnesota between 2011-2020. Variables including demographics, tumor grade and stage, type of immunosuppression, treatment techniques and site of first recurrence were recorded. Categorical variables were tested using Fisher's exact test, and continuous variables were tested via the Wilcoxon rank-sum test. All statistical analysis was conducted using JMP Pro 15.2.*Results We identified a total of 174 patients treated for cSCC-HN with history of BMT (n=25) and SOT (n=149) with a median follow-up of 53.9 months [Range: 1.4-118.8 months]. The majority (89%) of patients had well-differentiated or intermediate-grade tumors, and clinical T1 or T2 tumors (85%). Mohs micrographic surgery (MMS) was the most frequently utilized treatment modality (n=137), followed by WLE +/- elective neck dissection (n=20). A total of 13 patients received adjuvant radiotherapy. A total of 50 patients developed recurrent disease. Isolated local recurrence was the most common site of initial failure (54%), followed by regional (20%), distant (12%) and loco-regional failure (6%). The majority of local recurrences occurred with MMS as the definitive surgical modality (76%). Of the 13 patients who received adjuvant radiotherapy, 1 patient developed a nodal recurrence, and 1 developed distant disease. Zero patients who underwent adjuvant radiotherapy developed local recurrence.*Conclusions Immunosuppressed patients with cSCC-HN have significantly worse treatment outcomes compared to immunocompetent patients. Despite a preponderance of early stage and low or intermediate grade disease within our selected patients, we observed high rates of disease recurrence with local recurrence predominating as the most common site of failure. We observed no local recurrences in our population who underwent adjuvant radiotherapy.*Clinical Relevance/Application Higher risk patients, such as those chronically immunosuppressed, may benefit from more upfront, aggressive therapeutic strategies for cSCC-HN.

RESULTS

We identified a total of 174 patients treated for cSCC-HN with history of BMT (n=25) and SOT (n=149) with a median follow-up of 53.9 months [Range: 1.4-118.8 months]. The majority (89%) of patients had well-differentiated or intermediate-grade tumors, and clinical T1 or T2 tumors (85%). Mohs micrographic surgery (MMS) was the most frequently utilized treatment modality (n=137), followed by WLE +/- elective neck dissection (n=20). A total of 13 patients received adjuvant radiotherapy. A total of 50 patients developed recurrent disease. Isolated local recurrence was the most common site of initial failure (54%), followed by regional (20%), distant (12%) and loco-regional failure (6%). The majority of local recurrences occurred with MMS as the definitive surgical modality (76%). Of the 13 patients who received adjuvant radiotherapy, 1 patient developed a nodal recurrence, and 1 developed distant disease. Zero patients who underwent adjuvant radiotherapy developed local recurrence.

CLINICAL RELEVANCE/APPLICATION

Higher risk patients, such as those chronically immunosuppressed, may benefit from more upfront, aggressive therapeutic strategies for cSCC-HN.

Sub-Events

SPR-CA-1 **Motion Distortion In ECG-gated Photon-counting CT: Resolution Mode-dependency In A Coronary Tree Phantom**

Participants
Jayasai Rajagopal, BA, Durham, North Carolina (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the impact of differing pixel size on motion distortion in a photon-counting CT system*Methods and Materials An investigational single source photon-counting CT scanner (CounT, Siemens, Germany) with ECG gating was used to image a custom coronary tree phantom with models of healthy, stenotic, and stented arteries. A cardiac motion simulator (QRM, Germany) which mimics motion in the x, y, and z-planes was used. Images were acquired with matched parameters (140 kV, 120 mAs) at rest and at 60 beats per minute. Additionally, repeated high dose stationary images (140 kV, 330 mAs) were averaged to generate a motion-free, reduced noise reference standard. Scans were completed at both standard (0.5mm2) and high-resolution (0.25 mm2) pixel sizes. Reconstructions were performed using a manufacturer's standard adaptive filter to maximize the resolution of images. Motion acquisitions were reconstructed at four phases: 0%, 25%, 50%, 75%. Regions of interest were drawn around vessels and the vessels automatically segmented. Difference from the reference standard image was evaluated for vessel diameter and vessel circularity. Sorensen-Dice coefficient (DSC) between the reference standard and stationary or motion images were compared between the two resolutions.*Results PCCT exhibited motion artifacts similar to those in conventional CT including increased variability in diameter and circularity measurements compared to stationary images. High-resolution and standard resolution images showed similar rates of degradation from the reference standard. The stenotic vessel showed more variation than healthy or stented vessels in both standard and high-resolution settings. High-resolution motion images had an average DSC of 0.56 compared to 0.59 for standard resolution motion images.*Conclusions High-resolution images exhibited motion distortion similar to that in standard resolution images suggesting that changes in pixel size have limited impact on motion distortion.*Clinical Relevance/Application Photon-counting CT permits higher resolution than is currently available. However, that advantage does not seem to influence motion associated with the ECG-gated imaging of a coronary tree phantom.

RESULTS

PCCT exhibited motion artifacts similar to those in conventional CT including increased variability in diameter and circularity measurements compared to stationary images. High-resolution and standard resolution images showed similar rates of degradation from the reference standard. The stenotic vessel showed more variation than healthy or stented vessels in both standard and high-resolution settings. High-resolution motion images had an average DSC of 0.56 compared to 0.59 for standard resolution motion images.

CLINICAL RELEVANCE/APPLICATION

Photon-counting CT permits higher resolution than is currently available. However, that advantage does not seem to influence motion associated with the ECG-gated imaging of a coronary tree phantom.

SPR-CA-10 **Automated Coronary Calcium Scoring In Non-gated Chest CT With Multiple Protocols: Direct Comparison To ECG-gated CT**

Participants
Jiangtao Yu, Wuhan, China (*Presenter*) Nothing to Disclose

PURPOSE

Although several artificial intelligence (AI)-based methods have been developed for coronary calcium (CAC) quantification in non-gated chest CT, their performance directly compared to reference scores in electrography (ECG) gated CAC scans has not been investigated.*Methods and Materials From 1st August 2019 to 31st July 2020, 586 patients underwent non-gated chest CT and ECG-gated CAC scoring CT in the same session were included in this retrospective study. An AI-based software based on 3D U-Net deep learning model was used for automated CAC scoring in non-gated chest CT. Dedicated ECG-gated CAC scoring was severed as a reference, and Agatston score risk categories was defined as follows:0, 1-10, 11-100,101-400 and >400. The agreement and reliability between two methods and accuracy of automated method for risk categorization was determined. The analyses were performed for all non-gated scans, and scans at tube voltage of 100KVp and 120KVp separately.*Results Bland-Altman showed good agreement between automated method and the reference regardless CAC score in non-gated CT was slightly underestimated. The mean difference was -7.9, -1.7, -12.6 for all non-gated scans, non-gated scans at 100KVp and 120KVp respectively. The limits of agreement were narrower for automated software with respect to CAC scoring for all non-gated scans and scans at 100KVp. The reliability for AI-based software in relation to dedicate ECG-gated CAC scoring was excellent, the ICCs were 0.98(P<0.001) for all scans, and 0.98(P<0.001) for scans at 100KV and 0.97 (P<0.001) at 120KV, respectively. AI-based software showed a weighted ? values of 0.87(P<0.001), 0.84(P<0.001) and 0.89(P<0.001) and the accuracy of 83.8%,80.7% and 86.1% for all scans, scans at 100KVp and 120KVp, respectively. Particularly for diagnosis power of CAC of zero, 4 non-gated scans at 100KVp and 3 scans at 120KVp were misclassified into non-zero Agatston score group, the false positivity was 2.9% (4/137) and 1.6% (3/183) respectively. AI-based software missed CAC lesions in 17 non-gated scans at 100KVp and 18 scans at 120KVp, the false negativity

was 15.3% (17/111) and 11.6% (18/155).*Conclusions AI-based automated CAC scores in diverse non-gated chest CT was in good concordance with reference standard, and accurate for cardiovascular diseases risk categorizations. However, it should be continuously improved to deal with challenging non-gated scans.*Clinical Relevance/Application Since current evidence with respect to CAC score in cardiac risk prediction was mainly based on dedicated ECG-gated scans, this head-to-head comparison would facilitate the automated CAC scoring in daily routine chest CT examination, and patients would benefit from the evaluation without additional radiation exposure.

RESULTS

Bland-Altman showed good agreement between automated method and the reference regardless CAC score in non-gated CT was slightly underestimated. The mean difference was -7.9, -1.7, -12.6 for all non-gated scans, non-gated scans at 100KVp and 120KVp respectively. The limits of agreement were narrower for automated software with respect to CAC scoring for all non-gated scans and scans at 100KVp. The reliability for AI-based software in relation to dedicate ECG-gated CAC scoring was excellent, the ICCs were 0.98(P<0.001) for all scans, and 0.98(P<0.001) for scans at 100KV and 0.97 (P<0.001) at 120KV, respectively. AI-based software showed a weighted ? values of 0.87(P<0.001), 0.84(P<0.001) and 0.89(P<0.001) and the accuracy of 83.8%,80.7% and 86.1% for all scans, scans at 100KVp and 120KVp, respectively. Particularly for diagnosis power of CAC of zero, 4 non-gated scans at 100KVp and 3 scans at 120KVp were misclassified into non-zero Agatston score group, the false positivity was 2.9% (4/137) and 1.6% (3/183) respectively. AI-based software missed CAC lesions in 17 non-gated scans at 100KVp and 18 scans at 120KVp, the false negativity was 15.3% (17/111) and 11.6% (18/155).

CLINICAL RELEVANCE/APPLICATION

Since current evidence with respect to CAC score in cardiac risk prediction was mainly based on dedicated ECG-gated scans, this head-to-head comparison would facilitate the automated CAC scoring in daily routine chest CT examination, and patients would benefit from the evaluation without additional radiation exposure.

SPR-CA-11 Identify Ischemic, Infarcted, Hibernant, And Normal Myocardium By Stress And Rest T1 Mapping Without The Application Of Gadolinium Contrast Agents

Participants
Baiyan Zhuang, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

In chronic coronary artery disease (CAD), accurate detection of ischemic and hibernant myocardium is important because targeted revascularization improves clinical outcomes. T1 mapping using cardiac magnetic resonance (CMR) is sensitive to the changes in myocardial water content, including myocardial blood volume [1]. The aim of this study was to evaluate the potential of T1 mapping at rest and during adenosine triphosphate stress for the detection of ischemic, hibernant and infarct myocardium in a swine model using pathology as gold reference.*Methods and Materials Twelve adult male Chinese miniature swine aged 6-12 months with the induction of chronic coronary artery stenosis were enrolled in this study. The CMR imaging was performed at four time points: baseline, 1 week-, 2 weeks- and 4 weeks- after surgery. Pre- and post-contrast T1 mapping at rest and during adenosine triphosphate stress, first-pass perfusion and stress perfusion as well as late gadolinium enhancement were performed at all imaging time points. Myocardial perfusion reserve index (MPRI), stress MBF (myocardial blood flow) and MPR (myocardial perfusion reserve) as the ratio of stress to rest MBF were calculated. The native T1, extracelluar volume (ECV) and their percentage were also calculated based on T1 mapping.*Results The rest native T1 value of infarct, hibernant, ischemia and normal myocardium were 1586.4±159.0ms, 1350.7±165.5ms, 1218.8±153.4ms, 1101.8±107.7ms, respectively. The rest ECV value of infarct, hibernant, ischemia and normal myocardium were 73.89±8.27, 40.25±7.77, 34.09±3.00, 24.48±2.71, respectively. MPRI was associated with the change of native T1 (stress native T1 minus rest native T1, ?native T1) (r=-0.45, p=0.005) and native T1 percentage (?native T1/ rest native T1) (r=-0.50, p=0.034). Besides, there were correlation observed between MPRI and the change of ECV (r=-0.41, p<0.001) and ECV percentage (r=-0.41, p=0.005). It was also observed that MPR was associated with rest and stress native T1 (p<0.001, r=-0.634, -0.766 respectively).*Conclusions In this study, we identified the native T1 and ECV values of four myocardium types in chronic ischemic cardiomyopathy. The rest/stress T1 mapping has the potential to detect ischemia and hibernation without the need for gadolinium contrast.*Clinical Relevance/Application CMR rest/ stress native T1 mapping is a novel diagnostic test that can evaluate ischemic myocardium in coronary artery disease (CAD) which can target revascularization. Native T1 mapping doesn't need contrast, thus, could be used in renal insufficiency patients and could avoid unnecessary ICA, anaphylaxis and contrast deposit.

RESULTS

The rest native T1 value of infarct, hibernant, ischemia and normal myocardium were 1586.4±159.0ms, 1350.7±165.5ms, 1218.8±153.4ms, 1101.8±107.7ms, respectively. The rest ECV value of infarct, hibernant, ischemia and normal myocardium were 73.89±8.27, 40.25±7.77, 34.09±3.00, 24.48±2.71, respectively. MPRI was associated with the change of native T1 (stress native T1 minus rest native T1, ?native T1) (r=-0.45, p=0.005) and native T1 percentage (?native T1/ rest native T1) (r=-0.50, p=0.034). Besides, there were correlation observed between MPRI and the change of ECV (r=-0.41, p<0.001) and ECV percentage (r=-0.41, p=0.005). It was also observed that MPR was associated with rest and stress native T1 (p<0.001, r=-0.634, -0.766 respectively).

CLINICAL RELEVANCE/APPLICATION

CMR rest/ stress native T1 mapping is a novel diagnostic test that can evaluate ischemic myocardium in coronary artery disease (CAD) which can target revascularization. Native T1 mapping doesn't need contrast, thus, could be used in renal insufficiency patients and could avoid unnecessary ICA, anaphylaxis and contrast deposit.

SPR-CA-12 Detection Of Potentially Salvageable Myocardium In Acute Myocardial Infarcts: Tissue Characteristics And Functional Improvement Of Gray Areas On Late-gadolinium-enhanced, Parametric Mapping, And Cine MR Imaging On Initial And Follow-up Scans

Participants
Jun Cheol Park, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

We hypothesized that less-damaged myocardial tissue included in the hyperenhanced areas of acute myocardial infarcts (AMI) on late-gadolinium-enhanced MR imaging (LGE) could be further differentiated with the degree of signal intensity on LGE and T1- and T2-parametric mapping. We sought to correlate the areas with gray or white signal intensity on LGE on initial MR imaging with global

and segmental systolic functional recovery on follow-up imaging.*Methods and Materials This retrospective study included 55 patients with AMI who had undergone initial and follow-up (mean follow-up duration, 8.0 ± 5.1 months) cardiac MR imaging. The areas of AMI were classified into two groups according to the severity of the signal intensities of myocardial infarcts on LGE as gray or white AMI by visual analysis. Patients were divided into two groups according to the amount of gray AMI (GAMI): group 1 with GAMI = 33% of total volume of AMI, group 2 with GAMI < 33% of total volume of AMI. Initial, follow-up, and changes in global and segmental left ventricular function were assessed by comparing LV function parameters on cine MR imaging.*Results There were 47 patients (85.5%) with mixed GAMI and WAMI, 6 patients (10.9%) with WAMI only, and 2 patients (3.6%) with GAMI only. GAMI and WAMI showed significant differences in signal intensity ratio compared with remote normal myocardium (2.07 vs. 3.88, p<0.001), T1 relaxation times (1102 ms vs. 1224 ms, p<0.001), T2 relaxation times (57 ms vs. 72 ms, p < 0.001), and extracellular volume fraction (35% vs. 55%, p = 0.002). The percentage of AMI over total myocardial volume (volume [%]) proportionately decreased on follow-up as compared with initial volume (%) by 63.5% and 28.9% in group 1 and group 2 (p < 0.001). Global LV ejection fraction significantly differed between two groups ([initial CMR: group 1, 62.2%; group 2, 50.2%; p < 0.001]. [follow-up CMR, group 1, 67.7%; group 2, 55.1%; p < 0.001). Systolic wall thickening in segments with = 50% depth of AMI was significantly differed between the segments with GAMI = 50% depth of thickness and those with GAMI < 50% depth of thickness on initial (43.2% vs. 23.8%, p < 0.001) and follow-up (74.3% vs. 39.9%, p = 0.006) CMR.*Conclusions GAMI beneficially contributes to LV function in AMI patients and can be considered as a potentially salvageable myocardium.*Clinical Relevance/Application AMI with lower signal intensity (SI) on LGE implicates better functional recovery than that with higher SI on LGE.

RESULTS

There were 47 patients (85.5%) with mixed GAMI and WAMI, 6 patients (10.9%) with WAMI only, and 2 patients (3.6%) with GAMI only. GAMI and WAMI showed significant differences in signal intensity ratio compared with remote normal myocardium (2.07 vs. 3.88, p<0.001), T1 relaxation times (1102 ms vs. 1224 ms, p<0.001), T2 relaxation times (57 ms vs. 72 ms, p < 0.001), and extracellular volume fraction (35% vs. 55%, p = 0.002). The percentage of AMI over total myocardial volume (volume [%]) proportionately decreased on follow-up as compared with initial volume (%) by 63.5% and 28.9% in group 1 and group 2 (p < 0.001). Global LV ejection fraction significantly differed between two groups ([initial CMR: group 1, 62.2%; group 2, 50.2%; p < 0.001]. [follow-up CMR, group 1, 67.7%; group 2, 55.1%; p < 0.001). Systolic wall thickening in segments with = 50% depth of AMI was significantly differed between the segments with GAMI = 50% depth of thickness and those with GAMI < 50% depth of thickness on initial (43.2% vs. 23.8%, p < 0.001) and follow-up (74.3% vs. 39.9%, p = 0.006) CMR.

CLINICAL RELEVANCE/APPLICATION

AMI with lower signal intensity (SI) on LGE implicates better functional recovery than that with higher SI on LGE.

SPR-CA-13 Diagnostic Accuracy Of Myocardial Enhancement Ratio To Aorta Assumed Static Computed Tomography Perfusion For Identification Of Myocardial Ischemia

Participants
Takanori Kouchi, Toon, Japan (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this study was to evaluate the feasibility of myocardial enhancement ratio to aorta (MER) using stress dynamic computed tomography perfusion (CTP) for the detection of myocardial ischemia assessed by single photon emission computed tomography (SPECT).*Methods and Materials Nineteen patients who underwent dynamic CTP and SPECT for suspicion of myocardial ischemia were retrospectively evaluated. One static CTP image was selected from dynamic CTP images at sub-optimal phase for detecting myocardial ischemia. MER was calculated on a segment-based analysis by dividing myocardial enhancement (HU) obtained the static CTP image by peak enhancement of the ascending aorta (HU) in the timing bolus scan. Additionally, myocardial CT attenuation (HU) and transmural perfusion ratio (TPR) were also calculated as another quantitative parameter for the static CTP imaging. The diagnostic performance of MER, TPR, and myocardial CT attenuation were analyzed for detecting myocardial ischemia assessed by SPECT, and compared by receiver operating characteristic (ROC) analysis among MER, TPR, and myocardial CT attenuation.*Results Fifty-two of 304 segments (17%) had myocardial ischemia. MER, TPR and myocardial CT attenuation in ischemic segments were significantly lower than that in normal segments (MER; 0.65 (0.51-0.79) vs. 0.99 (0.88-1.11), TPR; 0.88 (0.76-0.96) vs. 1.00 (0.96-1.04), myocardial CT attenuation; 111 (95-126) HU vs. 131 (117-145) HU, p <0.05 in each). The area under the ROC curve of MER was significantly higher than both TPR (0.86 vs. 0.77, p <0.05) and myocardial CT attenuation (0.86 vs. 0.73, p <0.05) for identifying myocardial ischemia assessed by SPECT. Sensitivity, specificity, and accuracy were 79%, 86% and 85% for MER (cut-off: 0.81), 67%, 85% and 82% for TPR (cut-off: 0.92), and 79%, 60% and 63% for myocardial CT attenuation (cut-off: 127), respectively.*Conclusions MER assumed static CTP may be feasible for detecting myocardial ischemia assessed by SPECT, and had significantly higher diagnostic performance than conventional quantitative parameter of TPR and myocardial CT attenuation.*Clinical Relevance/Application MER is a novel quantitative parameter for static myocardial CTP imaging with high diagnostic accuracy. MER has a potential to contribute to reducing radiation dose associated with myocardial CTP imaging by encouraging the use of static CTP imaging instead of dynamic CTP imaging.

RESULTS

Fifty-two of 304 segments (17%) had myocardial ischemia. MER, TPR and myocardial CT attenuation in ischemic segments were significantly lower than that in normal segments (MER; 0.65 (0.51-0.79) vs. 0.99 (0.88-1.11), TPR; 0.88 (0.76-0.96) vs. 1.00 (0.96-1.04), myocardial CT attenuation; 111 (95-126) HU vs. 131 (117-145) HU, p <0.05 in each). The area under the ROC curve of MER was significantly higher than both TPR (0.86 vs. 0.77, p <0.05) and myocardial CT attenuation (0.86 vs. 0.73, p <0.05) for identifying myocardial ischemia assessed by SPECT. Sensitivity, specificity, and accuracy were 79%, 86% and 85% for MER (cut-off: 0.81), 67%, 85% and 82% for TPR (cut-off: 0.92), and 79%, 60% and 63% for myocardial CT attenuation (cut-off: 127), respectively.

CLINICAL RELEVANCE/APPLICATION

MER is a novel quantitative parameter for static myocardial CTP imaging with high diagnostic accuracy. MER has a potential to contribute to reducing radiation dose associated with myocardial CTP imaging by encouraging the use of static CTP imaging instead of dynamic CTP imaging.

SPR-CA-14 Correlation Of Myocardial Strain And Late Gadolinium Enhancement By Cardiac Magnetic Resonance After ST-segment Elevation Myocardial Infarction: A Sub-analysis Of OCTAMI

Participants
Shiqin Yu, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the correlation of cardiac magnetic resonance (CMR) feature-tracking with conventional CMR parameters in patients with ST-segment elevation myocardial infarction (STEMI).*Methods and Materials This sub-analysis of OCTAMI registry included 129 patients who finished a CMR follow-up one month after STEMI. Cine images were applied to calculate both global and segmental left ventricular peak strain parameters. The patients were divided into two groups by left ventricular ejection fraction (LVEF) and compared with 42 healthy controls. Segmental late gadolinium enhancement (LGE) was graded according to LGE transmurality as follows (1) > 0 to = 25% (2) > 25 to = 50% (3) > 50 to = 75% and (4) > 75%. Left ventricle was divided into infarcted, adjacent and remote region to assess regional function.*Results Compared with controls, global radial (28.39±5.08% vs 38.54±9.27%, p<0.05), circumferential (-16.91±2.11% vs -20.77±2.78%, p<0.05) and longitudinal (-13.06±2.15 vs -15.52±2.69, p<0.05) strain were impaired in STEMI patients with normal LVEF (=55%). Strain parameters were strongly associated with LGE (radial: r=0.65; circumferential: r=0.69; longitudinal: r=0.61; all p<0.05). A significant and stepwise impairment of global strains was observed in groups divided by LGE tertiles. Furthermore, segmental strain was different in various degree of LGE extent especially for radial and circumferential strain. Strains of adjacent region were better than infarcted region in radial and circumferential directions and worse than remote region in all three directions.*Conclusions Both global and regional strain could stratify different extent of LGE. Although without LGE, adjacent region had impaired strains comparing with remote region.*Clinical Relevance/Application CMR feature-tracking could permit detecting decline in left ventricular function with preserved LVEF and discriminating different degrees of myocardial infarction assessed by LGE. And CMR feature-tracking is a potential supplement to LVEF and LGE for assessment in STEMI patients.

RESULTS

Compared with controls, global radial (28.39±5.08% vs 38.54±9.27%, p<0.05), circumferential (-16.91±2.11% vs -20.77±2.78%, p<0.05) and longitudinal (-13.06±2.15 vs -15.52±2.69, p<0.05) strain were impaired in STEMI patients with normal LVEF (=55%). Strain parameters were strongly associated with LGE (radial: r=0.65; circumferential: r=0.69; longitudinal: r=0.61; all p<0.05). A significant and stepwise impairment of global strains was observed in groups divided by LGE tertiles. Furthermore, segmental strain was different in various degree of LGE extent especially for radial and circumferential strain. Strains of adjacent region were better than infarcted region in radial and circumferential directions and worse than remote region in all three directions.

CLINICAL RELEVANCE/APPLICATION

CMR feature-tracking could permit detecting decline in left ventricular function with preserved LVEF and discriminating different degrees of myocardial infarction assessed by LGE. And CMR feature-tracking is a potential supplement to LVEF and LGE for assessment in STEMI patients.

SPR-CA-16 Fractal Analysis Of 4D CT Myocardial Perfusion Imaging To Differentiate Macro- And Microvascular Causes Of Chronic Ischemia: A Multicenter Validation Study

Participants
Florian Michallek, Berlin, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Noninvasive differentiation of epicardial stenosis and microvascular causes of chronic myocardial ischemia is challenging. In this report, we validate previously established fractal analysis for the differentiation of macrovascular and microvascular chronic myocardial ischemia by quantifying chaos of perfusion patterns using the fractal dimension (FD).*Methods and Materials A total of 101 patients with suspected chronic myocardial ischemia and indication for invasive coronary angiography (ICA) underwent dual-source CT imaging workup including CT angiography, dynamic 4D perfusion CT (CTP) with i.v. adenosine stress testing and delayed enhancement (DE) imaging in a prospective multicenter study. ICA constituted the reference standard for differentiating macro- and microvascular ischemia. We defined macrovascular ischemia as visual =90% diameter stenosis on ICA, or =50% diameter stenosis and positive fractional flow reserve (FFR) (<0.8) alongside a perfusion defect in the downstream myocardium on CTP. Microvascular ischemia was defined as appreciable myocardial perfusion defect on CTP without criteria for macrovascular ischemia. Per-segment analysis was performed using the 17-segments model of the American Heart Association (AHA). Segments with signs of DE were excluded. Diagnostic accuracy of fractal analysis was evaluated by sensitivity, specificity and area under the receiver operating characteristic curve (AUC).*Results From a total of 1717 myocardial segments in 101 patients, 560 segments showed an appreciable perfusion defect on CTP with prevalences of n=185 for macrovascular and n=375 for microvascular ischemia. Fractal analysis identified perfusion patterns with a highly significant statistical difference (p<0.001): median FD was 4.26 (interquartile range [IQR]: 0.05) in macrovascular ischemia, and 4.36 (IQR: 0.05) in microvascular ischemia. The previously established FD threshold for differentiation of macro- from microvascular ischemia (FD<4.31) achieved a per-segment sensitivity of 0.93 (0.88-0.96) and specificity of 0.82 (0.78-0.86) with AUC of 0.90 (0.87-0.93) in diagnosing macro- over microvascular ischemia.*Conclusions In a prospective multicenter cohort with high prevalence of microvascular ischemia, fractal analysis of 4D CT perfusion accurately differentiated macro- and microvascular causes of myocardial ischemia.*Clinical Relevance/Application Fractal analysis of CTP might be used as a noninvasive gatekeeper test prior to invasive testing to pivot ICA indications.

RESULTS

From a total of 1717 myocardial segments in 101 patients, 560 segments showed an appreciable perfusion defect on CTP with prevalences of n=185 for macrovascular and n=375 for microvascular ischemia. Fractal analysis identified perfusion patterns with a highly significant statistical difference (p<0.001): median FD was 4.26 (interquartile range [IQR]: 0.05) in macrovascular ischemia, and 4.36 (IQR: 0.05) in microvascular ischemia. The previously established FD threshold for differentiation of macro- from microvascular ischemia (FD<4.31) achieved a per-segment sensitivity of 0.93 (0.88-0.96) and specificity of 0.82 (0.78-0.86) with AUC of 0.90 (0.87-0.93) in diagnosing macro- over microvascular ischemia.

CLINICAL RELEVANCE/APPLICATION

Fractal analysis of CTP might be used as a noninvasive gatekeeper test prior to invasive testing to pivot ICA indications.

SPR-CA-17 Cardiac Stress Perfusion For Assessment Of Cardiac Allograft Vasculopathy After Heart Transplantation

Participants
Yura Ahn, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To determine the role of stress myocardial CT perfusion (CTP) in identifying cardiac allograft vasculopathy (CAV)*Methods and Materials From December 2018 to April 2021, eighty heart transplant patients (59 male, age range of 18-76 years) underwent coronary angiography, intravascular ultrasound, and CTP. Two radiologists independently segmented the myocardium and measured the myocardial blood flow (MBF) in whole myocardium and in each 16 segments. Two cardiologists independently assessed and made consensus of the presence of CAV based on coronary angiography and intravascular ultrasound. The perfusion parameters was compared between patient with and without CAV. The receiver-operating characteristics analysis was performed to evaluate the diagnostic accuracy of CTP.*Results The CAV was diagnosed in 43 of 80 patients. Patients with CAV had significantly lower MBF than patient without CAV (MBF of whole myocardium, 146 ± 35 vs. 127 ± 30 mL/100mL/min, P=0.014; MBF of average of 16 myocardial segments, 141 ± 35 vs. 124 ± 32 mL/100mL/min, P=0.026). The area under the ROC curve for predicting CAV was 0.65.*Conclusions CTP revealed differences in MBF to CAV status in heart transplant patients, reflecting their histopathology.*Clinical Relevance/Application CTP is a noninvasive modality which could give the information predicting CAV, the major long-term complication in heart transplantation.

RESULTS

The CAV was diagnosed in 43 of 80 patients. Patients with CAV had significantly lower MBF than patient without CAV (MBF of whole myocardium, 146 ± 35 vs. 127 ± 30 mL/100mL/min, P=0.014; MBF of average of 16 myocardial segments, 141 ± 35 vs. 124 ± 32 mL/100mL/min, P=0.026). The area under the ROC curve for predicting CAV was 0.65.

CLINICAL RELEVANCE/APPLICATION

CTP is a noninvasive modality which could give the information predicting CAV, the major long-term complication in heart transplantation.

SPR-CA-19   Diagnostic Accuracy Of Subtraction Coronary CT Angiography In Patients With Severe Calcification Or Stents: Comparison Between Readers With Different Levels Of Experience

Participants
Fang Li, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

Subtraction coronary CT angiography (CCTA) may reduce blooming and beam-hardening artefacts. This study aimed to assess its value in improving the diagnostic accuracy and confidence of readers with different levels of CCTA imaging interpretation experience.*Methods and Materials We prospectively enrolled patients with severe calcification or stents who underwent CCTA and invasive coronary angiography (ICA). Target segment images were independently evaluated by three groups of radiologists with different experience levels with CCTA using ICA as the standard reference. Diagnostic accuracy was measured by the area under the curve (AUC), using =50% stenosis as the cut-off value. Diagnostic confidence was computed for each radiologist and each reading group with different levels of experience.*Results In total, 146 target segments with severe calcification or stents from 51 patients were analysed. The mean specificity of conventional CCTA for each group ranged from 22.1%-41.4% on a per-segment basis and 2.9-9.8 on a per-patient basis, which significantly improved following the inclusion of subtraction CCTA (range, 81.9%-85.4%; 52.9%-74.3%; all p<0.001). Following calcification subtraction, the mean sensitivity significantly decreased for novice (p<0.001). Following the addition of subtraction CCTA , the mean AUCs of subtraction CCTA were significantly increased, values ranged from 0.53,0,54 and 0.61 to 0.70, 0.74 and 0.85 for novice, junior, and senior groups on a per-segment basis ; and ranged from 0.52,0,50 and 0.53 to 0.73, 0.77 and 0.71 on a per-patient basis (all p<0.001). For conventional CCTA, the mean diagnostic confidence was 2.5±1.0, 3.2±0.7, and 2.6±0.7 for the novice, junior and senior reading groups, respectively. Comparatively, each reading group showed significantly stronger diagnostic confidence with subtraction CCTA, with mean values of 3.4±0.8, 3.9±0.9, and 4.5±0.7 (all p<0.001).*Conclusions Subtraction CCTA could improve the diagnostic accuracy and diagnostic confidence of radiologists at all experience levels of coronary angiography interpretation. Senior readers performed better than novices in evaluating lumen stenosis on subtraction CCTA images.*Clinical Relevance/Application Subtraction CCTA could improve the diagnostic accuracy and diagnostic confidence of radiologists at all experience levels of coronary angiography interpretation.

RESULTS

In total, 146 target segments with severe calcification or stents from 51 patients were analysed. The mean specificity of conventional CCTA for each group ranged from 22.1%-41.4% on a per-segment basis and 2.9-9.8 on a per-patient basis, which significantly improved following the inclusion of subtraction CCTA (range, 81.9%-85.4%; 52.9%-74.3%; all p<0.001). Following calcification subtraction, the mean sensitivity significantly decreased for novice (p<0.001). Following the addition of subtraction CCTA , the mean AUCs of subtraction CCTA were significantly increased, values ranged from 0.53,0,54 and 0.61 to 0.70, 0.74 and 0.85 for novice, junior, and senior groups on a per-segment basis ; and ranged from 0.52,0,50 and 0.53 to 0.73, 0.77 and 0.71 on a per-patient basis (all p<0.001). For conventional CCTA, the mean diagnostic confidence was 2.5±1.0, 3.2±0.7, and 2.6±0.7 for the novice, junior and senior reading groups, respectively. Comparatively, each reading group showed significantly stronger diagnostic confidence with subtraction CCTA, with mean values of 3.4±0.8, 3.9±0.9, and 4.5±0.7 (all p<0.001).

CLINICAL RELEVANCE/APPLICATION

Subtraction CCTA could improve the diagnostic accuracy and diagnostic confidence of radiologists at all experience levels of coronary angiography interpretation.

SPR-CA-20   Performance Of Machine Learning-based Coronary Computed Tomography Angiography For Selecting The Revascularization Candidates

Participants
Zengfa Huang, Wuhan, China (*Presenter*) Nothing to Disclose

PURPOSE

The study investigated the performance of machine learning based coronary computed tomography angiography (ML-CCTA) for therapeutic decision compared with invasive coronary angiography (ICA) based on 2018 European Society of Cardiology/European Association for Cardio-Thoracic Surgery (ESC/EACTS) guidelines.*Methods and Materials The study population consisted of 322 consecutive stable CAD patients with an interval of less than 30 days between CCTA and ICA who were divided as a test set was included from July 2017 to July 2019 for the final analysis. The therapeutic strategy and the appropriate revascularization procedure were selected using ML-CCTA, CCTA and ICA independently.*Results When using ICA as a standard reference, the sensitivity, specificity, PPV (positive predictive value), NPV (negative predictive value) and accuracy of ML-CCTA for selecting revascularization candidates were 87.01%, 96.43%, 95.71%, 89.01% and 91.93%, respectively. The AUC (area under the curve)

was 0.92 (95% CI: 0.88-0.95). The diagnostic performance of ML-CCTA for selecting PCI (percutaneous coronary intervention) candidates were 79.41%, 97.24%, 88.52%, 94.64% and 93.48%, respectively. The AUC was 0.88 (95% CI: 0.84-0.92). The diagnostic performance of ML-CCTA for selecting CABG (coronary artery bypass graft) candidates were 84.88%, 97.46%, 92.41%, 94.65% and 94.10%, respectively. The AUC was 0.91 (95% CI: 0.88-0.94).*Conclusions ML-CCTA had the ability to distinguish between patients who need revascularization or not and to make the appropriate decision for patients with revascularization strategy selection compared with traditional ICA.*Clinical Relevance/Application ML-CCTA enables the decision making to be performed rapidly within a clinical workflow. ML-CCTA had the ability to distinguish between patients who need revascularization or not and to make the appropriate decision for patients with revascularization strategy selection compared with traditional ICA.

RESULTS

When using ICA as a standard reference, the sensitivity, specificity, PPV (positive predictive value), NPV (negative predictive value) and accuracy of ML-CCTA for selecting revascularization candidates were 87.01%, 96.43%, 95.71%, 89.01% and 91.93%, respectively. The AUC (area under the curve) was 0.92 (95% CI: 0.88-0.95). The diagnostic performance of ML-CCTA for selecting PCI (percutaneous coronary intervention) candidates were 79.41%, 97.24%, 88.52%, 94.64% and 93.48%, respectively. The AUC was 0.88 (95% CI: 0.84-0.92). The diagnostic performance of ML-CCTA for selecting CABG (coronary artery bypass graft) candidates were 84.88%, 97.46%, 92.41%, 94.65% and 94.10%, respectively. The AUC was 0.91 (95% CI: 0.88-0.94).

CLINICAL RELEVANCE/APPLICATION

ML-CCTA enables the decision making to be performed rapidly within a clinical workflow. ML-CCTA had the ability to distinguish between patients who need revascularization or not and to make the appropriate decision for patients with revascularization strategy selection compared with traditional ICA.

SPR-CA-22   Reference Values Of Myocardial Native T1 And Extracellular Volume Fraction In Healthy Subjects At 3-Tesla Cardiac Magnetic Resonance Imaging: Standardization With Phantom-based Correction

Participants
Young Joo Suh, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

We aimed to provide reference values of myocardial native T1 and extracellular volume (ECV) fraction in healthy subjects and investigate the effect of the phantom-based correction method for standardization of myocardial T1 value.*Methods and Materials Seventy-one healthy asymptomatic adult (= 20 years) volunteers of 5 different age groups (34 men and 37 women, mean age 45.5 ± 15.5 years) were prospectively enrolled from three academic hospitals. Cardiac magnetic resonance imaging including Modified Look-Locker Inversion recovery T1 mapping sequence was performed using a 3-Tesla system with different type of scanner for each hospital. Native T1 and ECV fraction were measured at short-axis T1 map and analyzed for the mean values of the entire 16 segment. T1MES phantom was scanned and blood and myocardial T1 value of the each subject was corrected based on the site-specific equation derived from T1MES phantom. Mean native T1 and ECV fraction were compared between values before and after phantom-based correction using one-way analysis of variance, and variability in native T1 and ECV fraction among institutions were compared using a coefficient of variation (COV).*Results Mean native T1 value was significantly different between three institutions (1198.7 ± 32.1 ms for institution A, 1217.7 ± 39.9 ms for institution B, and 1232.7 ± 31.1 ms for institution C; P=0.002), but mean ECV was not significantly different between institutions (26.6-27.5%,P=0.355). After phantom-based correction, mean native T1 was 1289.7 ± 32.4 ms and ECV 25.0 ± 2.7% for all subjects. Corrected native T1 value was not significantly different between three institutions (1284.6 ± 31. 5 ms for institution A, 1296.5 ± 39.1 ms for institution B, and 1291.3 ± 29.3 ms for institution C; P=0.497), and ECV was also not significantly different between institutions (24.1-25.9%, P=0.078). After phantom-based correction, COV for native T1 value between three institutions was decreased from 3.0% to 2.5. Native T1 was longer in female compared to male up to the age of 40 years, after which there was no significant difference according to the sex.*Conclusions Standardized reference T1 values can be provided with phantom-based correction method in healthy subjects.*Clinical Relevance/Application Phantom-based correction method may allow standardization of myocardial T1 values, which can facilitate the application of T1 mapping in multi-institutional, large-scale clinical trials.

RESULTS

Mean native T1 value was significantly different between three institutions (1198.7 ± 32.1 ms for institution A, 1217.7 ± 39.9 ms for institution B, and 1232.7 ± 31.1 ms for institution C; P=0.002), but mean ECV was not significantly different between institutions (26.6-27.5%,P=0.355). After phantom-based correction, mean native T1 was 1289.7 ± 32.4 ms and ECV 25.0 ± 2.7% for all subjects. Corrected native T1 value was not significantly different between three institutions (1284.6 ± 31. 5 ms for institution A, 1296.5 ± 39.1 ms for institution B, and 1291.3 ± 29.3 ms for institution C; P=0.497), and ECV was also not significantly different between institutions (24.1-25.9%, P=0.078). After phantom-based correction, COV for native T1 value between three institutions was decreased from 3.0% to 2.5. Native T1 was longer in female compared to male up to the age of 40 years, after which there was no significant difference according to the sex.

CLINICAL RELEVANCE/APPLICATION

Phantom-based correction method may allow standardization of myocardial T1 values, which can facilitate the application of T1 mapping in multi-institutional, large-scale clinical trials.

SPR-CA-26   Correlation Between Non-contrast Chest CT Findings And Clinical Outcomes In Hospitalized Patients With COVID-19 Pneumonia With Positive PCR For SARS-Cov-2 During The First Wave

Participants
Jaime Verdugo, MD, Santiago, Chile (*Presenter*) Nothing to Disclose

PURPOSE

As the global Covid-19 pandemic continues, current efforts have shifted to determine early prognostic factors that may tailor the therapeutic options and subsequent mortality risk. Recent studies have shown a close relationship between cardiovascular (CV) risks and infected patients' evolution. Imaging biomarkers such as coronary artery calcium (CAC) score have an established role in long-term CV event risk stratification but might also provide prognostic information. The purpose of this study is to evaluate the relation between non-contrast chest CT findings and clinical outcomes on a representative sample of inpatients with Covid-19 during the first wave of the pandemic.*Methods and Materials This IRB-approved clinical series included 326 cases with a mean age of 56.8 years +/-16.5, ranging from 17 to 93 years hospitalized between May 1 and June 31. CT images were retrospectively analyzed, and multiple CT variables registered, such as the RSNA-STR-ACR Consensus Statement pattern, presence of organizing

pattern (OP), presence of CAC, total volume and average density of the pulmonary opacities (PO), lung injury extent, and average density of the liver, among others. On those with measurable CAC, Agatston Score (AS) from non-ECG gated chest CT was calculated using semi-automated software (SyngoVia). After a stepwise selection with a probability threshold of 10%, multivariable logistic regression was modeled to evaluate these variables' relationship, using patient outcomes as a dependent variable.*Results Of the 326 cases, 103 had CAC, with a mean score of 486 UA (SD 965 range: 2 - 5648 UA). In multivariate regression, the findings related to a higher mortality odd were the absence of an OP, a high average density of PO, and CAC in the LM and the RCA (table). Mortality risk was directly associated with AS values; for every 100 AU increase, the risk of dying increased by 5% (p-value= 0.003). The discrimination capacity is 60%. Hepatic steatosis was related to a greater probability of climbing on the therapeutic scale (OR: 1.89 p: 0.043 95% CI: 1.02 - 3.52), but there was no relation with a greater probability of dying.*Conclusions COVID-19 patients with CAC had a higher risk of dying, and the risk increased as AS value climb. The absence of OP, the higher average density of PO, and the presence of CAC in the LM and the RCA were associated with higher mortality risk.*Clinical Relevance/Application Determine early prognostic factors and score to tailor the treatment of Covid-19 patients.

RESULTS

Of the 326 cases, 103 had CAC, with a mean score of 486 UA (SD 965 range: 2 - 5648 UA). In multivariate regression, the findings related to a higher mortality odd were the absence of an OP, a high average density of PO, and CAC in the LM and the RCA (table). Mortality risk was directly associated with AS values; for every 100 AU increase, the risk of dying increased by 5% (p-value= 0.003). The discrimination capacity is 60%. Hepatic steatosis was related to a greater probability of climbing on the therapeutic scale (OR: 1.89 p: 0.043 95% CI: 1.02 - 3.52), but there was no relation with a greater probability of dying.

CLINICAL RELEVANCE/APPLICATION

Determine early prognostic factors and score to tailor the treatment of Covid-19 patients.

SPR-CA-27 Prognostic Value Of Late Gadolinium Enhancement In Left Ventricular Noncompaction: A Multicenter Study

Participants
Wei Huang, MBBS,MBBS, Chengdu, China (*Presenter*) Nothing to Disclose

PURPOSE

Current diagnostic criteria of left ventricular noncompaction (LVNC) may have poor relationship with adverse prognosis, late gadolinium enhancement(LGE) was a predictor of major adverse cardiovascular events (MACE), but the risk stratification of LGE in patients with LVNC remains unclearly.*Methods and Materials We retrospectively analyzed the clinical and cardiovascular magnetic resonance (CMR) data for 75 patients from three institutes,and examined the correlation between LGE and MACE based on the extent, pattern (including a specific ring-like pattern) and locations of LGE in LVNC.*Results A total of 51 patients (68%) presented LGE. Patients with LGE had higher diastolic blood pressures (p=0.023), lower LVEF (p=0.005), greater LVEDV (p=0.001) and LVESV (p<0.001), larger left ventricular systolic mass (p=0.001) and diastolic mass (p=0.001), and tended to have a worse New York Heart Association (NYHA)class (p=0.01). At 4.3 years follow-up (interquartile range: 2.1 to 5.7 years), MACE occurred in 29 (38.7%). Adjusted hazard ratios for patients with an LGE extent of 0 to 7.5%, 7.5% to 15% and >15%, respectively, were 2.01 (95% confidence interval [CI]: 0.50 to 8.03), 7.42 (95% CI: 1.76 to 31.3) and 9.02 (95% CI: 2.11 to 38.52) for MACE. The presence of ring-like, multiple segments, free-wall and mid-wall LGE were associated with increased risk of MACE after adjustment.*Conclusions In LVNC, the risk of MACE was increased significantly when the LGE extent higher than 7.5%, and the presence of ring-like, multiple segments and free-wall LGE were associated with MACE. These results suggested the value of risk stratification of LGE in patients with LVNC.*Clinical Relevance/Application Our study provides useful models based on the extent, pattern and location of LGE for the prediction of MACE in LVNC.

RESULTS

A total of 51 patients (68%) presented LGE. Patients with LGE had higher diastolic blood pressures (p=0.023), lower LVEF (p=0.005), greater LVEDV (p=0.001) and LVESV (p<0.001), larger left ventricular systolic mass (p=0.001) and diastolic mass (p=0.001), and tended to have a worse New York Heart Association (NYHA)class (p=0.01). At 4.3 years follow-up (interquartile range: 2.1 to 5.7 years), MACE occurred in 29 (38.7%). Adjusted hazard ratios for patients with an LGE extent of 0 to 7.5%, 7.5% to 15% and >15%, respectively, were 2.01 (95% confidence interval [CI]: 0.50 to 8.03), 7.42 (95% CI: 1.76 to 31.3) and 9.02 (95% CI: 2.11 to 38.52) for MACE. The presence of ring-like, multiple segments, free-wall and mid-wall LGE were associated with increased risk of MACE after adjustment.

CLINICAL RELEVANCE/APPLICATION

Our study provides useful models based on the extent, pattern and location of LGE for the prediction of MACE in LVNC.

SPR-CA-28 Relationship Between Max LCBI (4) Of NIRS-IVUS And CT Value Of Coronary Plaque In Coronary Artery Stenosis Lesions.

Participants
Daisuke Kittaka, RT, Kanagawa, Japan (*Presenter*) Nothing to Disclose

PURPOSE

We report a comparison of the CT values of coronary artery stenosis measured using coronary CT images and maximum lipid-core burden index (max LCBI (4))of Near infrared spectroscopy intravascular ultrasound (NIRS-IVUS).*Methods and Materials 1. We retrospectively collected 50 cases of NIRS-IVUS performed by PCI within 3 months after performing coronary CT. 2. The CT value of the plaque at the stenosis lesion were measured from the coronary CT images. CT values <50 HU were classified as lipid plaques, 50 = CT = 120 were classified as fibrous plaques, and 120 <CT values were classified as calcified plaques. The relationship between plaque properties divided into 3 groups and maxLCBI (4) of NIRS-IVUS were evaluated. 3. The CT value of plaque measured using coronary CT images was compared with maxLCBI (4) of NIRS-IVUS.*Results 1. The CT values of plaques measured using coronary CT images were divided into 3 groups and compared with maxLCBI (4) of NIRS-IVUS. As a result, there was a significant difference between maxLCBI (4) of calcified plaque and fibrous plaque. There was also a significant difference in maxLCBI (4) between calcified plaque and lipid plaque. There was no significant difference in maxLCBI (4) between fibrous and lipid plaques. 2. The CT value of plaque measured using coronary CT images and maxLCBI (4) of NIRS-IVUS showed a correlation (r2 = 0.245, p = 0.0003). 3. When the cut-off value of maxLCBI (4) of NIRS-IVUS was set to 400, the CT value of plaque measured using coronary CT images was 97HU with a sensitivity of 84.2% and a specificity of 67.5%.*Conclusions The CT value of coronary artery stenosis measured using coronary CT images and maxLCBI (4) of NIRS-IVUS showed a correlation. Therefore, it was suggested that the coronary

artery event could be predicted by evaluating the CT value of the coronary artery stenosis.*Clinical Relevance/Application Coronary events can be predicted by evaluating the CT value of coronary artery stenosis measured using coronary CT images and maxLCBI (4) of NIRS-IVUS.

RESULTS

1. The CT values of plaques measured using coronary CT images were divided into 3 groups and compared with maxLCBI (4) of NIRS-IVUS. As a result, there was a significant difference between maxLCBI (4) of calcified plaque and fibrous plaque. There was also a significant difference in maxLCBI (4) between calcified plaque and lipid plaque. There was no significant difference in maxLCBI (4) between fibrous and lipid plaques. 2. The CT value of plaque measured using coronary CT images and maxLCBI (4) of NIRS-IVUS showed a correlation (r2 = 0.245, p = 0.0003). 3. When the cut-off value of maxLCBI (4) of NIRS-IVUS was set to 400, the CT value of plaque measured using coronary CT images was 97HU with a sensitivity of 84.2% and a specificity of 67.5%.

CLINICAL RELEVANCE/APPLICATION

Coronary events can be predicted by evaluating the CT value of coronary artery stenosis measured using coronary CT images and maxLCBI (4) of NIRS-IVUS.

SPR-CA-29   High-pitch CT Angiography For TAVR Planning On A Novel Photon Counting Dual-source Scanner - Image Quality And Radiation Dose

Participants
Katharina Rippel, Augsburg, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To compare image quality and radiation dose of a novel photon counting dual-source CT scanner with a second generation dual-source CT with energy integrating detector in patients who undergo ECG-gated CT angiography of the thoracoabdominal aorta prior to Transcatheter Aortic Valve Replacement (TAVR).*Methods and Materials Here, we present initial data from 10 consecutive patients who underwent an ECG-triggered unenhanced scan for valvular calcium quantification followed by a high-pitch, wide-range CTA on a novel photon counting dual-source scanner (NAEOTOM Alpha, Siemens Healthineers, Erlangen, Germany) (PCD-CT group). For comparison, 10 consecutive patients who underwent a similar scan and contrast protocol on a second generation dual-source CT scanner were retrospectively included and used as a control group. Basic demographic data were compared. Enhancement and image noise were measured as mean CT values in the ascending aorta and standard deviation within surrounding air, respectively.*Results There were no significant differences between both groups in sex ratio (3 male, 7 female in both groups), age (81.5 ± 6.8 vs. 80.4 ± 9.3 years) or BMI (72.5 ± 15.7 vs. 68.4 ± 7.5 kg/m²). Intraaortic enhancement was significantly higher in the PCD-CT group (497 ± 121 HU vs. 375 ± 89 HU, p = 0.029) and image noise slightly higher (10.2 ± 1.9 HU vs. 6.8 ± 1.5 HU, p < 0.05). DLP was significantly lower in the PCD-CT group (242 ± 109 HU vs. 505 ± 118 HU, p < 0.01).*Conclusions In comparison with second generation dual-source CT scanners, the novel photon counting dual-source CT scanner allows radiation dose reductions of at least 50% for TAVR planning CT's while maintaining optimal image quality.*Clinical Relevance/Application In comparison with second generation dual-source CT scanners, the novel photon counting dual-source CT scanner allows for radiation dose reductions of at least 50% in TAVR planning CTA scans while maintaining optimal image quality.

RESULTS

There were no significant differences between both groups in sex ratio (3 male, 7 female in both groups), age (81.5 ± 6.8 vs. 80.4 ± 9.3 years) or BMI (72.5 ± 15.7 vs. 68.4 ± 7.5 kg/m²). Intraaortic enhancement was significantly higher in the PCD-CT group (497 ± 121 HU vs. 375 ± 89 HU, p = 0.029) and image noise slightly higher (10.2 ± 1.9 HU vs. 6.8 ± 1.5 HU, p < 0.05). DLP was significantly lower in the PCD-CT group (242 ± 109 HU vs. 505 ± 118 HU, p < 0.01).

CLINICAL RELEVANCE/APPLICATION

In comparison with second generation dual-source CT scanners, the novel photon counting dual-source CT scanner allows for radiation dose reductions of at least 50% in TAVR planning CTA scans while maintaining optimal image quality.

SPR-CA-30   Head To Head Comparison Reproducibility And Inter-reader Agreement Of An AI Based Coronary Stenosis Algorithm Vs Level 3 Readers

Participants
Elina Khasanova, MD, Vancouver, British Columbia (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate inter-reader (IRR) agreement and reproducibility in coronary stenosis assessment from coronary CT angiography (CCTA) between level 3 readers vs an AI-based algorithm (Heartflow, HF).*Methods and Materials 50 CCTAs were processed by the HF model by separate analysts. The same 50 CCTAs were interpreted by 3 certified Level 3 readers. Intra-reader reproducibility was generated for 15 of these 50 cases which were read by all readers 3 times, 1-2 weeks apart, and for the HF model processed by the same analysts 3 times. IRR agreement data was generated for all 50 cases which were read once by each reader independently. Percentage stenosis was collected per segment, per vessel and per patient. Stenosis severity was assessed according to the CAD-RADS™ classification and was additionally graded as mild (<39%), moderate (40-69%), and severe (>70%). Intrareader reproducibility, HF model reproducibility, IRR and HF model agreement were evaluated by Fleiss' kappa statistical method.*Results While inferior to the AI analysis, the readers exhibited good reproducibility and moderate agreement in per segment stenosis evaluation (K 0.66 and K 0.50) compared to excellent reproducibility and agreement of the HF model (K 0.81 and 0.85 respectively) in 15 cases.The analysis of total 50 cases demonstrated poor per segment (K 0.33) and moderate per vessel (K 0.48) IRR agreement compared to good and excellent HF model agreement (K 0.69 and 0.78). Moderate agreement for grading severe stenosis by using 3 stenosis buckets was observed among the readers (K 0.50) and HF model (K 0.56) whereas by using CAD-RADS™ grades the agreement was poor (K 0.33) for both. Good-to-moderate agreement in scoring moderate stenosis (40-69 %) in per segment, per vessel and per patient analysis by HF model (K 0.68; 0.68, 0.51) compared to poor IRR agreement (K 0.20; 0,28; 0.04) were shown. In grading 25-49% and 50-69% stenoses (CAD-RADS™ categories) the IRR agreement was poor in per segment, per vessel and per patient assessment (K 0.14 and 0.13; 0.30 and 0.16; 0.10 and 0.09) compared to good and moderate HF agreement (K 0.67 and 0.53; 0.68 and 0.55; 0.7 and 0.47).*Conclusions Our analysis of an AI based automated coronary stenosis assessment resulted in superior reproducibility and higher agreement than level 3 CCTA readers in this feasibility analysis.The use of reporting system with broader stenosis bucket improves inter-reader agreement. Further larger studies including evaluation of diagnostic accuracy compared to ICA are needed.*Clinical Relevance/Application The AI-based automated tool and with analyst input may improve readers agreement and reproducibility in reporting of moderate stenosis and non-obstructive disease

in a more targeted per-vessel and per segment manner.

RESULTS

While inferior to the AI analysis, the readers exhibited good reproducibility and moderate agreement in per segment stenosis evaluation (K 0.66 and K 0.50) compared to excellent reproducibility and agreement of the HF model (K 0.81 and 0.85 respectively) in 15 cases.The analysis of total 50 cases demonstrated poor per segment (K 0.33) and moderate per vessel (K 0.48) IRR agreement compared to good and excellent HF model agreement (K 0.69 and 0.78). Moderate agreement for grading severe stenosis by using 3 stenosis buckets was observed among the readers (K 0.50) and HF model (K 0.56) whereas by using CAD-RADS™ grades the agreement was poor (K 0.33) for both. Good-to-moderate agreement in scoring moderate stenosis (40-69 %) in per segment, per vessel and per patient analysis by HF model (K 0.68; 0.68, 0.51) compared to poor IRR agreement (K 0.20; 0,28; 0.04) were shown. In grading 25-49% and 50-69% stenoses (CAD-RADS™ categories) the IRR agreement was poor in per segment, per vessel and per patient assessment (K 0.14 and 0.13; 0.30 and 0.16; 0.10 and 0.09) compared to good and moderate HF agreement (K 0.67 and 0.53; 0.68 and 0.55; 0.7 and 0.47).

CLINICAL RELEVANCE/APPLICATION

The AI-based automated tool and with analyst input may improve readers agreement and reproducibility in reporting of moderate stenosis and non-obstructive disease in a more targeted per-vessel and per segment manner.

SPR-CA-4 MRI Derived Global Early Diastolic Longitudinal Strain Rate And Prognosis Of Patients With Heart Failure With Preserved Ejection Fraction (HFpEF)

Participants
Jian He, MD, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

To find the correlation of worse LV global early diastolic longitudinal strain rate (eGLSR) and outcomes (all-cause death or HF hospitalization) in patients with HFpEF.*Methods and Materials In this retrospective study, consecutive patients with HFpEF underwent cardiovascular magnetic resonance (CMR) imaging were enrolled from Jan 2010 to Mar 2013. Correlations between strain parameters derived from Feature Tracking and outcomes were analyzed using linear regression. Univariable and multivariable Cox proportional regression were performed to determine the prognostic relevance of myocardial strain for clinical outcomes.*Results A total of 186 HFpEF patients (mean age, 59 years, 41.4% women) were included. eGLSR was correlated with LV end-diastolic volume index (LVEDVi) (r = -0.39, P < .001), LV end-systolic volume index (LVESVi) (r = -.44, P < .001), heart rate (r = .35, P < .001), and LVEF (r = .30, P < .001). At a median follow-up of 9.2 years, 38.7% (72/186) patients experienced the primary composite outcome (all-cause death or HF hospitalization). Impaired eGLSR (< median, 0.57/s) was predictive of the composite outcome (adjusted hazard ratio, 2.61 , 95% confidence interval, 1.40-4.87; P = .002) after adjustment for clinical, laboratory, and imaging variables in multivariable Cox models.*Conclusions Left ventricular global early diastolic longitudinal strain rate is a simple and feasible marker and independently associated with the prognosis of heart failure with preserved ejection fraction patients. Further multi-center, larger sample prospective investigations are needed to verify the clinical value of myocardial strain in these patients.*Clinical Relevance/Application 1. Left ventricular early diastolic longitudinal strain rate (eGLSR) from feature tracking is increasingly becoming available in earlier subclinical LV diastolic dysfunction description of Heart Failure with preserved ejection fraction (HFpEF) patients.2. eGLSR may extend the application of feature-tracking and assist in clinical diagnosis and prognosis evaluation of HFpEF .

RESULTS

A total of 186 HFpEF patients (mean age, 59 years, 41.4% women) were included. eGLSR was correlated with LV end-diastolic volume index (LVEDVi) (r = -0.39, P < .001), LV end-systolic volume index (LVESVi) (r = -.44, P < .001), heart rate (r = .35, P < .001), and LVEF (r = .30, P < .001). At a median follow-up of 9.2 years, 38.7% (72/186) patients experienced the primary composite outcome (all-cause death or HF hospitalization). Impaired eGLSR (< median, 0.57/s) was predictive of the composite outcome (adjusted hazard ratio, 2.61 , 95% confidence interval, 1.40-4.87; P = .002) after adjustment for clinical, laboratory, and imaging variables in multivariable Cox models.

CLINICAL RELEVANCE/APPLICATION

1. Left ventricular early diastolic longitudinal strain rate (eGLSR) from feature tracking is increasingly becoming available in earlier subclinical LV diastolic dysfunction description of Heart Failure with preserved ejection fraction (HFpEF) patients.2. eGLSR may extend the application of feature-tracking and assist in clinical diagnosis and prognosis evaluation of HFpEF .

SPR-CA-5 Elevated Coronary Flow Vorticity Calculated Using A Mesh-free Simulation Is Related To Functionally Significant Coronary Stenosis

Participants
Nobuo Tomizawa, MD, Tokyo, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the relationship between coronary flow vorticity calculated using a mesh-free simulation from coronary CT angiography data and the presence of functionally significant stenosis assessed by invasive fractional flow reserve (FFR).*Methods and Materials We retrospectively included 37 consecutive patients (50 vessels) who underwent coronary CT angiography and subsequent coronary angiography including FFR measurement between October 2018 and March 2020. Minimal lumen area (MLA), diameter stenosis (DS), and lesion length (LL) of coronary CT angiography were recorded. Coronary flow simulation was performed using the CT data by the moving particle semi-implicit method, which is a particle-based mesh-free method of computational fluid dynamics. The simulation was performed in a 4 cm length including the stenosis segment. Vorticity was calculated based on the velocity data. A lesion with invasive FFR =0.80 was determined as significant stenosis.*Results The mean invasive FFR was 0.83 ± 0.10 and 18 vessels (36%) had significant stenosis. Vorticity was significantly higher in lesions with significant stenosis than the remaining lesions (1847 ± 717 vs 788 ± 492, p <0.001). Small MLA (R2 = 0.14, p = 0.007) and severe DS (R2 = 0.20, p = 0.001) significantly related to low FFR. The relationship between LL and FFR was not significant (R2 = 0.002, p = 0.75). Vessels with high vorticity showed low FFR (R2 = 0.47, p <0.001). Multivariate logistic regression analysis showed that vorticity (p = 0.003) remained a significant factor to predict significant stenosis when MLA (p = 0.04), DS (p = 0.36), and LL (p = 0.96) was considered. The area under the curve of the receiver operating characteristic analysis increased significantly when vorticity was considered along with MLA, DS, and LL (0.94 vs 0.83, p = 0.02), while the accuracy increased from 80% to 90% with marginal significance (p = 0.06).*Conclusions High coronary flow vorticity is a significant factor to predict functionally significant stenosis other than morphological factors such as DS, MLA, and LL.*Clinical Relevance/Application Assessment of coronary flow vorticity would be

important to predict functionally significant coronary stenosis other than conventional factors such as lumen area, stenosis grade, and lesion length.

RESULTS

The mean invasive FFR was 0.83 ± 0.10 and 18 vessels (36%) had significant stenosis. Vorticity was significantly higher in lesions with significant stenosis than the remaining lesions (1847 ± 717 vs 788 ± 492, p <0.001). Small MLA (R^2 = 0.14, p = 0.007) and severe DS (R^2 = 0.20, p = 0.001) significantly related to low FFR. The relationship between LL and FFR was not significant (R^2 = 0.002, p = 0.75). Vessels with high vorticity showed low FFR (R^2 = 0.47, p <0.001). Multivariate logistic regression analysis showed that vorticity (p = 0.003) remained a significant factor to predict significant stenosis when MLA (p = 0.04), DS (p = 0.36), and LL (p = 0.96) was considered. The area under the curve of the receiver operating characteristic analysis increased significantly when vorticity was considered along with MLA, DS, and LL (0.94 vs 0.83, p = 0.02), while the accuracy increased from 80% to 90% with marginal significance (p = 0.06).

CLINICAL RELEVANCE/APPLICATION

Assessment of coronary flow vorticity would be important to predict functionally significant coronary stenosis other than conventional factors such as lumen area, stenosis grade, and lesion length.

SPR-CA-6   The Impact Of Deep Learning Reconstruction On Image Quality And Machine LearningBased Coronary CT AngiographyDerived Fractional Flow Reserve Values

Participants
Cheng Xu, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

To explore the impact of deep learning reconstruction (DLR) on image quality and machine learning-based coronary CT angiography-derived fractional flow reserve (CT-FFRML) values.*Methods and Materials 30 consecutive patients with known or suspected CAD who underwent coronary CTA on a 320-slice CT scanner and subsequent invasive coronary angiography were enrolled. DLR was compared with filtered back projection (FBP), statistical-based iterative reconstruction (SBIR), and model-based iterative reconstruction (MBIR). Subjective and objective images quality evaluation were performed. Correlation coefficients were calculated using the nonparametric Spearman's rank correlation coefficient. Invasive fractional flow reserve FFR and quantitative flow ratio (QFR) were used as the reference standard respectively. An FFR/QFR value of 0.8 or less was considered hemodynamically significant.*Results 169 lesions in 30 patients (23 men and 7 women; 63.0±8.6 years) were finally enrolled for analysis. The image quality of DLR was superior to that of FBP, SBIR and MBIR, with the lowest image noise of 14.4. There were no significant differences of the CT-FFRML values among these four approaches. Of the 169 lesions, 10 had invasive FFR results and 70 had QFR results. The overall diagnostic performances of MBIR and DLP were slight higher than FBP and SBIR. The sensitivity, specificity and diagnostic accuracy to identify hemodynamically significant stenosis were 88.89%, 81.25%, 87.14% for MBIR, and 90.74%, 75.00%, 87.14% for DLP, respectively.*Conclusions Our study showed that DLR algorithm improved image quality and slightly improved diagnostic performances of CT-FFRML value compared with FBP and AIDR.*Clinical Relevance/Application DLR algorithm improved image quality of coronary CTA and slightly improved diagnostic performances of CT-FFRML value.

RESULTS

169 lesions in 30 patients (23 men and 7 women; 63.0±8.6 years) were finally enrolled for analysis. The image quality of DLR was superior to that of FBP, SBIR and MBIR, with the lowest image noise of 14.4. There were no significant differences of the CT-FFRML values among these four approaches. Of the 169 lesions, 10 had invasive FFR results and 70 had QFR results. The overall diagnostic performances of MBIR and DLP were slight higher than FBP and SBIR. The sensitivity, specificity and diagnostic accuracy to identify hemodynamically significant stenosis were 88.89%, 81.25%, 87.14% for MBIR, and 90.74%, 75.00%, 87.14% for DLP, respectively.

CLINICAL RELEVANCE/APPLICATION

DLR algorithm improved image quality of coronary CTA and slightly improved diagnostic performances of CT-FFRML value.

SPR-CA-7   Myocardial T1, T2 Mapping And Late Gadolinium Enhancement Using Cardiac Magnetic Resonance Imaging In Chemotherapy Patients: A Single Center Retrospective Study

Participants
Jinhee Kim, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

This study aimed to quantitatively assess cardiac magnetic resonance imaging (CMR) images using T1, T2 mapping, and late gadolinium enhancement (LGE) imaging in chemotherapy (CTx) patients.*Methods and Materials We retrospectively reviewed CMR images of patients who were diagnosed with cancer. Patients who underwent CMR (3T, Magnetom Trio Trim or Prisma fit, Siemens Hewalthineers) with T1 mapping (modified 5(3)3 MOLLI sequence), T2 mapping sequences (T2-prepared, single-shot TrueFISP sequence), and LGE imaging (phase-sensitive inversion recovery-prepared TrueFISP sequence) between January 2015 and January 2021 were included. CMR findings including ventricular functions, T1, T2 mapping, and ECV values, and the presence or patterns of LGE of the left ventricular myocardium were evaluated.*Results Of the 274 cancer patients, 79 patients with other cardiomyopathy and 31 patients with other scan protocols were excluded. A total of 164 patients were included. Of these, 75 (45.7%) patients underwent CTx, and 37 (49.3%) received anthracycline-based CTx. 43 (57.3%) patients had dilated cardiomyopathy (left ventricular ejection fraction <40%). The native T1, T2, and ECV values were higher in the CTx group than in the non-CTx group (1327.7ms, 51.4ms, 32.0% vs. 1284.9ms, 49.5ms, 29.9%, p<0.001, 0.003, 0.01, each other). In the CTx group, native T1, T2, and ECV values were higher in the anthracycline (AC) group than in the non-AC group (1333.2ms, 52.5ms, 32.9% vs. 1322.8ms, 50.4, 31.4% with insignificant p-value) LGE was positive in 48 (64%) patients in the CTx and 50 (56%) patients in the non-CTx groups. The most common pattern of LGE was linear LGE in the mid-ventricle and was noted in 27 (42.2%) patients.*Conclusions CMR is a useful diagnostic tool for the evaluation of chemotherapy-induced cardiotoxicity.*Clinical Relevance/Application As the number of cancer survivors is increasing because of the early diagnosis of cancer and advances in treatment, the importance of life expectancy is emerging. The adverse effects of anti-cancer drugs are important considerations. Cardiovascular disease is the second most critical factor related to the life expectancy of cancer patients after tumor recurrence. Chemotherapy-induced cardiotoxicity is a serious complication of cancer treatment that causes severe morbidity and mortality. Various anti-cancer drugs are known to induce cardiotoxicity. In particular, anthracycline agents are notorious for heart failure. CMR is useful for myocardial tissue characterization. However, the imaging findings for CTx-induced cardiomyopathy have not yet been fully determined.

RESULTS

Of the 274 cancer patients, 79 patients with other cardiomyopathy and 31 patients with other scan protocols were excluded. A total of 164 patients were included. Of these, 75 (45.7%) patients underwent CTx, and 37 (49.3%) received anthracycline-based CTx. 43 (57.3%) patients had dilated cardiomyopathy (left ventricular ejection fraction <40%). The native T1, T2, and ECV values were higher in the CTx group than in the non-CTx group (1327.7ms, 51.4ms, 32.0% vs. 1284.9ms, 49.5ms, 29.9%, p<0.001, 0.003, 0.01, each other). In the CTx group, native T1, T2, and ECV values were higher in the anthracycline (AC) group than in the non-AC group (1333.2ms, 52.5ms, 32.9% vs. 1322.8ms, 50.4, 31.4% with insignificant p-value) LGE was positive in 48 (64%) patients in the CTx and 50 (56%) patients in the non-CTx groups. The most common pattern of LGE was linear LGE in the mid-ventricle and was noted in 27 (42.2%) patients.

CLINICAL RELEVANCE/APPLICATION

As the number of cancer survivors is increasing because of the early diagnosis of cancer and advances in treatment, the importance of life expectancy is emerging. The adverse effects of anti-cancer drugs are important considerations. Cardiovascular disease is the second most critical factor related to the life expectancy of cancer patients after tumor recurrence. Chemotherapy-induced cardiotoxicity is a serious complication of cancer treatment that causes severe morbidity and mortality. Various anti-cancer drugs are known to induce cardiotoxicity. In particular, anthracycline agents are notorious for heart failure. CMR is useful for myocardial tissue characterization. However, the imaging findings for CTx-induced cardiomyopathy have not yet been fully determined.

SPR-CA-8   T1 Map-based Radiomics Score For Prediction Of Left Ventricular Reverse Remodeling In Non-ischemic Dilated Cardiomyopathy Patients

Participants
Suyon Chang, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the usefulness of the radiomics score (rad-score) in predicting left ventricular reverse remodeling (LVRR) in patients with non-ischemic dilated cardiomyopathy (NIDCM).*Methods and Materials We reviewed 314 patients with NIDCM who underwent cardiac magnetic resonance imaging (CMR) with T1 mapping (training set, n=274; external validation set, n=40). Radiomics features were extracted from the native T1 map of CMR. Rad-score was generated by using the least absolute shrinkage and selection operator (LASSO) logistic regression model. A traditional clinico-radiologic model, radiomic model, and combined model were built using a logistic regression method to predict LVRR in one year. A bootstrap stepwise selection was applied to select predictors for multivariable model construction. The results were further validated in the external validation set. C-index and calibration statistics with bootstrap were used to assess the performance of the models.*Results Rad-score was positively associated with LVRR (odds ratio 111.6, 95% confidence interval [CI]: 1.1, 17391.3). In a combined model, late gadolinium enhancement extent, ventricular natriuretic peptide, rad-score, systolic blood pressure, smoking history, age, and diastolic blood pressure were included as significant predictors. Combined model resulted in better performance for the estimation of LVRR (C-index 0.758, 95% CI: 0.698, 0.818) than the traditional model (C-index 0.738, 95% CI: 0.677, 0.800). In the external validation set, combined model also showed improvement for the prediction of LVRR (C-index 0.765, 95% CI: 0.593, 0.936) compared to the traditional model (C-index 0.758, 95% CI: 0.587, 0.929).*Conclusions The rad-score demonstrated incremental value to the traditional clinico-radiologic model for the estimation of individual LVRR in patients with NIDCM.*Clinical Relevance/Application Combination of the rad-score to the traditional clinico-radiologic risk factors may serve as a complementary biomarker for risk stratification for patients with NIDCM.

RESULTS

Rad-score was positively associated with LVRR (odds ratio 111.6, 95% confidence interval [CI]: 1.1, 17391.3). In a combined model, late gadolinium enhancement extent, ventricular natriuretic peptide, rad-score, systolic blood pressure, smoking history, age, and diastolic blood pressure were included as significant predictors. Combined model resulted in better performance for the estimation of LVRR (C-index 0.758, 95% CI: 0.698, 0.818) than the traditional model (C-index 0.738, 95% CI: 0.677, 0.800). In the external validation set, combined model also showed improvement for the prediction of LVRR (C-index 0.765, 95% CI: 0.593, 0.936) compared to the traditional model (C-index 0.758, 95% CI: 0.587, 0.929).

CLINICAL RELEVANCE/APPLICATION

Combination of the rad-score to the traditional clinico-radiologic risk factors may serve as a complementary biomarker for risk stratification for patients with NIDCM.

SPR-CA-9   A Validation And Observer Performance Study Of A Deep Learning-based Software For Automatic Measurement Of Native T1 Value And Extracellular Volume Fraction In Cardiac Magnetic Resonance Imaging

Participants
Suyon Chang, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To validate a deep learning-based software for automatic measurement of myocardial native T1 value and extracellular volume (ECV) fraction in T1 mapping cardiac magnetic resonance imaging.*Methods and Materials A deep learning-based software (based on Attention R2U-net) was used for automatic analysis of T1 map (segmentation of native T1 and post-T1 map, and measurement of native T1 value and ECV fraction). A data set for 95 patients (27 normal, 32 dilated cardiomyopathy, 36 left ventricular hypertrophy [12 hypertrophic cardiomyopathy, 12 Fabry disease, 12 amyloidosis]) was used to validate automatically calculated T1 value and ECV fraction. Ground truth was set by manual analysis in consensus of two expert readers. Additionally, four radiologist readers analyzed the same images and the results were compared. Dice similarity coefficient (DSC), Bland-Altman analysis, and intraclass correlation coefficient (ICC) were used to evaluate the performance of the software.*Results The software achieved fast segmentation (<5s/image) with high DSC (0.86 ± 0.05 on native T1 and 0.75 ± 0.17 on post-T1 map). Bland-Altman analysis showed good agreement between the automated method and ground truth (mean 9.8, 95% limit of agreement ± 32.4 for native T1; mean 0.9, 95% limit of agreement ± 4.8 for ECV). The ICC of native T1 and ECV by automatic method vs. ground truth (0.98 and 0.97, respectively) were comparable to those between ground truth vs. other radiologist readers (0.97-1 and 0.99-1, respectively).*Conclusions The deep learning-based software allows fast automatic analysis of T1 mapping images, which is comparable to the radiologist readers.*Clinical Relevance/Application Automatic measurement of T1 value and ECV fraction can be a beneficial assistance tool which mitigates the burden of manual analysis.

RESULTS

The software achieved fast segmentation (<5s/image) with high DSC (0.86 ± 0.05 on native T1 and 0.75 ± 0.17 on post-T1 map). Bland-Altman analysis showed good agreement between the automated method and ground truth (mean 9.8, 95% limit of agreement ± 32.4 for native T1; mean 0.9, 95% limit of agreement ± 4.8 for ECV). The ICC of native T1 and ECV by automatic method vs. ground truth (0.98 and 0.97, respectively) were comparable to those between ground truth vs. other radiologist readers (0.97-1 and 0.99-1, respectively).

CLINICAL RELEVANCE/APPLICATION

Automatic measurement of T1 value and ECV fraction can be a beneficial assistance tool which mitigates the burden of manual analysis.

PH05-A1   **A Comparative Study Of One-stop Head And Neck CTA+CTP And Conventional Head And Neck CTA+CTP**

Participants
Wei Jing, Shizuishan, China (*Presenter*) Nothing to Disclose

PURPOSE

To explore the difference in image quality, radiation dose and contrast agent dosage between one-stop head and neck computed tomography angiography(CTA) and computed tomography perfusion(CTP)and conventional head and neck CTA+CTP.*Methods and Materials sixty patients with clinically suspected acute stroke were collected in our hospital from September to December 2020, and randomly divide them into groups A and B. The head and neck CTA+CTP scan was performed with GE Revolution CT. In group A, a one-stop head and neck CTA+CTP examination was performed. A small-dose test of about 15ml was performed first to determine the CTA time. During the head and neck CTP, the head and neck CTA was performed quickly, and then the CTP was quickly switched to continue scanning. In group B, conventional head and neck CTA+CTP scans were performed. CTP was performed first. After 5 minutes, CTA scans were performed. Analyze and compare the differences in blood vessel CT value, image noise (SD) and signal-to-noise ratio (SNR=CT vessel/SD muscle) at the level of the aortic arch, common carotid artery, internal carotid artery, and middle cerebral artery in groups A and B. The efective radiation dose (ED) of the two groups of patients and the amount of contrast agent in the two groups were recorded. Using SPSS 23.0 software, the two groups of patients were compared by independent sample t test.*Results There were no statistically significant differences in the CT values, SD and SNR of blood vessels at the levels of the remaining aortic arch, common carotid artery, internal carotid artery, and middle cerebral artery in groups A and B (P>0.05); the ED of A and B groups were 2.27±0.09mSv and 2.52±0.54mSv, which was statistically significant (P<0.05). Group A was 10% less than group B; the amount of contrast medium in the two groups A and B was 70.20±9.99ml and 126.33±13.36ml respectively, which was statistically different (P<0.05). Compared with group B, group A decreased by 45%;. The average inspection time of group A was (2.35±0.45) min, the average time of group B inspection was (8.51±0.73) min, and the inspection time was reduced by 78%.*Conclusions Compared with conventional head and neck CTA+CTP, the one-stop head and neck CTA+CTP guarantees the image quality, while reducing the radiation hazard of patients and the harm of contrast agent nephropathy, and greatly reducing the examination time.*Clinical Relevance/Application Compared with conventional head and neck CTA+CTP, the one-stop head and neck CTA+CTP while reducing the radiation hazard of patients and the hazard of contrast agent nephropathy, and greatly reducing the examination time, so as to buy valuable time for emergency stroke patients.

RESULTS

There were no statistically significant differences in the CT values, SD and SNR of blood vessels at the levels of the remaining aortic arch, common carotid artery, internal carotid artery, and middle cerebral artery in groups A and B (P>0.05); the ED of A and B groups were 2.27±0.09mSv and 2.52±0.54mSv, which was statistically significant (P<0.05). Group A was 10% less than group B; the amount of contrast medium in the two groups A and B was 70.20±9.99ml and 126.33±13.36ml respectively, which was statistically different (P<0.05). Compared with group B, group A decreased by 45%;. The average inspection time of group A was (2.35±0.45) min, the average time of group B inspection was (8.51±0.73) min, and the inspection time was reduced by 78%.

CLINICAL RELEVANCE/APPLICATION

Compared with conventional head and neck CTA+CTP, the one-stop head and neck CTA+CTP while reducing the radiation hazard of patients and the hazard of contrast agent nephropathy, and greatly reducing the examination time, so as to buy valuable time for emergency stroke patients.

PH05-A11   **Application Of Deep Learning Reconstruction In MR: Higher Resolution MR Imaging In Shorter Scan Time**

Participants
Mo Kadbi, PhD, Irvine, California (*Presenter*) Employee, Canon Medical Systems Corporation;

PURPOSE

One inherent challenge in MRI is finding the optimal balance of Signal-to-Noise Ratio (SNR), image resolution, and scan time. As spatial resolution increases, voxel size is reduced and in turn available signal per voxel is decreased, resulting in more noise in the MR image. To compensate for this signal loss, signal averaging or phase oversampling are often used to restore SNR, at the consequence of longer scan times. In this study, a Deep Learning Reconstruction (DLR) is used to remove the noise from the MR images and improve SNR. This additional SNR can then be exploited to increase resolution without the need for additional signal averaging, phase oversampling and increased scan time.*Methods and Materials Routine clinical images of ankle, wrist, and lumbar spine, hip, and shoulder were acquired on volunteers on 1.5T and 3T scanners. Two sets of protocols were acquired in each scan session. First, a routine clinical protocol with conventional reconstruction (CR) method using typical post processing filters and reconstruction was optimized to for what would be considered typical image quality. Second, a modified protocol to achieve higher spatial resolution in a shorter scan time using the DLR method. Most sequence parameters were kept identical between the CR and DLR protocols. Wherever the DLR scan had an abundant SNR, spatial resolution was increased, and the number of acquisitions

(NAQ) and/or signal oversampling were reduced in order to shorten the scan time. To evaluate the impact of the DLR on image quality, the SNR and contrast change were measured in bone and muscle in various anatomies.*Results Clinical images acquired in various anatomies using the routine protocol and the modified protocol revealed that the DLR based images achieve a similar or better image quality to the CR images. Higher spatial resolution was achieved with the DLR scan which resulted in sharper images. The higher resolution images were obtained while the SNR was improved and the scan time was reduced in all anatomies. The scan time reduction varied between 22-52% for different anatomies, which can be advantageous for the orthopedic imaging wherein patients, usually experiencing severe pain, could benefit from the shorter scan time.*Conclusions Deep Learning Reconstruction can help to increase SNR and spatial resolution in neuro and orthopedic MR imaging. In addition, shorter scan time can be achieved by reducing number of signal averaging and/or oversampling. Thus, higher resolution images with improved image quality can be acquired in shorter scan times.*Clinical Relevance/Application Higher resolution images with high image quality and SNR were acquired in shorter scan times using a Deep Learning Reconstruction method on various anatomical regions.

RESULTS

Clinical images acquired in various anatomies using the routine protocol and the modified protocol revealed that the DLR based images achieve a similar or better image quality to the CR images. Higher spatial resolution was achieved with the DLR scan which resulted in sharper images. The higher resolution images were obtained while the SNR was improved and the scan time was reduced in all anatomies. The scan time reduction varied between 22-52% for different anatomies, which can be advantageous for the orthopedic imaging wherein patients, usually experiencing severe pain, could benefit from the shorter scan time.

CLINICAL RELEVANCE/APPLICATION

Higher resolution images with high image quality and SNR were acquired in shorter scan times using a Deep Learning Reconstruction method on various anatomical regions.

PH05-A4   Tin Prefiltration In Extremity Cone-beam CT Imaging With A Twin Robotic X-ray System

Participants
Andreas Kunz, MD, Wuerzburg, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Spectral shaping is an established approach to achieve dose reduction in various CT applications, whereas in cone-beam CT, the benefits of tin prefiltration relative to already optimized spectra have not been thoroughly assessed thus far. To investigate the effect of tin filer application on radiation exposure and image quality of extremity cone-beam CT scans with a twin-robotic X-ray system.*Methods and Materials Elbow, wrist and ankle joints of two cadaveric specimens were examined in a laboratory setup using a high-resolution scan mode with various combinations of prefiltration (standard copper, experimental tin filter), tube voltage and current-time product. Volume CT dose indices were computed for a 16 cm polymethylmethacrylate phantom. Image quality of protocols was assessed subjectively by five radiologists and compared with Wilcoxon signed rank tests. Fleiss' kappa was calculated to measure interrater agreement. To provide an additional semiquantitative criterion for image quality, contrast-to-noise ratios (CNR) were computed in standardized regions of interest.*Results Radiation dose ranged from 17.4 mGy in the clinical standard protocol without tin filter to as low as 0.7 mGy with tin prefiltration. Image quality ratings and CNR for tin-filtered scans with 100 kV were lower than for 80 kV studies with copper filtration despite higher dose (11.2 and 5.6 vs. 4.5 mGy; p<0.001). Observer evaluation and CNR showed no difference between 100 kV scans with tin filtration and 60 kV copper-filtered scans with 75% dose reduction (subjective: p=0.101; CNR: p=0.706). Moderate to substantial interrater agreement was indicated by Fleiss' kappa of 0.597 (95% confidence interval 0.567-0.626; p<0.001).*Conclusions While considerable dose reduction could also be achieved with tin filter application, the twin-robotic X-ray system's potential for low-dose extremity joint imaging was maximized with a dedicated low-kilovolt scan protocol in patients without metal implants.*Clinical Relevance/Application In situations without extensive beam-hardening artifacts, lowering the tube voltage appears more promising than tin prefiltration for dose reduction in peripheral joint cone-beam CT imaging.

RESULTS

Radiation dose ranged from 17.4 mGy in the clinical standard protocol without tin filter to as low as 0.7 mGy with tin prefiltration. Image quality ratings and CNR for tin-filtered scans with 100 kV were lower than for 80 kV studies with copper filtration despite higher dose (11.2 and 5.6 vs. 4.5 mGy; p<0.001). Observer evaluation and CNR showed no difference between 100 kV scans with tin filtration and 60 kV copper-filtered scans with 75% dose reduction (subjective: p=0.101; CNR: p=0.706). Moderate to substantial interrater agreement was indicated by Fleiss' kappa of 0.597 (95% confidence interval 0.567-0.626; p<0.001).

CLINICAL RELEVANCE/APPLICATION

In situations without extensive beam-hardening artifacts, lowering the tube voltage appears more promising than tin prefiltration for dose reduction in peripheral joint cone-beam CT imaging.

PH05-A6   Technical Performance Of A Novel Dual-energy CT System With Deep Learning-based Dual Energy Reconstruction

Participants
Luuk J. Oostveen, DIPLPHYS, Nijmegen, Netherlands (*Presenter*) Research Grant, Canon Medical Systems Corporation

PURPOSE

To evaluate the technical performance of a novel dual-energy (DE) CT system and compare it to that of standard single-energy (SE) CT at the same dose level.*Methods and Materials DE and SE images of three different phantoms were acquired with a CT system with rapid tube voltage switching (80 / 135 kV) that uses deep learning to complete the sinogram data (Aquilion One Prism Edition, Canon Medical Systems Corporation, Otawara, Japan). The dose for the DE and SE acquisitions of each phantom were set to those selected by the automatic exposure control (AEC) set at the manufacturer-recommended settings for DE mode. For reference, the dose that the AEC would have selected in SE mode for each phantom was also recorded. Virtual monochromatic images (VMIs) from 40 keV to 130 keV in 10 keV steps as well as iodine maps were reconstructed from the DE data. SE images were acquired at 120 kV and reconstructed with a hybrid iterative algorithm (HIR; AIDR 3D standard, FC18). All reconstructions were at 0.5 mm slice thickness. Modulation transfer functions (MTFs) were determined using a 50 μm tungsten wire. Noise magnitude (SD), noise power spectrum (NPS), and homogeneity were calculated from a 320 mm water phantom. Iodine quantification accuracy and contrast-to-noise ratios (CNR) relative to water for 2, 5, 10, and 15 mg I/ml were determined using a multi-energy CT (MECT) phantom (Gammex 1472, Sun Nuclear, Melbourne, Australia). Low-contrast visibility was determined using the Catphan 500 phantom (The Phantom Laboratory, Salem, NY, USA) at 10 mm slice thickness.*Results The MTF of DE VMIs was

higher than that of SE images (20% MTF: 7.2 lp/cm at 40 keV, 8.1 lp/cm at =70 keV, 6.3 lp/cm for SE). SD was lowest at 70 keV VMI (12.0 HU) and lower than that of SE (18.3 HU). The average NPS frequency was 2.2 lp/cm for SE and varied between 2.3 and 4.2 lp/cm for VMIs. Iodine quantification inaccuracy was on average 0.5 mg I/ml with a maximum of 1 mg I/ml (at 5 mg I/ml). The highest CNR for all iodine concentrations was at 60 keV, 2.5 times higher than the CNR for SE. At 70 keV the number of visible low contrast objects was comparable to that in SE. CTDIvol for the DE acquisitions of the water, MECT, and Catphan phantoms were 12.6, 15.4, and 12.6 mGy, respectively. AEC-driven SE acquisitions would have resulted in CTDIvol of 5.0, 8.6, and 2.5 mGy, respectively.*Conclusions Deep learning-based DE CT can create sharper, lower noise VMIs with up to 2.5 times higher iodine CNR compared to SE at the same dose. At manufacturer-recommended settings, the dose used in DE is higher than that in SE.*Clinical Relevance/Application For applications in which visibility of iodine or iodine quantification is crucial, deep learning-based dual-energy might be a better option than single-energy acquisitions.

RESULTS

The MTF of DE VMIs was higher than that of SE images (20% MTF: 7.2 lp/cm at 40 keV, 8.1 lp/cm at =70 keV, 6.3 lp/cm for SE). SD was lowest at 70 keV VMI (12.0 HU) and lower than that of SE (18.3 HU). The average NPS frequency was 2.2 lp/cm for SE and varied between 2.3 and 4.2 lp/cm for VMIs. Iodine quantification inaccuracy was on average 0.5 mg I/ml with a maximum of 1 mg I/ml (at 5 mg I/ml). The highest CNR for all iodine concentrations was at 60 keV, 2.5 times higher than the CNR for SE. At 70 keV the number of visible low contrast objects was comparable to that in SE. CTDIvol for the DE acquisitions of the water, MECT, and Catphan phantoms were 12.6, 15.4, and 12.6 mGy, respectively. AEC-driven SE acquisitions would have resulted in CTDIvol of 5.0, 8.6, and 2.5 mGy, respectively.

CLINICAL RELEVANCE/APPLICATION

For applications in which visibility of iodine or iodine quantification is crucial, deep learning-based dual-energy might be a better option than single-energy acquisitions.

PH05-A8   Detection Of Juxta-vascular Pulmonary Nodules Based On Deep Learning Artificial Intelligence (DL-AI) System In Chest Low-dose CT(LDCT) Images

Participants
Fang Wang, Yinchuan, China (*Presenter*) Nothing to Disclose

PURPOSE

Juxta-vascular pulmonary nodules (JVPN) have a high risk of being malignant yet are often challenging to be detected due to vascular interference. This study evaluated the performance of a DL-AI system in assisting the detection of JVPN in chest LDCT images.*Methods and Materials 104 participants who underwent chest LDCT screening (effective dose 1.5mSv for each participant) on a 256-slice wide-detector CT (Revolution, GE Healthcare) were enrolled. Two senior chest radiologists reviewed the LDCT images with the assistance of a DL-AI system (InferRead CT Lung Research). A total of 216 JVPNs (34 nodules were near pulmonary hilum, 56 nodules were central and 126 nodules were peripheral) were confirmed by two senior chief radiologists' consensus readings and were served as the reference standard. Two residents independently reviewed the CT images for the presence of pulmonary nodules, first without the DL-AI system, and then with the assistance of the DL-AI system and consensus readings were obtained and utilized for analysis. The sensitivity (true-positive rate) was calculated as the number of detected nodules divided by the total number of reference standard nodules. The false-positive rate was calculated as the number of false-positive nodules divided by the total number of participants.*Results The sensitivity for detecting JVPNs near the pulmonary hilum was remarkably increased from 58.8% without DL-AI to 94.1% with DL-AI. For central JVPNs, detection sensitivity was also improved with the assistance of the DL-AI system, from 64.3% to 94.6% with the DL-AI. The sensitivity of JVPNs in the peripheral lung was increased from 79.4% without DL-AI to 97.6% with DL-AI. False-positive rates were also greatly reduced with the assistance of the DL-AI system, from 4.8% to 1.0%, from 3.8% to 1.9% and from 2.9% to 1.0% for JVPNs near the pulmonary hilum area, central and peripheral, respectively.*Conclusions DL-AI improved diagnostic performance in the detection of all regions JVPNs on LDCT for junior residents, with the greatest help in the region that is the most difficult for residents.*Clinical Relevance/Application It is potentially feasible to detect more juxta-vascular pulmonary nodules with the assistance of DL-AI system for the early lung cancer detection.

RESULTS

The sensitivity for detecting JVPNs near the pulmonary hilum was remarkably increased from 58.8% without DL-AI to 94.1% with DL-AI. For central JVPNs, detection sensitivity was also improved with the assistance of the DL-AI system, from 64.3% to 94.6% with the DL-AI. The sensitivity of JVPNs in the peripheral lung was increased from 79.4% without DL-AI to 97.6% with DL-AI. False-positive rates were also greatly reduced with the assistance of the DL-AI system, from 4.8% to 1.0%, from 3.8% to 1.9% and from 2.9% to 1.0% for JVPNs near the pulmonary hilum area, central and peripheral, respectively.

CLINICAL RELEVANCE/APPLICATION

It is potentially feasible to detect more juxta-vascular pulmonary nodules with the assistance of DL-AI system for the early lung cancer detection.

IR02-A3   The Association Between Gut Hormones And Weight Changes After Bariatric Arterial Embolization During The Beat Obesity Trial

Participants

Muhammad Latif, MBBS, Dundalk, Maryland (*Presenter*) Nothing to Disclose

PURPOSE

Bariatric arterial embolization (BAE) is an endovascular procedure with promising results for the treatment of obesity. It induces ischemia in the gastric fundus, the main site of endogenous ghrelin, the only known orexigenic hormone. Preliminary results suggest that BAE-induced changes in gut hormones contribute to postprocedural weight loss by influencing satiety, hunger, and energy homeostasis. Our study objective was to evaluate the association between ghrelin, peptide YY 3-36 (PYY3-36), and glucagon-like peptide 1 (GLP-1) and weight changes post-BAE during the course of 1-year follow-up.*Methods and Materials Patients enrolled in the BEAT Obesity Trial were evaluated at 1- and 2-weeks and 3- , 6- , and 12-months post-embolization. Patients were instructed to fast after dinner before their appointments and were fed a mixed meal test. At each follow-up appointment, blood work was collected after 0, 15, 30, 60, 120, 180, and 240 minutes to measure ghrelin, PYY3-36, and GLP-1 levels. To facilitate longitudinal data analysis, data from a representative group of responders (defined as patients consistently in the top tertile of weight loss at each visit throughout the yearlong study) were compared with data from a representative group of non-responders (defined as patients who were consistently in the bottom tertile of weight loss at each visit).*Results There was a significant decrease in percent change ghrelin in non-responders, at 60- and 180-minute timepoint at the week-2 appointment (estimated difference between 60 vs. 0 minute: -29; 95% CI: -49, -9; p = 0.008) and estimated difference between 180 vs. 0 minutes: -30, 95%CI: -53, -7, p = 0.016). Responders showed statistically decreased serum ghrelin compared with non-responders at months 6 and 12, corresponding with greater weight loss in these patients over this time. PYY3-36 and GLP-1 levels showed no difference between the two groups. Area-under-the-curve (AUC) hormone analysis at each visit showed a significant difference in ghrelin between the two groups. No significant difference was found in AUC values for GLP-1 and PYY3-36.*Conclusions Responders to BAE who had consistent weight loss throughout follow-up showed decreased ghrelin levels compared with non-responders, supporting decreased ghrelin as a mechanism underlying BAE-induced weight loss, similar to vertical sleeve gastrectomy surgery. Similar PYY3-36 and GLP-1 levels between the groups, unlike traditional bariatric surgery, may be attributed to lack of direct effect of BAE on the distal small intestine.*Clinical Relevance/Application Bariatric embolization is feasible and appears to be well tolerated in severely obese patients.

RESULTS

There was a significant decrease in percent change ghrelin in non-responders, at 60- and 180-minute timepoint at the week-2 appointment (estimated difference between 60 vs. 0 minute: -29; 95% CI: -49, -9; p = 0.008) and estimated difference between 180 vs. 0 minutes: -30, 95%CI: -53, -7, p = 0.016). Responders showed statistically decreased serum ghrelin compared with non-responders at months 6 and 12, corresponding with greater weight loss in these patients over this time. PYY3-36 and GLP-1 levels showed no difference between the two groups. Area-under-the-curve (AUC) hormone analysis at each visit showed a significant difference in ghrelin between the two groups. No significant difference was found in AUC values for GLP-1 and PYY3-36.

CLINICAL RELEVANCE/APPLICATION

Bariatric embolization is feasible and appears to be well tolerated in severely obese patients.

IR02-A4   Causal Effect Of Transjugular Intrahepatic Portosystemic Shunt On Perioperative Clinical Outcomes In Patients Undergoing Orthotopic Liver Transplantation: 2002-2021 United Network For Organ Sharing Registry

Participants

John Moon, MD, Atlanta, Georgia (*Presenter*) Nothing to Disclose

PURPOSE

To estimate the causal effect of TIPS on key perioperative biomarkers and clinical outcomes including ascites, hepatic encephalopathy (HE), albumin, bilirubin, creatinine, International Normalized Ratio (INR), Child Pugh score (CPS), and Model for End-stage Liver Disease (MELD) score in HCC and non-HCC patients waiting for OLT.*Methods and Materials We applied an inverse probability of treatment weighted (IPTW) model to estimate the causal effect of TIPS on each of the above outcomes. Causal effects were estimated by applying weighted regression models, ordinary least squares regression for continuous outcomes, multinomial logistic regression for nominal outcomes, and ordered logistic regression for ordinal variables. Regression weights were estimated using the IPTW framework, or, a binomial logistic regression to estimate the probability of receiving TIPS given baseline confounders from the time of patient enrollment into UNOS.*Results Among non-HCC patients, TIPS was causally associated with a decrease in perioperative levels of albumin (95% CI: -0.179, -0.166; p<0.001), bilirubin (95% CI: -1.003, -0.789; p<0.001), creatinine (95% CI: -0.148, -0.129; p<0.001), INR (95% CI: -0.127, -0.105; p<0.001), and the MELD score (95% CI: -1.16079, -0.984; p<0.001). TIPS was also causally associated with an increase in proportional odds ratio (i.e. higher ratio meaning lower score) for CPS (95% CI: 1.133, 1.161; p<0.001), ascites (95% CI: 1.279, 1.314; p<0.001), and HE (95%CI: 1.305, 1.342;

p<0.001). Among HCC patients, TIPS was causally associated with a decrease in albumin (95% CI: -0.394, -0.322; p<0.001). However, TIPS was causally associated with an increase in bilirubin (95% CI: 0.789, 0.984; p<0.001), creatinine (95% CI: 0.070, 0.110; p<0.001), INR (95% CI: 0.070, 0.147; p<0.01), and the MELD score (95% CI: 2.493, 2.996; p<0.001). TIPS was also causally associated with an increased proportional odds ratio (i.e. higher ratio meaning lower score) for CPS (95% CI: 3.016, 3.625; p<0.001), ascites (95% CI: 2.268, 2.790; p<0.001), and HE (95% CI: 2.456, 3.035; p<0.001).*Conclusions Biomarkers associated 30-day mortality are favorably decreased in non-HCC but not in HCC patients. Clinical symptom severity and scoring are favorably decreased in both groups.*Clinical Relevance/Application In both HCC and non-HCC patients, TIPS decreases hepatic encephalopathy and ascites. Child-Pugh Score, as a surrogate to life expectancy and perioperative mortality, is also decreased in both HCC and non-HCC patients.

RESULTS

Among non-HCC patients, TIPS was causally associated with a decrease in perioperative levels of albumin (95% CI: -0.179, -0.166; p<0.001), bilirubin (95% CI: -1.003, -0.789; p<0.001), creatinine (95% CI: -0.148, -0.129; p<0.001), INR (95% CI: -0.127, -0.105; p<0.001), and the MELD score (95% CI: -1.16079, -0.984; p<0.001). TIPS was also causally associated with an increase in proportional odds ratio (i.e. higher ratio meaning lower score) for CPS (95% CI: 1.133, 1.161; p<0.001), ascites (95% CI: 1.279, 1.314; p<0.001), and HE (95%CI: 1.305, 1.342; p<0.001). Among HCC patients, TIPS was causally associated with a decrease in albumin (95% CI: -0.394, -0.322; p<0.001). However, TIPS was causally associated with an increase in bilirubin (95% CI: 0.789, 0.984; p<0.001), creatinine (95% CI: 0.070, 0.110; p<0.001), INR (95% CI: 0.070, 0.147; p<0.01), and the MELD score (95% CI: 2.493, 2.996; p<0.001). TIPS was also causally associated with an increased proportional odds ratio (i.e. higher ratio meaning lower score) for CPS (95% CI: 3.016, 3.625; p<0.001), ascites (95% CI: 2.268, 2.790; p<0.001), and HE (95% CI: 2.456, 3.035; p<0.001).

CLINICAL RELEVANCE/APPLICATION

In both HCC and non-HCC patients, TIPS decreases hepatic encephalopathy and ascites. Child-Pugh Score, as a surrogate to life expectancy and perioperative mortality, is also decreased in both HCC and non-HCC patients.

IR02-A6   Repetitive Transarterial Hepatic Chemoperfusion For The Treatment Of Advanced Hepatic Uveal Melanoma Metastases - Assessment Of Prognostic Determinants

Participants
Julia Isabelle Wimmer, MD, Essen, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Evaluation of prognostic determinants in patients with advanced hepatic uveal melanoma metastases treated with repetitive whole liver transarterial hepatic chemoperfusion (THC) as palliative treatment.*Methods and Materials 105 patients (50,5% male; 92% bilobar disease) with a median age of 61.7 years (range 27-81) first treated between 2010-2017 were retrospectively assessed. A median of 5 (range: 1-10) THC sessions with melphalan (88%, median: 40mg) or fotemustin (12%, median: 180mg) were performed. The inflammatory marker SII (Systemic immune inflammation index) was calculated as follows: (platelets/nl × neutrophils/nl)/ (lymphocytes/nl). Kaplan-Meier analysis for median overall survival in months (OS; 95%CI), univariate (UVA) and multivariate (MVA) analyses (Hazard ratio; 95%CI) were performed.*Results Median OS after first THC was 8.2 (95%CI: 6.4-11.1) months. Regarding prognostic OS markers, UVA identified number of hepatic tumor lesions <10 (0.4; 0.2-0.6; p<.0001), long axis of largest hepatic lesion <median of 58.8mm (0.4; 0.3-0.6; p<.0001), SII <median of 975.2 (0.4; 0.3-0.7; p=.0001), normal bilirubin (0.3; 0.2-0.7; p=.003), normal AST values (0.3; 0.2-0.5; p<.0001), normal ALT values (0.4; 0.3-0.6; p<.0001), normal AP values (0.5; 0.3-0.8; p=.002), normal LDH values in comparison to intermediate (248-1000 U/l; 0.5; 0.3-0.9; p<.0001) and high (>1000 U/l; 0.1; 0.06-0.3; p<.0001) LDH values and normal whole protein (0.3; 0.2-0.6; p=.0001) as significant predictors for longer survival. MVA confirmed size of largest liver lesion <median (0.36; 0.18-0.7; p=.003), normal bilirubin (0.26; 0.1-0.69; p=.007) and normal whole protein (0.2; 0.09-0.5; p=.0005) as independent predictors for longer OS. Survival prediction could further be improved combining significant factors from MVA: Patients with size of largest lesion <median, normal bilirubin, and normal whole protein survived the longest with 12.5 months (95%CI: 10.2-15.8) compared to patients with only two (8.2; 3.5-18.9), one (5.2; 4.3-6.4) and none (1.1; 0.3-3.5) of the beneficial factors, p<.0001. The difference between each group was statistically significant in UVA.*Conclusions THC is an effective palliative treatment option for patients with advanced uveal melanoma liver metastases. In addition, the size of the largest liver lesion, bilirubin, and whole protein serve as relevant prognostic determinants of survival, aiding in identifying patients potentially profiting from therapy.*Clinical Relevance/Application Clinical decision-making regarding appropriate patient selection and treatment effectiveness may be improved with information on essential predictors for the overall survival of patients with uveal melanoma liver metastases undergoing THC.

RESULTS

Median OS after first THC was 8.2 (95%CI: 6.4-11.1) months. Regarding prognostic OS markers, UVA identified number of hepatic tumor lesions <10 (0.4; 0.2-0.6; p<.0001), long axis of largest hepatic lesion <median of 58.8mm (0.4; 0.3-0.6; p<.0001), SII <median of 975.2 (0.4; 0.3-0.7; p=.0001), normal bilirubin (0.3; 0.2-0.7; p=.003), normal AST values (0.3; 0.2-0.5; p<.0001), normal ALT values (0.4; 0.3-0.6; p<.0001), normal AP values (0.5; 0.3-0.8; p=.002), normal LDH values in comparison to intermediate (248-1000 U/l; 0.5; 0.3-0.9; p<.0001) and high (>1000 U/l; 0.1; 0.06-0.3; p<.0001) LDH values and normal whole protein (0.3; 0.2-0.6; p=.0001) as significant predictors for longer survival. MVA confirmed size of largest liver lesion <median (0.36; 0.18-0.7; p=.003), normal bilirubin (0.26; 0.1-0.69; p=.007) and normal whole protein (0.2; 0.09-0.5; p=.0005) as independent predictors for longer OS. Survival prediction could further be improved combining significant factors from MVA: Patients with size of largest lesion <median, normal bilirubin, and normal whole protein survived the longest with 12.5 months (95%CI: 10.2-15.8) compared to patients with only two (8.2; 3.5-18.9), one (5.2; 4.3-6.4) and none (1.1; 0.3-3.5) of the beneficial factors, p<.0001. The difference between each group was statistically significant in UVA.

CLINICAL RELEVANCE/APPLICATION

Clinical decision-making regarding appropriate patient selection and treatment effectiveness may be improved with information on essential predictors for the overall survival of patients with uveal melanoma liver metastases undergoing THC.

IR02-A7   An Overview Of Techniques To Improve Future Liver Remnant (FLR)

Awards
Identified for RadioGraphics

Participants

Pouya Entezari, MD, Chicago, Illinois (*Presenter*) Nothing to Disclose

TEACHING POINTS

1. Insufficient future liver remnant (FLR) precludes many patients with hepatic malignancy from undergoing curative surgery.2. Different methods of FLR hypertrophy have been developed to convert patients with small FLR into surgical candidates. However, there is a lack of consensus regarding the method of choice. Knowledge of these techniques can help to choose the optimum method, based on individual characteristics, for the patients.

TABLE OF CONTENTS/OUTLINE

1. Introduction 1.1. Concept of FLR 1.2. Calculating FLR 1.3. Methods to improve FLR 2. Two-stage Liver Resection 2.1. Principles and Technical Considerations 2.2. Outcomes of FLR hypertrophy 2.3. Challenges 3. Portal Vein Embolization (PVE) and Ligation (PVL) 3.1. Principles and Technical Considerations 3.2. Outcomes of FLR hypertrophy 3.3. Challenges 4. Radiation Lobectomy 4.1. Principles and Technical Considerations 4.2. Outcomes of FLR hypertrophy 4.3. Challenges 5. Associating Liver Partition and Portal Vein Ligation for Staged hepatectomy (ALPPS) 5.1. Principles and Technical Considerations 5.2. Outcomes of FLR hypertrophy 5.3. Challenges 6. Hepatic Venous Deprivation (HVD) 6.1. Principles and Technical Considerations 6.2. Outcomes of FLR hypertrophy 6.3. Challenges 7. Comparing the outcomes of different methods in FLR hypertrophy

HN04-D1   Multi-parametric MR Imaging Of Head And Neck Cancer: Imaging Biomarker For Tumor Hypoxia And Heterogeneity

Participants
Yoshimi Anzai, MD,MPH, Salt Lake City, Utah (*Presenter*) Nothing to Disclose

PURPOSE

Tumor hypoxia is one of the physiological factors for treatment resistance and likely contributes to poor overall survival among patients with head and neck cancer (HNC). Identifying hypoxic features of HNC may allow the personalizing treatment plan. A prospective cohort study was conducted used multiparametric MR (MPMR) imaging correlated with treatment response assessed by 3 months FDG-PET. The image analysis approach was developed to incorporate FDG-PET and quantitative MRI characteristics of tumor (ADC, oxygen-enhanced T1 and T2* maps, and Ktrans) to facilitate 3D visualization of multiparametric information.*Methods and Materials In this prospective pilot study, 13 patients with newly diagnosed HNC were recruited. All patients provided written consent. Subjects underwent MPMR imaging on a 3T MRI scanner with 20 channel head and neck coil. MRI protocol included air and oxygen-enhanced T1 and T2* mapping, DWI, and DCE MRI. R2* (1/T2*) and T1 of blood decreases with O2 saturation. It is expected that normoxic tumor regions show a reduction of R2* and T1, whereas hypoxic tumor regions show stable or increased R2* and T1. Primary tumors and metastatic lymph nodes were manually traced on T2w images. 1D and 2D histograms of all pixels from a primary tumor and lymph node metastases were generated for ADC, Ktrans, ADC, and R2* and R1 (1/T1). In addition, a multiparametric color map was developed as a proof of concept. *Results 8 subjects completed the 3 months post-treatment FDG-PET scan to assess treatment response. Tumor pixels for non-responders had a higher volume fraction of lower Ktrans, higher ADC, and lower R2* than those for responders. 3D composite color maps demonstrate areas of perfusion uncoupling, a feature of hypoxia, as well as intra-tumoral heterogeneity (figure 1).*Conclusions Oxygen-enhanced T1 and T2* mapping MRI may show a slight change in R2* and R1, where oxygen is delivered. MPMR imaging has the potential to reveal the spatial distribution of hypoxic regions within a tumor. MPMR imaging has the potential to serve as a non-invasive imaging of tumor hypoxia and predict treatment failure.*Clinical Relevance/Application A composite color map combining quantitative information from multiparametric imaging (oxygen-enhanced T1 and T2* mapping, DWI, DCE, and FDG-PET) has the potential to reveal the spatial distribution of the area of hypoxia within a tumor.

RESULTS

8 subjects completed the 3 months post-treatment FDG-PET scan to assess treatment response. Tumor pixels for non-responders had a higher volume fraction of lower Ktrans, higher ADC, and lower R2* than those for responders. 3D composite color maps demonstrate areas of perfusion uncoupling, a feature of hypoxia, as well as intra-tumoral heterogeneity (figure 1).

CLINICAL RELEVANCE/APPLICATION

A composite color map combining quantitative information from multiparametric imaging (oxygen-enhanced T1 and T2* mapping, DWI, DCE, and FDG-PET) has the potential to reveal the spatial distribution of the area of hypoxia within a tumor.

VA03-B1   **Dose Management Capabilities Of Digital Variance Angiography: 70 % Decrease Of DSA-related Radiation Exposure In Lower Limb X-ray Angiography**

Participants

Marcell Gyano, MD, Budakeszi, Hungary (*Presenter*) Employee, Kinepict Health Ltd;Researcher, Kinepict Health Ltd

PURPOSE

In previous clinical studies Digital Variance Angiography (DVA), a new image processing method provided higher contrast-to-noise ratio (CNR) and better image quality than Digital Subtraction Angiography (DSA). The aim of this study was to investigate, whether the previously observed quality reserve of DVA can be used to reduce radiation exposure in lower limb X-ray angiography.*Methods and Materials Our prospective study enrolled 30 peripheral artery disease patients (Fontaine IIb-IV, mean age 70 years, range 52-85 years; 10 females, mean age 73 years, range 55-85 years; and 20 males, mean age 69 years, range 52-85) undergoing diagnostic lower limb X-ray angiography between April and July 2019. In all enrolled patients, both normal (1.2 μGy/frame) and low-dose (0.36 μGy/frame) protocols were used for the acquisition of images in three anatomical regions. The CNR of DSA and retrospectively generated DVA images were calculated, and the quality was evaluated by seven specialists using a 5-grade Likert scale. For investigating non-inferiority, the difference of low-dose DVA and normal dose DSA scores (DVA30-DSA100) was analyzed by the one-sample Wilcoxon test.*Results DVA produced consistently higher (two to threefold) CNR than DSA. The highest ratios (3.0-3.1) were observed in the crural region. In the visual evaluation, DVA30 received significantly higher scores than DSA100 (difference 0.25±0.07, p=0.001). There was no significant difference in the femoral region (-0.08±0.06, p=0.435), but DSA100 received significantly higher score in the abdominal region (-0.26±0.12, p=0.036). However, after exclusion of patients with excessive intestinal gases (3/30, 10% of patients), the difference in the abdominal region decreased to (-0.10 ± 0.09, p=0.350) and was no longer significant.*Conclusions Our data show that, with some caveats, DVA allows a very substantial (70%) reduction of DSA-related radiation exposure in lower limb interventions, therefore this technology might increase the safety of these endovascular procedures.*Clinical Relevance/Application The previously observed quality reserve of Digital Variance Angiography allows for a substantial DSA-related radiation exposure reduction (up to 70%) in lower limb X-ray angiography without compromising the image quality.

RESULTS

DVA produced consistently higher (two to threefold) CNR than DSA. The highest ratios (3.0-3.1) were observed in the crural region. In the visual evaluation, DVA30 received significantly higher scores than DSA100 (difference 0.25±0.07, p=0.001). There was no significant difference in the femoral region (-0.08±0.06, p=0.435), but DSA100 received significantly higher score in the abdominal region (-0.26±0.12, p=0.036). However, after exclusion of patients with excessive intestinal gases (3/30, 10% of patients), the difference in the abdominal region decreased to (-0.10 ± 0.09, p=0.350) and was no longer significant.

CLINICAL RELEVANCE/APPLICATION

The previously observed quality reserve of Digital Variance Angiography allows for a substantial DSA-related radiation exposure reduction (up to 70%) in lower limb X-ray angiography without compromising the image quality.

RI05-B1   **Imaging Overdiagnosis Of Acquired Uterine Arteriovenous Malformation**

Participants
Julia Saltalamacchia, MD, Portland, Oregon (*Presenter*) Nothing to Disclose

PURPOSE

The true incidence of uterine arteriovenous malformation (AVM) is unknown, but it has been increasingly reported in case series, usually without pathologic confirmation. Radiographic diagnosis of uterine AVM often discourages intervention such as dilation and curettage (D+C) due to concern for uncontrollable hemorrhage. As such, there have been increasing preemptive uterine artery embolizations (UAE). However, few examples in literature reliably distinguishes the presentation or imaging findings of a true uterine AVM from hypervascular retained products of conception (RPOC). This study aims to (1) assess the predictive value of an imaging diagnosis of AVM, and (2) evaluate the clinical course and outcomes of patients with imaging findings suspicious for uterine AVM at a single institution.*Methods and Materials This IRB-approved, retrospective study from 2000-2021, included all patients with imaging reports raising concerns for uterine AVM and excluded those with incomplete data or who were lost to follow up. Search terms included "uterine AVM," "uterine arteriovenous malformation," "uterus AND AVM," "uterus AND arteriovenous malformation". Initial presentation, b-HCG level, imaging reports, management, and pathology were collected and analyzed. Using the pathologic specimen as the standard when available, the positive predictive value of US was calculated.*Results A total of 22 patients were identified. All patients had transvaginal US, 10/22 (45%) had subsequent MRI, and 2/22 (9%) had subsequent CTA . Pathology specimen was available in 16/22 (73%) patients. The positive predictive value of US diagnosis of AVM was 6.3%. Subsequent MRI and CTA did not differ from initial US diagnosis. Most common final pathologic diagnosis was RPOC: 9/16 (56%). Others included normal endometrium, retained placenta accreta, and polyps. Of the 22 patients, 3/22 (14%) underwent hysterectomy, 6/22 (27%) UAE, 9/22 (40%) D&C, and 4/22 (18%) were managed conservatively. Only one out of six who underwent UAE had pathologically confirmed AVM; pathology from others included RPOC (3), normal endometrium (1), and placenta increta (1). Notably, of the patients with confirmed RPOC, (4/9) 45% had a negative b-HCG at presentation.*Conclusions US significantly overdiagnoses uterine AVM. MRI, CTA and b-HCG are unlikely to be helpful. The diagnosis of AVM may also result in unnecessary or over-treatment of these patients including UAE and hysterectomy.*Clinical Relevance/Application This study questions the true incidence of acquired AVM in existing literature. Knowing how significant the overdiagnosis is can encourage consideration of D+C or direct visualization and removal of tissue with hysteroscopy prior to pursuing more invasive treatment with UAE or hysterectomy.

RESULTS

A total of 22 patients were identified. All patients had transvaginal US, 10/22 (45%) had subsequent MRI, and 2/22 (9%) had subsequent CTA . Pathology specimen was available in 16/22 (73%) patients. The positive predictive value of US diagnosis of AVM was 6.3%. Subsequent MRI and CTA did not differ from initial US diagnosis. Most common final pathologic diagnosis was RPOC: 9/16 (56%). Others included normal endometrium, retained placenta accreta, and polyps. Of the 22 patients, 3/22 (14%) underwent hysterectomy, 6/22 (27%) UAE, 9/22 (40%) D&C, and 4/22 (18%) were managed conservatively. Only one out of six who underwent UAE had pathologically confirmed AVM; pathology from others included RPOC (3), normal endometrium (1), and placenta increta (1). Notably, of the patients with confirmed RPOC, (4/9) 45% had a negative b-HCG at presentation.

CLINICAL RELEVANCE/APPLICATION

This study questions the true incidence of acquired AVM in existing literature. Knowing how significant the overdiagnosis is can encourage consideration of D+C or direct visualization and removal of tissue with hysteroscopy prior to pursuing more invasive treatment with UAE or hysterectomy.

GU02-B2   **Bosniak Classification Version 2019: Validation And Comparison To Original Classification In Pathologically Confirmed Cystic Masses.**

Participants
Jin Hui Yan, MD, Ottawa, Ontario (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate Bosniak Classification v2019 definitions in pathologically confirmed cystic renal masses.*Methods and Materials IRB approved, cross-sectional study. 73 cystic (=25% solid) masses with histological confirmation (57 malignant, 16 benign) imaged by CT (N=28) or CT+MRI (N=56) between 2009-2019 were independently evaluated by three blinded radiologists using Bosniak v2019 and original classifications. Discrepancies were resolved by consensus with a fourth blinded radiologist. Overall class and v2019 features were compared to pathology.*Results Interobserver agreement was slightly improved comparing v2019 to Original Bosniak Classification (Kappa=0.26-0.47 versus 0.24-0.34 respectively). v2019 proportion of IIF and III masses (20.5% [15/73, 95% Confidence Interval [[CI]] 12.0-31.6%], 38.6% [28/73, 95%CI 27.2-50.5%]) differed from Original classification (6.8% [5/73, 95%CI 2.3-15.3%], 61.6% [45/73, 95%CI 49.5-72.8%]) with overlapping proportion of malignancy in each class. Mean septa number (7±4[range:1-10]) was not associated with malignancy (p=0.89). Mean wall, septa thickness were: 3±3(1-14) and 3±2(1-10) mm and higher in malignancies (p=0.03, 0.20 respectively). Area under receiver-operator-characteristic curve for wall, septa thickness were: 0.66 (95%CI 0.54-0.79) and 0.61 (95%CI 0.45- 0.78) with optimal cutpoint of =3 mm (sensitivity 33.3%, specificity 86.7% and sensitivity 53%, specificity 73% respectively). Proportion of malignancy occurring in masses with the v2019 features 'irregularity' (76.9% [10/13], 95% CI 46.2-94.9%) and 'nodule' (89.7% [26/29], 95%CI 72.7-97.8%) overlapped. Angle of 'nodule' (p=0.27) was not associated with malignancy.*Conclusions Bosniak v2019 definitions for wall/septa thickness and protrusions are associated with malignancy. Overall, Bosniak v2019 categorizes a higher proportion of malignant masses in Class IIF with slight improvement in inter-observer agreement.*Clinical Relevance/Application Overall Bosniak v2019 offers improvements to Original Classification and proposed definitions are associated with malignancy. Further simplifications to Bosniak v2019 may improve ease of use without compromising accuracy but will require further study.

RESULTS

Interobserver agreement was slightly improved comparing v2019 to Original Bosniak Classification (Kappa=0.26-0.47 versus 0.24-0.34 respectively). v2019 proportion of IIF and III masses (20.5% [15/73, 95% Confidence Interval [[CI]] 12.0-31.6%], 38.6% [28/73, 95%CI 27.2-50.5%]) differed from Original classification (6.8% [5/73, 95%CI 2.3-15.3%], 61.6% [45/73, 95%CI 49.5-72.8%]) with overlapping proportion of malignancy in each class. Mean septa number (7±4[range:1-10]) was not associated with malignancy (p=0.89). Mean wall, septa thickness were: 3±3(1-14) and 3±2(1-10) mm and higher in malignancies (p=0.03, 0.20 respectively). Area under receiver-operator-characteristic curve for wall, septa thickness were: 0.66 (95%CI 0.54-0.79) and 0.61 (95%CI 0.45- 0.78) with optimal cutpoint of =3 mm (sensitivity 33.3%, specificity 86.7% and sensitivity 53%, specificity 73% respectively). Proportion of malignancy occurring in masses with the v2019 features 'irregularity' (76.9% [10/13], 95% CI 46.2-94.9%) and 'nodule' (89.7% [26/29], 95%CI 72.7-97.8%) overlapped. Angle of 'nodule' (p=0.27) was not associated with malignancy.

CLINICAL RELEVANCE/APPLICATION

Overall Bosniak v2019 offers improvements to Original Classification and proposed definitions are associated with malignancy. Further simplifications to Bosniak v2019 may improve ease of use without compromising accuracy but will require further study.

NR03-B10   **Molecular MRI Targeting Myeloperoxidase Activity Reveals Effects Of D-mannose On Host Response And Glioma Progression**

Participants
Negin Jalali Motlagh, MD, Boston, Massachusetts (*Presenter*) Nothing to Disclose

PURPOSE

Host immune response in the tumor microenvironment plays key roles in tumorigenesis. We aimed to determine the effect D-mannose, a drug with anti-inflammatory properties, has on oxidative stress and glioma progression using molecular MRI targeting myeloperoxidase (MPO), a highly oxidizing enzyme secreted in host defense, in a mouse glioma model.*Methods and Materials Twenty-three immunocompetent C57BL/6J mice were intracranially implanted with CT-2A-luc mouse glioma stem cells. Three days after tumor implantation, mice were randomly divided into two groups (n= 11-12 per group) and treated intraperitoneally daily with 450mg/kg either D-mannose or with PBS as control. To evaluate MPO activity in vivo, mice were imaged on a 4.7T MRI scanner with 0.3mmol/kg of bis-5HT-DTPA-Gd (MPO-Gd) administered intravenously at 4 weeks after implantation. MPO activity assay and flowcytometry of brain leukocytes were also performed after MRI. Tumor size was tracked by bioluminescence (BLI) and MRI. In vitro MPO activity experiments were performed using activated leukocytes incubated with D-mannose (1 mg/ml, 2 mg/ml, 4 mg/ml). P<0.05 was considered statistically significance.*Results D-mannose treatment decreased the size of gliomas compared to those that were PBS-treated (mean ± SEM, p=0.0042 for BLI and p=0.0014 for MRI). Surprisingly, D-mannose increased MPO-Gd enhancement in the peritumoral brain parenchyma (p=0.015) a result corroborated by ex vivo MPO activity assays (mean ± SEM, p=0.0345 for MPO protein , p=0.0242 for MPO activity). On flowcytometry, D-mannose-treated glioma mice contained fewer MPO-containing cells compared to PBS-treated glioma mice (mean ± SEM, p<0.0001), revealing that D-mannose increased MPO secretion. In vitro experiments further confirmed that D-mannose increased MPO activity.*Conclusions Our results revealed that D-mannose unexpectedly increased secretion of active MPO from inflammatory leukocytes into the glioma microenvironment and this increased host immune response acted to reduce tumor size.*Clinical Relevance/Application Our study suggests that increasing MPO activity such as D-mannose administration may be potential new therapeutic direction for glioma treatment

RESULTS

D-mannose treatment decreased the size of gliomas compared to those that were PBS-treated (mean ± SEM, p=0.0042 for BLI and p=0.0014 for MRI). Surprisingly, D-mannose increased MPO-Gd enhancement in the peritumoral brain parenchyma (p=0.015) a result corroborated by ex vivo MPO activity assays (mean ± SEM, p=0.0345 for MPO protein , p=0.0242 for MPO activity). On flowcytometry, D-mannose-treated glioma mice contained fewer MPO-containing cells compared to PBS-treated glioma mice (mean ± SEM, p<0.0001), revealing that D-mannose increased MPO secretion. In vitro experiments further confirmed that D-mannose increased MPO activity.

CLINICAL RELEVANCE/APPLICATION

Our study suggests that increasing MPO activity such as D-mannose administration may be potential new therapeutic direction for glioma treatment

NR03-B11   **Spinal Cord Iatrogenesis!: Posttreatment Changes And Complications Of The Spinal Cord**

Participants
Sevcan Turk, MD, Ann Arbor, Michigan (*Presenter*) Nothing to Disclose

TEACHING POINTS

1. With ongoing therapeutic advances, adverse health care induced effects in the central nervous system are being encountered more commonly. In some cases, these may result in severe morbidity. Radiologists who interpret neuroimaging exams must be aware of these entities in order to provide the correct diagnosis and help facilitate timely clinical management. 2. Our presentation will demonstrate common and rare iatrogenic injuries in the spinal cord that radiologists must recognize in routine practice.

TABLE OF CONTENTS/OUTLINE

1. Overview of imaging characteristics of a spectrum of common as well as rare spinal cord lesions after therapy with the review of acute/chronic complications- Post-radiation changeso Post-radiation changes may mimic tumor progression; DWI can provide additional information in the discrimination of radiation necrosis- Post-infectious changeso Post-infectious or post-chemotherapy enhancing lesions may mimic residual disease, however, decreasing edema may favor posttreatment sequela.- Changes after ischemiao Ischemia related myelopathy should always be considered after surgery and especially in patients with coagulopathy. DWI is the best sequence to diagnose.- Changes after trauma- Post-surgical spinal cord- Medication related spinal cord complicationso Medication related complications should always be considered in the differential for nonspecific spinal cord pathologies, especially when CSF is normal.- Immunosuppressed patients

NR03-B2   **Predictors Of Poor Functional Outcomes And Symptomatic Intracranial Hemorrhage After**

Endovascular Treatment In Early Versus Extended Time Windows

Participants
Sriharsha Voleti, BS, Mason, Ohio (*Presenter*) Nothing to Disclose

PURPOSE

The safety profile of endovascular therapy (EVT) including incidence of symptomatic intracranial hemorrhage (sICH) is well studied in the early treatment window of 0-6 hours; however, there are limited data for extended windows of 6-24 hours. Our objective was to evaluate the risk factors for sICH after EVT for acute stroke treated in the early vs. extended time windows.*Methods and Materials We performed a retrospective review of our prospectively identified stroke registry at our Comprehensive Stroke Center. We included all patients receiving EVT between May 2016 to January 2019. We recorded demographics, clinical characteristics, procedure details, modified treatment in cerebral ischemia (mTICI) score, functional outcomes (mRS) and ICH on post-procedural head CT. Heidelberg Bleeding Classification was used to assign sICH. Multivariable regression analysis was performed to evaluate independent predictors for sICH.*Results Of the 424 patients who received EVT during the study period, 309 patients met our inclusion criteria. 205 (66.3%) patients received EVT in the early window and 104 (33.7%) patients received EVT in the extended window. Successful recanalization (mTICI 2B-3) was observed in 174 (84.9%) patients in the early window and 85 (81.7%) patients in the extended window. sICH was observed in 29 (14.1%) patients in the early window and 7 (6.7%) patients in the extended window. Differences in recanalization success (P = 0.53) and sICH (P = 0.055) were not statistically significant in early vs. extended window groups. Differences in favorable functional outcome (90-day mRS=2) in early vs. extended window groups (28.5% vs. 26.2%; P=0.675) were also not statistically significant. Pooled multivariable regression analysis showed >3 device passes (OR 5.64, 95% CI: 1.65-19.3, P = <0.05), initial NIHSS =21 (OR 4.66, 95% CI: 2.15-10.1, P = <0.05) and recanalization failure (OR 2.87, 95% CI: 1.11-7.38, P = <0.05) as independent predictors of poor outcomes (mRS >2) for all patients. In the extended window, NIHSS >10 was the only risk factor associated with poor functional outcome (NIHSS 11-20: OR 4.9, 95% CI: 1.67-14.4, P = <0.05; NIHSS =21: OR 7.02, 95% CI: 1.25-39.4, P = <0.05). There were no statistically significant predictors of sICH in either group.*Conclusions Incidence of sICH after EVT in the early vs extended windows is not significantly different. Poor functional outcomes are associated with >3 device passes, initial NIHSS =21, and recanalization failure for all patients receiving EVT.*Clinical Relevance/Application With the expanded EVT treatment windows for acute ischemic stroke, it is critical for radiologists and interventionalists to understand the predictors for symptomatic ICH.

RESULTS

Of the 424 patients who received EVT during the study period, 309 patients met our inclusion criteria. 205 (66.3%) patients received EVT in the early window and 104 (33.7%) patients received EVT in the extended window. Successful recanalization (mTICI 2B-3) was observed in 174 (84.9%) patients in the early window and 85 (81.7%) patients in the extended window. sICH was observed in 29 (14.1%) patients in the early window and 7 (6.7%) patients in the extended window. Differences in recanalization success (P = 0.53) and sICH (P = 0.055) were not statistically significant in early vs. extended window groups. Differences in favorable functional outcome (90-day mRS=2) in early vs. extended window groups (28.5% vs. 26.2%; P=0.675) were also not statistically significant. Pooled multivariable regression analysis showed >3 device passes (OR 5.64, 95% CI: 1.65-19.3, P = <0.05), initial NIHSS =21 (OR 4.66, 95% CI: 2.15-10.1, P = <0.05) and recanalization failure (OR 2.87, 95% CI: 1.11-7.38, P = <0.05) as independent predictors of poor outcomes (mRS >2) for all patients. In the extended window, NIHSS >10 was the only risk factor associated with poor functional outcome (NIHSS 11-20: OR 4.9, 95% CI: 1.67-14.4, P = <0.05; NIHSS =21: OR 7.02, 95% CI: 1.25-39.4, P = <0.05). There were no statistically significant predictors of sICH in either group.

CLINICAL RELEVANCE/APPLICATION

With the expanded EVT treatment windows for acute ischemic stroke, it is critical for radiologists and interventionalists to understand the predictors for symptomatic ICH.

NR03-B3   Likelihood Of Fluoroscopic Guided Lumbar Puncture Based On Patient Demographics And Consulting Service

Participants
Mark Oswood, MD,PhD, Shoreview, Minnesota (*Presenter*) Speakers Bureau, Koninklijke Philips NV

PURPOSE

Recent studies have demonstrated a shift of lumbar puncture performance from medicine services to the radiology department. The goal of this study is to examine the relationship of patient demographics and diagnosis to the likelihood that lumbar puncture would be performed with fluoroscopy (FLP) as well as assess trends over time.*Methods and Materials This is a retrospective study where all lumbar punctures performed at our institution over the span of 7 years were reviewed. Patients were divided into fluoroscopically assisted (FLP) and non-fluoroscopic groups. Variables such as age, BMI, HIV status, suspicion for MS and lumbar fusion history were compared between the groups. Patient location was also compared between emergency department and several outpatient clinics. The statistical significance of observed proportion differences was calculated using a ?2 test.*Results We identified a total of 2706 lumbar punctures during the study period. 541 (20%) lumbar punctures were performed by radiology. An overall higher percentage of elderly population (age>60) were FLP compared to other services (37.6% vs. 32.4%, p=0.03). Additionally, higher BMI (>30) significantly increased the likelihood of FLP (46.6% vs. 32.7%, p<0.001). Patients with prior lumbar spinal instrumentation or a suspicion for MS had a higher likelihood of FLP (4.1% vs. 0.7%, p<0.001; and 15.9% vs. 2.4%, p<0.001, respectively). Patients undergoing evaluation for HIV were also more likely to have FLP (9% vs. 6.2%, p=0.03). Patients from the neurology or oncology services were more likely to have FLP, compared to the ED (41.6% and 35% vs. 19.2%, p<0.001, respectively). The trend of procedures done in radiology increased over the study period, going from 6.3% in 2013 to 19.3% in 2019 (3%/year, r^2=0.58).*Conclusions Patients age>60 and BMI>30 were more likely to undergo FLP, which may be due to difficulties in bedside LP in these patients. Diagnosis associated with increased FLP included HIV and suspected MS. There was also a significantly increased likelihood of patients undergoing FLP when referred from the neurology or oncology services as opposed to patients treated in the ED. At our hospital, the ED makes an effort to train all providers in bedside LP. This training is not performed in other departments, which may result in increased use of radiology by other services. Finally, our data shows an increasing trend of FLP consistent with findings of Kroll et al (2015).*Clinical Relevance/Application At our institution, the use of FLP over this 7-year period resulted in approximately $541,000 of added costs for the patient and hospital. In a time with ever increasing healthcare costs, this could potentially be mitigated by additional training in bedside LP techniques.

RESULTS

We identified a total of 2706 lumbar punctures during the study period. 541 (20%) lumbar punctures were performed by radiology.

An overall higher percentage of elderly population (age>60) were FLP compared to other services (37.6% vs. 32.4%, p=0.03). Additionally, higher BMI (>30) significantly increased the likelihood of FLP (46.6% vs. 32.7%, p<0.001). Patients with prior lumbar spinal instrumentation or a suspicion for MS had a higher likelihood of FLP (4.1% vs. 0.7%, p<0.001; and 15.9% vs. 2.4%, p<0.001, respectively). Patients undergoing evaluation for HIV were also more likely to have FLP (9% vs. 6.2%, p=0.03). Patients from the neurology or oncology services were more likely to have FLP, compared to the ED (41.6% and 35% vs. 19.2%, p<0.001, respectively). The trend of procedures done in radiology increased over the study period, going from 6.3% in 2013 to 19.3% in 2019 (3%/year, r^2=0.58).

CLINICAL RELEVANCE/APPLICATION

At our institution, the use of FLP over this 7-year period resulted in approximately $541,000 of added costs for the patient and hospital. In a time with ever increasing healthcare costs, this could potentially be mitigated by additional training in bedside LP techniques.

NR03-B4   Prevalence Of White Matter Hyperintensities In Young Subjects With And Without Mild Traumatic Brain Injury

Participants
Eric Miller, MD, Columbus, Ohio (*Presenter*) Spouse, Employee, Boehringer Ingelheim GmbH

PURPOSE

White matter hyperintensities (WMH) on T2 FLAIR MRI are a frequently encountered neuroimaging finding of varying clinical significance. WMH have been found to be associated with an increased risk of adverse neurologic events, including impaired cognition, balance, dementia and mortality, and have been described in several neurological conditions such as migraine, cerebrovascular, and demyelinating diseases as well as the result of traumatic brain injury. These are also commonly reported in normal aging. Appropriate interpretation of WMH on young patients in the setting of mild Traumatic Brain Injury (mTBI) is currently a diagnostic challenge.*Methods and Materials All 412 mTBI patients and 182 healthy controls (ages 15-50) previously enrolled in Phase I and II of a large prospective multicenter clinical trial of advanced neuroimaging techniques in mTBI were included . MR imaging was performed utilizing 3T GE Signa MR750 (GE Healthcare, Waukesha, WI) scanners with a 32-channel brain radiofrequency coil (Nova Medical, Wilmington, MA). Imaging protocol included high resolution volumetric 3D T1 MPRAGE and T2 FLAIR CUBE sequences. MRI data was standardized by use of a uniform protocol, scanner manufacturer and model, radiofrequency (RF) coil, and sequences as well as centralized processing. MRI images were reviewed by 2 blinded board certified neuroradiologists. WMH were counted and classified as "abnormal" if =5 objective punctate white matter foci were present, any single lesion was >3 mm in maximal diameter were present, or if any lesion was located in atypical location (defined as outside the most commonly encountered subcortical locations of frontoparietal regions).*Results There was no significant difference in the mean age and gender among the healthy controls and mTBI patients (p=0.570 and 0.238). WMH were observed in 32% of mTBI patients and 39% of the controls (p=0.143). Abnormal WMH by any qualifier were seen in 33% mTBI patients and 41% of controls (p= 0.813). Subjects with WMH categorized as abnormal were significantly older than patients with WMH without abnormal features (27±12 vs 22±8, p<0.000).*Conclusions Our study found no statistical difference in the presence of WMH or in abnormal appearing WMH between mTBI population and healthy controls.*Clinical Relevance/Application This study is the largest-to-date on the incidence of WMH between patients with mTBI and healthy controls on high resolution 3T MRI. We used a highly standardized protocol for data acquisition, collection, interpretation, and analysis which are strengths of this study. Our findings also differs from the commonly held dogma of an association with WMH and mTBI from previously published underpowered or outdated studies.

RESULTS

There was no significant difference in the mean age and gender among the healthy controls and mTBI patients (p=0.570 and 0.238). WMH were observed in 32% of mTBI patients and 39% of the controls (p=0.143). Abnormal WMH by any qualifier were seen in 33% mTBI patients and 41% of controls (p= 0.813). Subjects with WMH categorized as abnormal were significantly older than patients with WMH without abnormal features (27±12 vs 22±8, p<0.000).

CLINICAL RELEVANCE/APPLICATION

This study is the largest-to-date on the incidence of WMH between patients with mTBI and healthy controls on high resolution 3T MRI. We used a highly standardized protocol for data acquisition, collection, interpretation, and analysis which are strengths of this study. Our findings also differs from the commonly held dogma of an association with WMH and mTBI from previously published underpowered or outdated studies.

NR03-B6   Automated Early Ischemic Change Segmentation And Aspects Scoring On Non-contrast Computed Tomography: A Comparison To Expert Neuroradiologists

Participants
Luis Souto Maior Neto, MSc, Calgary, Alberta (*Presenter*) Developer, Circle Cardiovascular Imaging Inc

PURPOSE

Non-Contrast Computed Tomography (NCCT) is used to diagnose and make treatment decisions in most patients with acute ischemic stroke (AIS). Estimating the extent of Early Ischemic Changes (EIC) on NCCT is therefore an important task. The Alberta Stroke Program Early Computed Tomography Score (ASPECTS) was introduced to standardize assessment of EIC extent. Due to the low contrast and signal-to-noise ratio, detecting EIC, and subsequently determining ASPECTS, is challenging. In this study, we present StrokeSENS ASPECTS: a deep-learning-based tool for EIC segmentation and automatic ASPECTS assessment and compare it to expert ratings.*Methods and Materials 538 subjects were included. StrokeSENS ASPECTS was used to segment EIC via a 3D convolutional neural network developed on 438 subjects. ASPECTS regions were segmented by means of atlas-based registration. ASPECTS regions were deemed affected via their overlap with the predicted EIC segmentation. The affected hemisphere is determined based on the side with greater overlap, and the ASPECTS is computed by subtracting the number of affected regions from 10. For the remaining unseen 100 subjects, data labelled by two expert neuro-radiologists was used as the inter-rater performance benchmark. EIC segmentation was evaluated using the Dice Similarity Coefficient (DSC), and lesion volumetric agreement by means of Intraclass Correlation Coefficient (ICC). Total ASPECT score was evaluated by means of ICC. ASPECT region-level classification performance is reported in terms of clustered Area-Under-the-Curve (AUC).*Results We compare Expert-2 vs. Expert-1, the model vs. Expert-1, and the model vs. Expert-2 on the test set of 100 patients; we report all the metrics for the combinations listed in this order. Median lesion DSC with Interquartile Range were 54.8% [41%-69%], 41.7% [22%-60%], and 42.3% [14%-59%] respectively. Lesion volume ICCs [95% Confidence Interval (CI)] were 94.9% [92%-97%], 83.8% [77%-89%], 80.8% [73%-87%]. Total ASPECTS ICCs [95% CI] were 94.1% [91%-96%], 75.5% [66%-83%], and 75.4% [66%-83%]. Region

level ASPECTS AUC [95% CI] were 91.2% [89%-93%], 84.7% [81%-89%], 84.0% [80%-88%].*Conclusions The proposed algorithm can segment EIC on NCCT and predict ASPECTS with reasonable accuracy when compared to the human gold standard i.e., an expert neuro-radiologist.*Clinical Relevance/Application This model has been integrated into the commercial StrokeSENS software and will be readily available for use by clinicians. This can be a valuable tool in assisting clinicians making rapid, accurate diagnosis and treatment decisions for AIS patients in hospitals and clinical centers. It can be especially useful in remote regions where clinical expertise and neuroimaging techniques may be limited.

RESULTS

We compare Expert-2 vs. Expert-1, the model vs. Expert-1, and the model vs. Expert-2 on the test set of 100 patients; we report all the metrics for the combinations listed in this order. Median lesion DSC with Interquartile Range were 54.8% [41%-69%], 41.7% [22%-60%], and 42.3% [14%-59%] respectively. Lesion volume ICCs [95% Confidence Interval (CI)] were 94.9% [92%-97%], 83.8% [77%-89%], 80.8% [73%-87%]. Total ASPECTS ICCs [95% CI] were 94.1% [91%-96%], 75.5% [66%-83%], and 75.4% [66%-83%]. Region level ASPECTS AUC [95% CI] were 91.2% [89%-93%], 84.7% [81%-89%], 84.0% [80%-88%].

CLINICAL RELEVANCE/APPLICATION

This model has been integrated into the commercial StrokeSENS software and will be readily available for use by clinicians. This can be a valuable tool in assisting clinicians making rapid, accurate diagnosis and treatment decisions for AIS patients in hospitals and clinical centers. It can be especially useful in remote regions where clinical expertise and neuroimaging techniques may be limited.

NR03-B9   Comparison Of Qualitative And Quantitative Assessment Of Hypoxic Ischemic Brain Injury Severity On MRI

Participants
Evan Calabrese, MD, PhD, San Francisco, California (*Presenter*) Nothing to Disclose

PURPOSE

To compare radiologists' subjective assessment of hypoxic ischemic brain injury severity in cardiac arrest patients with quantitative severity assessment based on volumetric analysis of diffusion weighted images.*Methods and Materials We retrospectively analyzed MR images from 100 patients who underwent radiologic assessment for neuroprognostication following cardiac arrest at a single hospital over a 5 year period. Neuroradiologist readers evaluated diffusion MRI using a previously published 4 point scale (no significant abnormality, mild abnormality, moderate abnormality, and severe abnormality).Diffusion weighted MR images (DWIs) were quantitatively evaluated using a custom image processing pipeline implemented in Python 3.7. Processing steps included diffeomorphic registration to a standard atlas space, skull stripping, and thresholding of brain parenchyma with apparent diffusion coefficient (ADC) less than 650×10^{-6} mm2/s to identify areas of injury.A data driven quantitative severity index was developed using k-means clustering of thresholded ADC data with k=4 corresponding to a 4 point qualitative scale. Qualitative and quantitative assessments of injury severity were compared using Spearman rank correlation and the Mann-Whitney U test with P < 0.05 considered significant.*Results Radiologists' qualitative assessment corresponded to median ± interquartile range of brain parenchyma with ADC < 650×10^{-6} mm2/s of 75 ± 44 mL for "no significant abnormality", 94 ± 11 mL for "mild abnormality", 156 ± 193 mL for "moderate abnormality", and 449 ± 330 mL for "severe abnormality". Radiologists' subjective severity index was moderately well correlated with the data driven severity index (Spearman rank correlation = 0.75). Subjective severity rank was lower than the data driven severity index by 0.05 ranks, on average, though this difference did not reach statistical significance (P = 0.29).*Conclusions Radiologists' subjective assessment of hypoxic ischemic brain injury severity on MRI was moderately well correlated with a quantitative data driven severity index and tended to underestimate severity, though this difference was not significant with a sample size of 100. Regional assessment of brain injury and correlation with functional outcomes are important remaining questions that will be addressed in future work.*Clinical Relevance/Application Imaging evaluation of hypoxic ischemic brain injury is important for neuroprognostication in cardiac arrest patients, yet quantitative validation of radiologists' subjective severity assessment is lacking.

RESULTS

Radiologists' qualitative assessment corresponded to median ± interquartile range of brain parenchyma with ADC < 650×10^{-6} mm2/s of 75 ± 44 mL for "no significant abnormality", 94 ± 11 mL for "mild abnormality", 156 ± 193 mL for "moderate abnormality", and 449 ± 330 mL for "severe abnormality". Radiologists' subjective severity index was moderately well correlated with the data driven severity index (Spearman rank correlation = 0.75). Subjective severity rank was lower than the data driven severity index by 0.05 ranks, on average, though this difference did not reach statistical significance (P = 0.29).

CLINICAL RELEVANCE/APPLICATION

Imaging evaluation of hypoxic ischemic brain injury is important for neuroprognostication in cardiac arrest patients, yet quantitative validation of radiologists' subjective severity assessment is lacking.

GI01-B2   **Her-2 Differentiation In Gastric Cancer: The Value Of CT Perfusion And Spectral CT Quantitative Parameters**

Participants
Zhang Min, Jinan, China (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the feasibility of Revolution CT perfusion imaging combined with energy spectrum enhanced scanning in evaluating the status of HER-2 expression in gastric cancer.*Methods and Materials 68 patients confirmed of gastric cancer with gastroscopy were examined preoperative perfusion CT (PCT) and energy spectrum enhanced CT and curative gastrectomy. The enrolled cases were divided according to HER2 expression in term of positive (n=15)and negative group(n=53). Blood-flow (BF), blood volume (BV), mean transmit time (MTT), time to peak (TTP), permeability surface (PS) ,arterial phase and venous phase enhanced spectral CT quantitative indicators were compared were calculated. One-way analysis of variance (ANOVA) were performed in each group. A receiver operating characteristic (ROC) analysis was applied to evaluate the diagnostic performance of meaningful parameters.*Results There were statistical differences in PS and BV between HER2 positive group and negative group. The area under the ROC curve for the diagnosis of HER2 positive gastric cancer by BV and PS was 0.843(sensitivity, 73.6%; specificity, 93.3%) and 0.819(sensitivity, 77.4%; specificity, 80.0%), with the cut-off value of 38.25 ml/100g/min and 5.01ml/100g, respectively. volume iodine content and Slope of energy spectrum curve in both artery and venous phases were significantly different between HER2 positive group and negative group.(p<0.05)The area under the ROC curve for the diagnosis of HER2 positive gastric cancer by volume iodine content and Slope of energy spectrum curve in both artery and venous phases was 0.697(sensitivity, 84.9%; specificity, 66.7%) ,0.730 (sensitivity, 60.4%; specificity, 86.7%),0.786(sensitivity, 60.4%; specificity, 93.3%),0.787(sensitivity, 64.0%; specificity, 86.7%)with the cut-off value of 8.265(100 µg / mL),1.415 , 30.87(100 µg / mL)and 1.905.*Conclusions PCT and energy spectrum enhanced scanning can accurately evaluate the HER2 positive gastric cancer with certain quantitative indicators.*Clinical Relevance/Application The PCT and energy spectrum enhanced scanning can serve as alternative diagnosis method to distinguish HER2 positive gastric cancer.

RESULTS

There were statistical differences in PS and BV between HER2 positive group and negative group. The area under the ROC curve for the diagnosis of HER2 positive gastric cancer by BV and PS was 0.843(sensitivity, 73.6%; specificity, 93.3%) and 0.819(sensitivity, 77.4%; specificity, 80.0%), with the cut-off value of 38.25 ml/100g/min and 5.01ml/100g, respectively. volume iodine content and Slope of energy spectrum curve in both artery and venous phases were significantly different between HER2 positive group and negative group.(p<0.05)The area under the ROC curve for the diagnosis of HER2 positive gastric cancer by volume iodine content and Slope of energy spectrum curve in both artery and venous phases was 0.697(sensitivity, 84.9%; specificity, 66.7%) ,0.730 (sensitivity, 60.4%; specificity, 86.7%),0.786(sensitivity, 60.4%; specificity, 93.3%),0.787(sensitivity, 64.0%; specificity, 86.7%)with the cut-off value of 8.265(100 µg / mL),1.415 , 30.87(100 µg / mL)and 1.905.

CLINICAL RELEVANCE/APPLICATION

The PCT and energy spectrum enhanced scanning can serve as alternative diagnosis method to distinguish HER2 positive gastric cancer.

GI01-B4   **Bounding Box-based Radiomic Model For Detecting Occult Peritoneal Metastasis In Advanced Gastric Cancer: A Multicenter Study**

Participants
Dan Liu, Chengdu, China (*Presenter*) Nothing to Disclose

PURPOSE

To develop a radiomic model based on the region of interest annotated by bounding box for the preoperative diagnosis of occult peritoneal metastasis (OPM) in patients with advanced gastric cancer(AGC), by taking both primary tumor and peritumoral tissues into consideration.*Methods and Materials A total of 599 patients with AGC from 3 centers were retrospectively enrolled in this study, and were divided into a training cohort, a validation cohort, and a testing cohort for externally validation purpose. The ROIs (the regions of interest for the largest tumor area), BBOX (minimum circumscribed rectangle of the ROIs), peritumoral or PERI (non-overlapping area between the ROIs and BBOX) and M_BBOX(the smallest rectangular that could completely contain the lesion determined by radiologist) were used as inputs to extract the radiomic features, respectively. Multivariate logistic regression was used to construct the radiomic classification model for evaluating prediction ability. A clinical model using multivariable logistic regression was also developed to estimate the pretest probability of OPM in patients with GC.*Results The BBOX radiomic model considering both primary tumour and near surrounding tissue performed highest area under the ROC curve (AUC) of 0.873[0.820-0.940], outperforming other radiomic models. The M_BBOX model was not significantly different from BBOX in the validation cohort (AUC: M_BBOX model 0.871 [0.814-0.940] vs. BBOX model 0.873 [0.820-0.940]; p = 0.937). The M_BBOX was used as the final radiomic model because of its extremely low annotation cost and superior discrimination performance of OPM, with a higher sensitivity of 85.7% and a higher specificity of 82.8% than that of the clinical model. Besides, the radiomic model showed

comparable diagnostic efficacy in the testing cohort.*Conclusions The bounding box is of low annotation cost. The proposed radiomic model based on the bounding box annotation containing both primary tumor and proximal peritumoral tissue achieved higher diagnostic accuracy for OPM diagnosis in AGC patients than the clinical model. And, the proposed radiomic model had potential generalization ability.*Clinical Relevance/Application The bounding box—an easy-to-use, time-saving and inexpensive procedure to annotate medical images, was of lower annotation cost than the manual delineation. The proposed radiomic model based on the bounding box annotation achieved satisfied diagnostic performance, and may have significant clinical implications in the early detection and diagnosis of OPM in patients with AGC.

RESULTS

The BBOX radiomic model considering both primary tumour and near surrounding tissue performed highest area under the ROC curve (AUC) of 0.873[0.820-0.940], outperforming other radiomic models. The M_BBOX model was not significantly different from BBOX in the validation cohort (AUC: M_BBOX model 0.871 [0.814-0.940] vs. BBOX model 0.873 [0.820-0.940]; p = 0.937). The M_BBOX was used as the final radiomic model because of its extremely low annotation cost and superior discrimination performance of OPM, with a higher sensitivity of 85.7% and a higher specificity of 82.8% than that of the clinical model. Besides, the radiomic model showed comparable diagnostic efficacy in the testing cohort.

CLINICAL RELEVANCE/APPLICATION

The bounding box—an easy-to-use, time-saving and inexpensive procedure to annotate medical images, was of lower annotation cost than the manual delineation. The proposed radiomic model based on the bounding box annotation achieved satisfied diagnostic performance, and may have significant clinical implications in the early detection and diagnosis of OPM in patients with AGC.

GI01-B7   Natural History Of Arterial Phase Hyperenhancing Lesions In Fontan Associated Liver Disease

Participants
Mariana Yalon, MD, Rochester, Minnesota (*Presenter*) Nothing to Disclose

PURPOSE

To determine the natural history of arterial phase hyper enhancing (APHE) lesions developing in patients with Fontan-associated liver disease (FALD) on a long-term follow-up on CT and MRI.*Methods and Materials We retrospectively reviewed 259 post-Fontan patients with APHE at baseline CT/MRI. With exclusion criteria of at least one follow-up CT/MRI and >3months from baseline, the final study group comprised of 70 patients (M: F=42:28; median age, 35 years) with 349 lesions. APHE were classified into : a) Typical focal nodular hyperplasia (FNH)-like lesion when APHE lesion demonstrated isodensity/isointensity on portal venous phase (PVP) ± washout on delayed phase (DP); b) Atypical when there was washout in PVP ± washout on delayed phase (DP); and c) uncharacterizable when all three dynamic phases were not available for assessment. The size of lesion at baseline and at follow ups, change in size, duration of follow-up per lesion, and change in imaging characteristics were recorded.*Results Median APHE lesion size at baseline was 9mm (range 2-73mm) and had a median follow-up of 2.2 years (range 0.2-18.5) years. The majority (73%) of lesions did not show any increase in size during follow up: 77 lesions (22%) were stable, 69 lesions (20%) decreased in size, and 109 lesions (31%) disappeared during follow-up. Ninety-three lesions (27%) showed increase in size. 88% of all APHE lesions had typical features and 12% had atypical features. The lesion size at baseline or atypical/typical imaging features were not predictors of lesion growth or regression. Similarly, the size of the lesion was not determinant of characteristic of the lesion. A final diagnosis of HCC was made in 5 lesions (1.4%). All HCCs had atypical imaging features and showed interval increase in size.*Conclusions APHE lesions are common in patients with FALD. Majority of the APHE lesions remain stable, decrease in size, or completely disappear on follow up imaging with CT/MRI. Most APHE lesions show typical FNH like lesions. HCCs show atypical features on CT and MRI and increase in size. Serial imaging follow-up is important in this population to determine the nature of the lesion.*Clinical Relevance/Application Most APHE lesions in FALD tend to remain stable, regress, or disappear during long term follow up. Only a small number turn out to be HCCs. Imaging follow up is important in determining the nature of these lesions.

RESULTS

Median APHE lesion size at baseline was 9mm (range 2-73mm) and had a median follow-up of 2.2 years (range 0.2-18.5) years. The majority (73%) of lesions did not show any increase in size during follow up: 77 lesions (22%) were stable, 69 lesions (20%) decreased in size, and 109 lesions (31%) disappeared during follow-up. Ninety-three lesions (27%) showed increase in size. 88% of all APHE lesions had typical features and 12% had atypical features. The lesion size at baseline or atypical/typical imaging features were not predictors of lesion growth or regression. Similarly, the size of the lesion was not determinant of characteristic of the lesion. A final diagnosis of HCC was made in 5 lesions (1.4%). All HCCs had atypical imaging features and showed interval increase in size.

CLINICAL RELEVANCE/APPLICATION

Most APHE lesions in FALD tend to remain stable, regress, or disappear during long term follow up. Only a small number turn out to be HCCs. Imaging follow up is important in determining the nature of these lesions.

GI01-B9   Feasibility of Abdominal MRI in Patients With Residual Concentrated Enteric Contrast After Fluoroscopic Abdominal Examination

Participants
Bari Dane, MD, New York, New York (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of our study was to evaluate the image quality, image artifacts, radiologist confidence, and ability to provide definitive diagnosis for all patients with MRI performed after an abdominal fluoroscopic examination, to determine the utility of MRI in this setting.*Methods and Materials Thirty-one MRI examinations performed median 2 days after fluoroscopic bowel evaluation, 20 within 3 days of MRI, were retrospectively reviewed. The image quality, artifact emanating from bowel, inhomogeneity artifact, radiologist confidence, ability to render a definitive diagnosis, and identification of emergent or important findings for all MRI examinations were assessed. These same features were evaluated on 5 CTs performed after fluoroscopy (prior to the MRI) in the same cohort.*Results All 31 MRI examinations performed after fluoroscopic studies with concentrated barium or iodine solutions were diagnostic for answering the clinical question according to radiologist and report review, regardless of magnet strength and type of fluoroscopic contrast ingested. MRI after fluoroscopy had excellent overall image quality (mean score 4.74/5), minimal to no artifact emanating from bowel (mean 4.63/5), minimal inhomogeneity artifact (mean 4.38/5), and excellent diagnostic confidence (mean 4.98/5). No additional imaging was necessary for diagnosis after MRI. CT after fluoroscopy had lower overall image quality, more image artifacts, and lower diagnostic confidence (p<0.05).*Conclusions MRI is a useful tool for evaluating patients with

retained concentrated enteric contrast from recent fluoroscopic examinations. In the absence of contraindication, MRI should be considered in the evaluation of urgent clinical problems in patients who recently underwent a fluoroscopic bowel evaluation.*Clinical Relevance/Application Abdominal MRI is a useful diagnostic clinical examination that can be performed immediately after the administration of high density orally administered contrast from a fluoroscopic procedure, without compromising exam quality. Although CT is readily available and often preferentially utilized in urgent settings, the streak artifact emanating from residual high-density concentrated enteric contrast from fluoroscopy may render CT examinations in this setting nondiagnostic.

RESULTS

All 31 MRI examinations performed after fluoroscopic studies with concentrated barium or iodine solutions were diagnostic for answering the clinical question according to radiologist and report review, regardless of magnet strength and type of fluoroscopic contrast ingested. MRI after fluoroscopy had excellent overall image quality (mean score 4.74/5), minimal to no artifact emanating from bowel (mean 4.63/5), minimal inhomogeneity artifact (mean 4.38/5), and excellent diagnostic confidence (mean 4.98/5). No additional imaging was necessary for diagnosis after MRI. CT after fluoroscopy had lower overall image quality, more image artifacts, and lower diagnostic confidence ($p < 0.05$).

CLINICAL RELEVANCE/APPLICATION

Abdominal MRI is a useful diagnostic clinical examination that can be performed immediately after the administration of high density orally administered contrast from a fluoroscopic procedure, without compromising exam quality. Although CT is readily available and often preferentially utilized in urgent settings, the streak artifact emanating from residual high-density concentrated enteric contrast from fluoroscopy may render CT examinations in this setting nondiagnostic.

CA03-B1   **Early Detection And Serial Monitoring During Chemotherapy-radiation Therapy: Using T1 And T2 Mapping Cardiac Magnetic Resonance Imaging**

Participants
Yaotian Tian, Jinan, China (*Presenter*) Nothing to Disclose

PURPOSE

The study aimed to explore the feasibility of Native T1 and T2 Mapping for detecting and monitoring the early changes in left ventricular function and tissue characteristics in patients with chemotherapy-radiation therapy.*Methods and Materials 45 participants were enrolled in this prospective study, 15 participants (40% women; mean age, 60 years; range, 48-71 years) received non-anthracycline chemotherapy and chest radiotherapy, 30 were age/gender matched controls. CMR scan were performed before, at 48 hours, at 3 months, and at 6 months after chest radiotherapy. Myocardial native T1 and T2 were measured in irradiated areas and nonirradiated areas and the parameters about left ventricular function were obtained.*Results There were no significant differences in left ventricular function, native T1 and T2 between patients and controls before chest radiotherapy. In 15 participants who were followed up for 6 months, left ventricular ejection fraction(LVEF) had a transient decline At 48 hours after chest radiotherapy compared with baseline (57.30±3.20 vs 62.25±4.55; P=0.005), but returned to normal level since 3 months after chest radiotherapy. Native T1 were elevated at 3 months and 6 months in irradiated areas compared with baseline (1288.72±21.06 vs 1212.51±14.36 ; 1348.01±17.13 vs 1212.51±14.36; P=0.001 for both). But T2 only changed at 3 months in irradiated areas compared with baseline (44.21±3.35 vs 39.13±1.43; P = 0.003). Neither the native T1 nor T2 changed in nonirradiated areas during the follow-up period (all P >0.1).*Conclusions Native T1 could detect the early persistent changes in myocardium at 3 months and 6 months after chest radiotherapy, whereas LVEF and T2 showed abnormality reversibly. But non-anthracycline chemotherapy may have no influence in changes in left ventricular tissue characteristics.*Clinical Relevance/Application Chest radiotherapy can increase the long-term risk of cardiac death in cancer survivors. However, early detecting markers are needed. Native T1 and T2 mapping could detect the early myocardial injuries of cardiotoxicity due to cancer-related treatment. Therefore, they may help identify the myocardial changes caused by chest radiotherapy.

RESULTS

There were no significant differences in left ventricular function, native T1 and T2 between patients and controls before chest radiotherapy. In 15 participants who were followed up for 6 months, left ventricular ejection fraction(LVEF) had a transient decline At 48 hours after chest radiotherapy compared with baseline (57.30±3.20 vs 62.25±4.55; P=0.005), but returned to normal level since 3 months after chest radiotherapy. Native T1 were elevated at 3 months and 6 months in irradiated areas compared with baseline (1288.72±21.06 vs 1212.51±14.36 ; 1348.01±17.13 vs 1212.51±14.36; P=0.001 for both). But T2 only changed at 3 months in irradiated areas compared with baseline (44.21±3.35 vs 39.13±1.43; P = 0.003). Neither the native T1 nor T2 changed in nonirradiated areas during the follow-up period (all P >0.1).

CLINICAL RELEVANCE/APPLICATION

Chest radiotherapy can increase the long-term risk of cardiac death in cancer survivors. However, early detecting markers are needed. Native T1 and T2 mapping could detect the early myocardial injuries of cardiotoxicity due to cancer-related treatment. Therefore, they may help identify the myocardial changes caused by chest radiotherapy.

PD04-D1 **Performance And Dose Dependency Of Computer-aided Detection (CAD) Of Pulmonary Nodules In Tin-filtered Pediatric Ultra-low-dose Chest CT**

Participants
Philipp Josef Kuhl, MD, Wuerzburg, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the diagnostic performance of a CAD system for pulmonary nodules and its dependence on radiation dose in pediatric ULDCT.*Methods and Materials 382 consecutive ULDCT scans were retrospectively reviewed. Scans with present inflammatory consolidations were excluded (n=128). Remaining 254 data sets were included, and 2 study groups were built based on the scan protocol applied: While tube voltage of 100kV was identical in both ULDCT protocols, the reference mAs (ref. mAs) was set to 30 mAs in 72 patients (m=34; mean age 11.0±4.8 years) whereas 182 patients (m=108; 11.6±5.1 years) were scanned using 96 ref. mAs. Three radiologists assessed the data sets regarding presence of pulmonary nodules in consensus reading and each nodule was categorized by size (2-3mm; >3mm). Their findings were compared to the CAD results and total CAD errors were quantified. Objective image noise (OIN) and measured and radiation dose was estimated using size-specific dose estimates (SSDE).*Results Using the 30 ref mAs setup, radiation dose was significantly lower when compared to the 96 ref. mAs group (0.15±0.09 vs. 0.49±0.19 mGy; p< 0.001). Image noise was significantly higher in all measured regions (all p<0.001). Detection rates differed significantly for pulmonary nodules 2-3mm (0.24 vs. 0.48, p=0.002) as well as >3mm (0.44 vs. 0.71, p=0.007). No significant difference was found regarding false positive findings per scan (0.33 vs. 0.39, p=0.53). No significant correlation between radiation dose and CAD errors was found for both nodule sizes.*Conclusions Lowering the parameters for automatic tube current modulation in pediatric ULDCT results in significant dose reduction but also in reduced detection rates of pulmonary nodules, suggesting a dose dependency of evaluated CAD system. Its performance was subpar especially for small pulmonary nodules. However, it can assist radiologists as second observer tool especially in detection of nodules >3mm even in tin-filtered ULDCT.*Clinical Relevance/Application Computer-aided detection (CAD) systems can assist in the detection of pulmonary nodules >3mm even in tin-filtered ULDCT but should be used with extreme care when reducing automatic tube current modulation.

RESULTS

Using the 30 ref mAs setup, radiation dose was significantly lower when compared to the 96 ref. mAs group (0.15±0.09 vs. 0.49±0.19 mGy; p< 0.001). Image noise was significantly higher in all measured regions (all p<0.001). Detection rates differed significantly for pulmonary nodules 2-3mm (0.24 vs. 0.48, p=0.002) as well as >3mm (0.44 vs. 0.71, p=0.007). No significant difference was found regarding false positive findings per scan (0.33 vs. 0.39, p=0.53). No significant correlation between radiation dose and CAD errors was found for both nodule sizes.

CLINICAL RELEVANCE/APPLICATION

Computer-aided detection (CAD) systems can assist in the detection of pulmonary nodules >3mm even in tin-filtered ULDCT but should be used with extreme care when reducing automatic tube current modulation.

BR02-B1 Screening Analysis With Mammographic AI Of A Full Three Year Round. Standalone Performance In A Real World Study In A Novel Trusted Research Environment

Participants
Gerald Lip, MBBCh, Aberdeen, United Kingdom (*Presenter*) Nothing to Disclose

PURPOSE

We detail use of a novel trusted research environment for the retrospective evaluation of a standalone artificial intelligence (AI) tool. The AI tool was evaluated on a new population and region not previously used for algorithmic development or training.*Methods and Materials We describe the evaluation of two sets of mammographic images stored within a trusted research environment hosted by a University. Data linkage was performed with a paperless breast screening reporting system. This environment allows for complete anonymisation of data to facilitate external analysis. The corresponding structured outcome data provides a high level of data integrity. The dataset comprises 3 years of consecutively acquired national breast screening activity at a medium-sized centre. Institutional permissions were also obtained.The AI tool analysis followed a standard machine learning (ML) format with a validation set of 12,120 cases and a final test set of 27,824 cases. No model alterations or re-training were conducted during or prior to the AI evaluation. Positive cases are defined as pathologically confirmed screen-detected breast cancers, not including cancers detected between screening rounds (interval cancers).*Results All cases were successfully analysed in the research environment.The number of cases in the 2016-17 year sample and 2017-19 sample respectively was 12,120 with 100 positives; and 27,824 with 229 positives. The AI results on the 2016-17 year sample revealed an AUC of 97.52; sensitivity of 91.00%; specificity of 91.11% and recall rate of 9.56%.The AI results on the 2017-19 year sample revealed an AUC of 95.69; sensitivity of 88.21%; specificity of 90.92% and recall rate of 9.73%.*Conclusions Successful use of a novel trusted research environment to conduct robust evaluation of an external AI tool was demonstrated on previously unseen, unenriched, sequential local data at-scale, whilst satisfying all regional governance and security requirements.The performance of the AI tool shows a high degree of sensitivity, specificity and an acceptable recall rate. The findings demonstrate generalisability of the AI tool to a previously unseen screening population.*Clinical Relevance/Application Use of a trusted research environment enabled close collaboration between academia, industry and clinical teams to enable a large-scale, real-world evaluation of an AI tool. This study demonstrates how an AI tool would perform as a standalone reader and its potential to contribute to the double reading workflow.

RESULTS

All cases were successfully analysed in the research environment.The number of cases in the 2016-17 year sample and 2017-19 sample respectively was 12,120 with 100 positives; and 27,824 with 229 positives. The AI results on the 2016-17 year sample revealed an AUC of 97.52; sensitivity of 91.00%; specificity of 91.11% and recall rate of 9.56%.The AI results on the 2017-19 year sample revealed an AUC of 95.69; sensitivity of 88.21%; specificity of 90.92% and recall rate of 9.73%.

CLINICAL RELEVANCE/APPLICATION

Use of a trusted research environment enabled close collaboration between academia, industry and clinical teams to enable a large-scale, real-world evaluation of an AI tool. This study demonstrates how an AI tool would perform as a standalone reader and its potential to contribute to the double reading workflow.

BR02-B10 New Horizons: Artificial Intelligence (AI) In Digital Breast Tomosynthesis (DBT)

Awards
Identified for RadioGraphics
Certificate of Merit

Participants
Julia Goldberg, MD, New York, New York (*Presenter*) Nothing to Disclose

TEACHING POINTS

DBT is a new standard of care in breast cancer screening with increased cancer detection and accuracy, though also brings new diagnostic challenges such as large quantity of images and doubling of reading time. While most current AI applications are for digital mammography (DM) rather than DBT, there are multiple potential opportunities for AI within the DBT breast imaging value chain. AI has been shown to improve radiologists' cancer detection rates and reduce reading time for DBT. Post-processing AI reconstruction techniques have been used to enhance the conspicuity of malignancies in DBT slices. Further development of AI models for DBT may facilitate prediction of breast cancer risk through analysis of health records, visual removal of normal dense breast tissue for improved cancer detection, and generation of synthetic images.

TABLE OF CONTENTS/OUTLINE

1. Technical overview of DBT. 2. Benefits and challenges of DBT within the breast imaging value chain. 3. Technical overview of DL models for DBT, especially in comparison to CAD. 4. Review literature of AI applications for DBT. 5. Identify technical challenges of AI for DBT. 6. Identify future opportunities of AI for DBT.

BR02-B11   Burnout And Stressors In Breast Radiologists Before Versus During The COVID-19 Pandemic

Participants
Grayson Baird, PhD, Providence, Rhode Island (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate burnout and stressors among breast radiologists during the COVID-19 pandemic compared with the year prior to COVID-19.*Methods and Materials Practicing members of the Society of Breast Imaging were electronically emailed a weblink to IRB-approved surveys in January 2021, 2020, and 2019. Surveys included questions from the Maslach Burnout Inventory(C) and specific stressors. Stressors evaluated included work pace, work-life balance, care of dependents, financial strain, job security, working in medicine. The 2021 survey also asked if radiologists were considering leaving their current practice and why. Data were compared between 2019-2021. Comparisons were made with generalized linear modeling.*Results The response rate for 2021 was 25% (261/1061) for those who opened the email. Of the respondents, 74% (194/261) were female, 82% (214/261) were white, 73% (191/261) were full time, 71% (185/261) were fellowship trained, 41% (106/261) had more than 20 years of experience, and 30% (79/261) were in academic practice. Respondents in 2021 reported levels of depersonalization (10.9) and emotional exhaustion (31.0) that exceed burnout thresholds while reporting high levels of personal accomplishment (42.0), a protective factor. These values were almost identical before the pandemic in 2020: (11.2 [10.2, 12.2], 31.1 [29.6, 32.6], 42.0 [41.3, 42.6], respectively, p=0.9). Respondents rated work/life balance as the highest stressor followed by having to practice faster than they would like (see Figure 1); however, 5 of the 6 stressors improved after the pandemic compared with in 2019 (p<.05). Conversely, when asked, participants perceived these stresses had gotten slightly worse since the pandemic p<.01). Almost 50% of respondents reported they were considering leaving their practice; the most common reason was work/life balance followed by interpersonal/cultural issues.*Conclusions Burnout rates amongst breast radiologists remain high but are unchanged during the COVID-19 pandemic. While participants perceived that some stressors were slightly worse during the pandemic, there was actually slight improvement in most measured stressors between the pre-pandemic and pandemic cohorts. Almost 50% of respondents reported they were considering leaving their current practice.*Clinical Relevance/Application Although symptoms of burnout and stressors are reported high in breast radiologists, they appeared to have not worsened during the COVID-19 pandemic. Nevertheless, almost 50% of respondents reported they were considering leaving their current practice.

RESULTS

The response rate for 2021 was 25% (261/1061) for those who opened the email. Of the respondents, 74% (194/261) were female, 82% (214/261) were white, 73% (191/261) were full time, 71% (185/261) were fellowship trained, 41% (106/261) had more than 20 years of experience, and 30% (79/261) were in academic practice. Respondents in 2021 reported levels of depersonalization (10.9) and emotional exhaustion (31.0) that exceed burnout thresholds while reporting high levels of personal accomplishment (42.0), a protective factor. These values were almost identical before the pandemic in 2020: (11.2 [10.2, 12.2], 31.1 [29.6, 32.6], 42.0 [41.3, 42.6], respectively, p=0.9). Respondents rated work/life balance as the highest stressor followed by having to practice faster than they would like (see Figure 1); however, 5 of the 6 stressors improved after the pandemic compared with in 2019 (p<.05). Conversely, when asked, participants perceived these stresses had gotten slightly worse since the pandemic p<.01). Almost 50% of respondents reported they were considering leaving their practice; the most common reason was work/life balance followed by interpersonal/cultural issues.

CLINICAL RELEVANCE/APPLICATION

Although symptoms of burnout and stressors are reported high in breast radiologists, they appeared to have not worsened during the COVID-19 pandemic. Nevertheless, almost 50% of respondents reported they were considering leaving their current practice.

BR02-B2   Differences And Similarities Between Ai Cad And Radiologist False Assessments In Screening Mammography

Participants
Mattie Salim, MD, Stockholm, Sweden (*Presenter*) Nothing to Disclose

PURPOSE

We aimed to evaluate the differences and similarities in false assessments between an artificial intelligence system (AI CAD) and a human reader in screening mammography.*Methods and Materials The retrospective study included 714 screening examinations for women diagnosed with breast cancer and 8,003 randomly selected healthy controls. Women flagged due to symptoms were excluded. Oversampling of controls was applied to attain a similar cancer proportion as in the source screening cohort. Cancer at screening or within 12 months defined positive ground truth. The abnormality threshold was predefined from a prior study. We examined how false positive (FP) and false negative (FN) assessments by AI CAD and the first radiologist (RAD), were associated with density and cancer invasiveness.*Results Among 113,120 screening examinations, there were 617 invasive and 83 in-situ cancers (14 missing). The FP assessments were 3,836 (33.9 per 1000) for AI CAD and 3,402 (30.1 per 1000) for RAD; FN were 125 (1.1 per 1000) for AI CAD and 163 (1.4 per 1000) for RAD. For both AI CAD and RAD, FN were more common for high-density than low-density women (p < 0.05) and, for radiologists only, for invasive than for in-situ (p = < 0.05). FP assessments were distributed between low- and high-density women with 1,820 (47%) and 2,016 (53%) for AI CAD; with 1,568 (46%) and 1,834 (54%) for RAD. FN assessments were distributed between low- and high-density women with 53 (42%) and 72 (58%) for AI CAD; with 59 (36%) and 104 (64%) for RAD; between in-situ and invasive cancer with 13 (11%) and 102 (89%) for AI CAD; 9 (6%) and 145 (94%) for RAD.*Conclusions False negative assessments were further biased towards high-density women for RAD compared to AI CAD; and towards in-situ compared to invasive cancer for AI CAD compared to RAD. False positive assessments were distributed similarly between high- and low-density women for AI CAD and RAD.*Clinical Relevance/Application Our findings support that AI can have an important complementary role when combined with radiologists - especially to increase sensitivity for high-density women.

RESULTS

Among 113,120 screening examinations, there were 617 invasive and 83 in-situ cancers (14 missing). The FP assessments were 3,836 (33.9 per 1000) for AI CAD and 3,402 (30.1 per 1000) for RAD; FN were 125 (1.1 per 1000) for AI CAD and 163 (1.4 per 1000) for RAD. For both AI CAD and RAD, FN were more common for high-density than low-density women (p < 0.05) and, for radiologists only, for invasive than for in-situ (p = < 0.05). FP assessments were distributed between low- and high-density women with 1,820 (47%) and 2,016 (53%) for AI CAD; with 1,568 (46%) and 1,834 (54%) for RAD. FN assessments were distributed between low- and high-density women with 53 (42%) and 72 (58%) for AI CAD; with 59 (36%) and 104 (64%) for RAD; between in-situ and invasive cancer with 13 (11%) and 102 (89%) for AI CAD; 9 (6%) and 145 (94%) for RAD.

CLINICAL RELEVANCE/APPLICATION

Our findings support that AI can have an important complementary role when combined with radiologists - especially to increase sensitivity for high-density women.

BR02-B4   Principles And Implications In The Selection Of Abnormality Threshold For An AI Algorithm As An Independent Reader Of Screening Mammography

Participants
Karin Dembrower, MD, Stockholm, Sweden (*Presenter*) Nothing to Disclose

PURPOSE

AI algorithms are developed rapidly worldwide to improve efficiency and address the massive lack of breast radiologists. To prepare for a prospective study on replacing one of two readers in a double-reading setting, we explored a retrospective dataset to determine the implications of two alternative principles for choosing the abnormality threshold - above which an examination should go to consensus discussion.*Methods and Materials All women with breast cancer and randomly selected controls during 2012 to 2015 in our uptake area, who had mammograms from Philips equipment, were included. Mammograms were scored by a commercial AI (Insight MMG version 1.1.6, from Lunit Inc., South Korea). We evaluated two principles to decide the abnormality threshold. Principle one: The sensitivity of the AI algorithm should match the sensitivity of second-readers. Principle two: The sensitivity of combined AI and first-readers should match the sensitivity of combined first- and second-readers. We determined the sensitivity and abnormal interpretation rate (AIR) for each reader and combination of readers.*Results 1684 women were diagnosed with breast cancer and 5024 remained healthy. Observations of healthy women were upsampled to mimic the 0.5% proportion of screen-detected cancer in the source screening cohort. The overall sensitivity for first-readers, second-readers and combined was 69.7%, 75.6% and 78.6% respectively. The corresponding AIRs were 4.44%, 4.56% and 6.06% respectively. Principle one implied AI sensitivity 75.6%, and combined first-reader and AI sensitivity became 82.4% with AIR 12.6%. Principle two led to AI sensitivity 65.9%, with combined first-reader and AI sensitivity of 78.6% with AIR 6.99%.*Conclusions When implementing AI as an independent reader in a double-reading setting, the choice of abnormality threshold will have important consequences. If set to have AI operate at the same sensitivity as one radiologist, a marked increase in abnormal assessments must be accepted. If set to maintain the combined double-reader sensitivity, a lower sensitivity of AI alone compared to one radiologist must be accepted.*Clinical Relevance/Application A reasonable implementation of AI in a double-reading setting to maintain double-reader sensitivity will mean that AI operates at a markedly lower stand-alone sensitivity compared to one radiologist. The rationale must be clearly communicated to involved radiologists to avoid immediate distrust in AI before cancer detection results are available. This insight was valuable in a recent launch of a prospective clinical trial at our institution.

RESULTS

1684 women were diagnosed with breast cancer and 5024 remained healthy. Observations of healthy women were upsampled to mimic the 0.5% proportion of screen-detected cancer in the source screening cohort. The overall sensitivity for first-readers, second-readers and combined was 69.7%, 75.6% and 78.6% respectively. The corresponding AIRs were 4.44%, 4.56% and 6.06% respectively. Principle one implied AI sensitivity 75.6%, and combined first-reader and AI sensitivity became 82.4% with AIR 12.6%. Principle two led to AI sensitivity 65.9%, with combined first-reader and AI sensitivity of 78.6% with AIR 6.99%.

CLINICAL RELEVANCE/APPLICATION

A reasonable implementation of AI in a double-reading setting to maintain double-reader sensitivity will mean that AI operates at a markedly lower stand-alone sensitivity compared to one radiologist. The rationale must be clearly communicated to involved radiologists to avoid immediate distrust in AI before cancer detection results are available. This insight was valuable in a recent launch of a prospective clinical trial at our institution.

BR02-B5   Impact Of Extramammary Labels And Artifacts On Performance Of Deep Learning Algorithms In Mammography

Participants
Bonnie Joe, MD,PhD, San Francisco, California (*Presenter*) Institutional Research Grant, Kheiron Medical Technologies Institutional Research Agreement, GE Medical SystemsInstitutional Research Agreement, Siemens Healthineers

PURPOSE

To determine impact of objects external to breast tissue (laterality/view identifiers, jewelry, nonbreast body parts) on performance of deep learning algorithms for cancer detection at screening mammography.*Methods and Materials As part of an academic-industrial collaboration, a dataset from the academic institution of 82,398 de-identified screening 2D mammograms labelled with breast density, BI-RADS assessment and final pathology outcomes was collected as part of an IRB-approved, HIPAA-compliant study. A randomized holdout of 19,564 mammograms was set aside for benchmarking and not used for model training. No enrichment for cancers or any patient subgroup was performed. Using an automated process, the holdout was labeled as having (n=13231) or not having (n=6333) extramammary artifacts. Accuracy of the automated labeling was evaluated in a 2700 cancer-enriched subset of the holdout manually labelled for presence of artifacts. A research-only deep learning model naïve to academic institution's data was applied to the holdout. AUC performance on mammograms with and without artifacts was compared. Comparison was repeated after applying an automated segmentation algorithm to remove artifacts. Accuracy of this algorithm was evaluated against the 2700 mammogram subset. Demographics across total dataset, holdout, and subsets with/without artifacts were analyzed to confirm no confounding factors.*Results A range of extramammary artifacts were identified, most frequently a Lucite calibration phantom used to quantify breast density. Research-only model performance showed a 14.4% drop in AUC in mammograms with artifacts relative to those without. The drop was reduced to 4.4% with application of the segmentation algorithm. In the manually labelled 2700 case subset the segmentation algorithm demonstrated 99.8% accuracy for removing artifacts.*Conclusions Research-only model naïve to academic institution's data performed worse on mammograms with extramammary artifacts compared to mammograms without. Processing images with segmentation algorithm to remove artifacts mitigated but did not eliminate the drop in AUC performance. Investigation to understand impact of segmentation algorithm is ongoing.*Clinical Relevance/Application Deep learning algorithms can support screening mammography interpretation. Understanding how extramammary artifacts can impact model performance is key to avoid inadvertent bias.

RESULTS

A range of extramammary artifacts were identified, most frequently a Lucite calibration phantom used to quantify breast density. Research-only model performance showed a 14.4% drop in AUC in mammograms with artifacts relative to those without. The drop was reduced to 4.4% with application of the segmentation algorithm. In the manually labelled 2700 case subset the segmentation

algorithm demonstrated 99.8% accuracy for removing artifacts.

CLINICAL RELEVANCE/APPLICATION

Deep learning algorithms can support screening mammography interpretation. Understanding how extramammary artifacts can impact model performance is key to avoid inadvertent bias.

BR02-B6   Comparison Of Performance Metrics Of Prevalence Versus Incidence Screening Contrast Enhanced Mammograms

Participants
Janice S. Sung, MD, New York, New York (*Presenter*) Research Grant, General Electric Company

PURPOSE

To compare the performance of contrast enhanced digital mammograms (CEDM) on prevalence versus incidence rounds of breast cancer screening.*Methods and Materials IRB approved retrospective review was performed to identify women who had their first CEDM performed for breast cancer screening between December 2012 -April 2016. Medical records were reviewed for risk factors (family history or personal history of breast cancer, BRCA status, high risk lesion, or thoracic radiation). The number of subsequent screening studies performed per women and the recall, short-term interval follow-up, biopsy recommendation, and cancer detection (CDR) rates were determined.*Results To date, the results of 803 screening CEDMs in 315 women have been reviewed. 177 women had a FH of breast cancer in a 1stdegree relative and 113 a PH of breast cancer. 188 women had 1 screening CEDM, and 127 between 2-8 studies (mean: 3.8). On the prevalence screen, the recall rate was 10% (32/315), BI-RADS 3 rate 2% (6/315), and biopsy recommendation rate 5% (16/315), compared to 12% (59/488), 3% (16/488), and 3%(17/488) respectively on incidence screens. For contrast only findings, the recall rate on the prevalence screen was 5% (16/315), compared to 3% (16/488) on incidence screens. Cancer was detected in 9 women, 4 on the prevalence screen (CDR: 13/1000) and 5 on incidence screens (CDR: 10/1000). The PPV3 of biopsy on prevalence screens was 25% (17% for contrast only findings), compared to 19% (20% for contrast only findings) on incidence screens.*Conclusions A high cancer detection rate is maintained with screening CEDM beyond the prevalence screen. Recall rate and PPV3 of biopsy related to contrast only findings improved with the availability of comparison studies.*Clinical Relevance/Application Screening CEDM maintains high performance beyond the prevalence screen. This is the first study to report on the performance of CEDM on subsequent screening rounds.

RESULTS

To date, the results of 803 screening CEDMs in 315 women have been reviewed. 177 women had a FH of breast cancer in a 1stdegree relative and 113 a PH of breast cancer. 188 women had 1 screening CEDM, and 127 between 2-8 studies (mean: 3.8). On the prevalence screen, the recall rate was 10% (32/315), BI-RADS 3 rate 2% (6/315), and biopsy recommendation rate 5% (16/315), compared to 12% (59/488), 3% (16/488), and 3%(17/488) respectively on incidence screens. For contrast only findings, the recall rate on the prevalence screen was 5% (16/315), compared to 3% (16/488) on incidence screens. Cancer was detected in 9 women, 4 on the prevalence screen (CDR: 13/1000) and 5 on incidence screens (CDR: 10/1000). The PPV3 of biopsy on prevalence screens was 25% (17% for contrast only findings), compared to 19% (20% for contrast only findings) on incidence screens.

CLINICAL RELEVANCE/APPLICATION

Screening CEDM maintains high performance beyond the prevalence screen. This is the first study to report on the performance of CEDM on subsequent screening rounds.

BR02-B8   Differentiating Malignant From Benign Breast Lesions Using Quantitative Analysis In Contrast-enhanced Spectral Mammography

Participants
Huizhi Cao, PhD, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

To quantitatively analyze the enhancement of breast lesions in contrast-enhanced spectral mammography (CESM) to improve the differential diagnosis ability.*Methods and Materials A total of 283 patients with breast lesions admitted from August 2020 to May 2021 were retrospectively analyzed. Quantitative analysis of all enhancing lesions was performed to measure the gray values of the lesion area of interest (ROI), tissue surrounding the lesion (ROI1), tissue away from the lesion and close to the chest (ROI2), and the tissue at the level of the maximum diameter of the normal pectoralis major muscle on the ipsilateral side of the lesion (ROI3). rROI1, rROI2 and rROI3 were relative gray value between (ROI1,ROI2 and ROI3) and ROI . Differences in gray values between different ROIs of benign and malignant lesions were compared. Taking the pathological results as the gold standard, we used the receiver operating characteristic (ROC) curve to evaluate the diagnostic efficacy of the ROI gray value and rROI for the lesions.*Results A total of 299 lesions were found in 283 patients, including 101 benign lesions and 198 malignant lesions. The ROI gray value, rROI1, rROI2, and rROI3 of malignant lesions were all significantly greater than those of benign lesions. For gray values of benign and malignant lesions of ROI, rROI1, rROI2 and rROI3 , AUC was 0.795, 0.833, 0.812 and 0.741, respectively. The statistically significant difference in the AUC was only found between rROI1 and ROI gray value, and rROI1 had the greatest diagnostic value.*Conclusions The gray value of malignant breast lesions was higher than that of benign lesions. The quantitative analysis of the gray value was useful in the differential diagnosis of benign and malignant breast lesions.*Clinical Relevance/Application Quantitative analysis in Contrast-enhanced spectral mammography has the potential value in the differential diagnosis of benign and malignant breast lesions.

RESULTS

A total of 299 lesions were found in 283 patients, including 101 benign lesions and 198 malignant lesions. The ROI gray value, rROI1, rROI2, and rROI3 of malignant lesions were all significantly greater than those of benign lesions. For gray values of benign and malignant lesions of ROI, rROI1, rROI2 and rROI3 , AUC was 0.795, 0.833, 0.812 and 0.741, respectively. The statistically significant difference in the AUC was only found between rROI1 and ROI gray value, and rROI1 had the greatest diagnostic value.

CLINICAL RELEVANCE/APPLICATION

Quantitative analysis in Contrast-enhanced spectral mammography has the potential value in the differential diagnosis of benign and malignant breast lesions.

MK01-B2   Imaging Findings Of False Negative Lesions In Patients With Negative CT-guided Bone Biopsy

Participants
Eun ji Choi, seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Differentiating benign bone lesions with secondary bone malignancies (including hematologic malignancies) in imaging may be challenging and lead to pathological misclassification of these lesions. This study aimed to differentiate true negative lesions from false negative lesions in patients with a negative CT-guided bone biopsy in the spine or pelvic bone using imaging findings and clinical data.*Methods and Materials Of the 1205 patients who had undergone initial spine or pelvic bone biopsy between November 2008 and November 2019, 66 patients with negative bone biopsy results for suspected secondary bone malignancy were included. At least 6 months of imaging follow-up or re-biopsy were necessary for final diagnosis. Exclusion criteria were when infectious or inflammatory lesion was suspected, primary bone tumor, other benign conditions including fracture such as metallosis, osteoarthritis et al., or when CT guided biopsy was failed due to patient's non-cooperation. Two independent readers analyzed the MRI and CT images. Clinical data and formal reports of FDG-PET/CT and bone scans were collected. Univariate logistic regression analysis was performed for each finding, and statistically significant covariates were assessed using multivariate logistic regression.*Results Sixty-six lesions consisted of 38 true negative lesions and 28 false negative lesions. Grade 0 (lowest T1WI and highest T1WI of the lesion higher than that of undegenerated disc or muscle) T1WI (P < 0.001), isointense signal T2WI (P = 0.03), no or faint enhancement (P = 0.03), occult lesion on CT (P < 0.001), absence of cortical breakage or fracture (P < 0.001), maximum Standard Uptake Value below 3.6 (P = 0.001), and neutrophil to lymphocyte ratio lower than 3 (P = 0.042) were the variables associated with true negative lesions. Grade 0 T1WI and occult lesion on CT were the two most significant variables in the multivariate analysis. The odds ratio for the multivariable logistic regression model for the grade of T1-weighted signal and CT density of the lesions were 1.7 (95% CI: 0.4-3.1) and 2.6 (95% CI: 0.4-4.7), respectively.*Conclusions The lesions with grade 0 T1WI and unidentifiable CT lesions were associated with true negative lesions. Lesions without these imaging characteristics require vigorous imaging follow-up.*Clinical Relevance/Application Determining whether a negative biopsy result of spine or pelvis lesions is a true negative or a false negative based on imaging characteristics enables to decide optimal strategy including follow-up or rebiopsy.

RESULTS

Sixty-six lesions consisted of 38 true negative lesions and 28 false negative lesions. Grade 0 (lowest T1WI and highest T1WI of the lesion higher than that of undegenerated disc or muscle) T1WI (P < 0.001), isointense signal T2WI (P = 0.03), no or faint enhancement (P = 0.03), occult lesion on CT (P < 0.001), absence of cortical breakage or fracture (P < 0.001), maximum Standard Uptake Value below 3.6 (P = 0.001), and neutrophil to lymphocyte ratio lower than 3 (P = 0.042) were the variables associated with true negative lesions. Grade 0 T1WI and occult lesion on CT were the two most significant variables in the multivariate analysis. The odds ratio for the multivariable logistic regression model for the grade of T1-weighted signal and CT density of the lesions were 1.7 (95% CI: 0.4-3.1) and 2.6 (95% CI: 0.4-4.7), respectively.

CLINICAL RELEVANCE/APPLICATION

Determining whether a negative biopsy result of spine or pelvis lesions is a true negative or a false negative based on imaging characteristics enables to decide optimal strategy including follow-up or rebiopsy.

MK01-B3   Mri Lumbar Vertebrae Trabecular Parameters Correlates With Bone Mineral Density, But Not With Fragility Fractures

Participants
Jamilly Maciel, Fortaleza, Brazil (*Presenter*) Nothing to Disclose

PURPOSE

Evaluate trabecular bone parameters extracted from magnetic resonance imaging (MRI) of the L3 vertebra of volunteers with and without fragility fractures (FF) in the spine and to evaluate potential correlations with lumbar spine (LS) bone mineral density (BMD).*Methods and Materials 64 volunteers performed Dual X-ray Absorptiometry of LS, being classified as: normal (CG), osteopenia and osteoporosis. Whole spine radiographs were performed for the diagnosis of subclinical vertebral FF. Gradient-echo (FFE) MRI sequence was acquired from L3 vertebra: TR/TE (ms): 7.9 / 3.9; flip angle: 25 °; FOV (mm): 50 x 60 x 50; 7:43 min, spatial resolution: 260 x 260 x 500 μm. Segmentation and image binarization were performed using 3D slicer and trabecular parameters were extracted with the Image J software: Euler (E), connectivity (C), trabecular thickness, trabecular spacing, bone volume and trabecular bone volume. Statistical difference between the groups was evaluated using the ANOVA and Duncan post-test. Correlation analyzes were performed using Spearman's correlation coefficient (r).*Results E and C showed significant differences between the CG (E = -89.31 ± 33.57, C = 60.81 ± 24.06) compared to the other groups (osteopenia without FF, E = -60,00 ± 18.04, C = 26.70 ± 20.97), (osteopenia with FF, E = -70.08 ± 25.84, C = 51.36 ± 27.42), (osteoporosis without FF, E = -81.92 ± 24.57, C = 44.60 ± 30.39) and (osteoporosis with FF, E = -62.50 ± 23.01, C = 37.60 ± 29.86). There was no significant difference in C and E between groups with and without FF, and nonsignificant difference between the groups in relation to the other trabecular parameters. We observed a negative correlation between BMD and E (r = -0.26) and a positive correlation

between BMD and C (r = 0.26). We did not observe a significant correlation between BMD and the other trabecular parameters. MRI extracted trabecular parameters did not differ between groups with and without FF.*Conclusions MRI trabecular parameters (E and C) correlated with BMD and showed significant difference between the CG and osteopenia/osteoporosis groups.*Clinical Relevance/Application Demonstrate the potential role of MRI to assess bone fragility.

RESULTS

E and C showed significant differences between the CG (E = -89.31 ± 33.57, C = 60.81 ± 24.06) compared to the other groups (osteopenia without FF, E = -60,00 ± 18.04, C = 26.70 ± 20.97), (osteopenia with FF, E = -70.08 ± 25.84, C = 51.36 ± 27.42), (osteoporosis without FF, E = -81.92 ± 24.57, C = 44.60 ± 30.39) and (osteoporosis with FF, E = -62.50 ± 23.01, C = 37.60 ± 29.86). There was no significant difference in C and E between groups with and without FF, and nonsignificant difference between the groups in relation to the other trabecular parameters. We observed a negative correlation between BMD and E (r = -0.26) and a positive correlation between BMD and C (r = 0.26). We did not observe a significant correlation between BMD and the other trabecular parameters. MRI extracted trabecular parameters did not differ between groups with and without FF.

CLINICAL RELEVANCE/APPLICATION

Demonstrate the potential role of MRI to assess bone fragility.

MK01-B4   Qualitative And Quantitative MR Imaging Features Of Syndromic Versus Sporadic Benign Peripheral Nerve Sheath Tumors

Participants
Shivani Ahlawat, MD, Ellicott City, Maryland (*Presenter*) Nothing to Disclose

PURPOSE

To compare the qualitative and quantitative magnetic resonance imaging (MRI) features of syndrome-related (associated with Neurofibromatosis type 1 (NF1), NF2, and Schwannomatosis) versus sporadic benign peripheral nerve sheath tumors (PNSTs).*Methods and Materials In this retrospective IRB-approved, HIPPA-compliant study, our pathology database was searched for "neurofibroma or schwannoma" from 2014-2019. Exclusion criteria were lack of available MRI and intradural or plexiform PNSTs. Qualitative and quantitative features (location, size, relationship with the nerve, shape, tumoral signal characteristics, peritumoral edema, target sign, fascicular sign, extra-compartmental extension, muscle denervation, early arterial enhancement on time-resolved perfusion sequence, ADC) were recorded. Imaging characteristics and clinical findings of sporadic and SR tumors were compared. Statistical significance was assumed for p< 0.05.*Results Eighty-three histologically-proven PNSTs (schwannomas [64/83, 77.1%] and neurofibromas [19/83, 22.9%]) were included. Of those, 42 schwannomas (65,6%) and 7 neurofibromas (36.8%) were sporadic, and 22 schwannomas (34.3%) and 12 neurofibromas (63.1%) were syndrome-related (SR) PNSTs. Sporadic schwannomas tended to be similar in size to SR schwannomas (2.9±1.2cm vs. 3.7±3.2cm, p=0.6), with greater heterogeneity on T2W (p=0.02) and static post-contrast sequences (p=0.01). Sporadic neurofibromas tended to be larger (4.6±1.5cm vs. 3.4±2.4cm, p=0.03), more heterogeneous on T2W (7/7(100%) vs. 2/12(16.4%),p=0.03), with decreased contrast enhancement (25-75%:4/5(80%) vs. 50-100%:11/12(91.7%), p=0.04) compared with SR neurofibromas. Skeletal muscle denervation (sporadic vs. SR schwannomas: 1/42(2.3%) vs. 3/22(13.6%) p=0.9; sporadic and SR neurofibroma: 0 vs. 0, p=1.0) was rarely present with schwannomas. SR PNSTs often had multiple additional lesions along an affected nerve (sporadic vs. SR schwannomas: 0 vs. 7/22(31.8%), p=0.08; sporadic and SR neurofibroma: 0 vs. 5/12(41.7%), p=0.55). Pain as an isolated symptom was more often associated with SR-schwannomas (sporadic vs. SR schwannomas: 21/42(50%) vs. 14/22(63.6%), p=0.005; sporadic and SR neurofibroma: 4/7(57.1%) vs. 5/12(41.7%), p=0.1).*Conclusions Although sporadic and syndrome-related schwannomas and neurofibromas overlap in their MRI appearance, isolated pain, homogeneity on T2W, and presence of multiple lesions along a nerve are characteristic features of syndrome-related PNSTs referred for histologic work-up.*Clinical Relevance/Application In patients with PNST on MRI, detection of small lesions along a nerve may indicate an underlying nerve tumor syndrome and impact patient management.

RESULTS

Eighty-three histologically-proven PNSTs (schwannomas [64/83, 77.1%] and neurofibromas [19/83, 22.9%]) were included. Of those, 42 schwannomas (65,6%) and 7 neurofibromas (36.8%) were sporadic, and 22 schwannomas (34.3%) and 12 neurofibromas (63.1%) were syndrome-related (SR) PNSTs. Sporadic schwannomas tended to be similar in size to SR schwannomas (2.9±1.2cm vs. 3.7±3.2cm, p=0.6), with greater heterogeneity on T2W (p=0.02) and static post-contrast sequences (p=0.01). Sporadic neurofibromas tended to be larger (4.6±1.5cm vs. 3.4±2.4cm, p=0.03), more heterogeneous on T2W (7/7(100%) vs. 2/12(16.4%),p=0.03), with decreased contrast enhancement (25-75%:4/5(80%) vs. 50-100%:11/12(91.7%), p=0.04) compared with SR neurofibromas. Skeletal muscle denervation (sporadic vs. SR schwannomas: 1/42(2.3%) vs. 3/22(13.6%) p=0.9; sporadic and SR neurofibroma: 0 vs. 0, p=1.0) was rarely present with schwannomas. SR PNSTs often had multiple additional lesions along an affected nerve (sporadic vs. SR schwannomas: 0 vs. 7/22(31.8%), p=0.08; sporadic and SR neurofibroma: 0 vs. 5/12(41.7%), p=0.55). Pain as an isolated symptom was more often associated with SR-schwannomas (sporadic vs. SR schwannomas: 21/42(50%) vs. 14/22(63.6%), p=0.005; sporadic and SR neurofibroma: 4/7(57.1%) vs. 5/12(41.7%), p=0.1).

CLINICAL RELEVANCE/APPLICATION

In patients with PNST on MRI, detection of small lesions along a nerve may indicate an underlying nerve tumor syndrome and impact patient management.

CH03-D1 Highly Robust Deep Learning Model For Lung-RADS Category 4X Classification

Participants
Joonhyung Lee, MENG, Seoul, Korea, Republic Of (*Presenter*) Research Scientist, VUNO

PURPOSE

Substantial inter-reader variability in Lung CT Screening Reporting and Data System (Lung-RADS) 4X categorization necessitates a robust decision support tool. We aimed to evaluate the agreement between radiologists and a deep learning (DL) model for identification of two features of pulmonary malignancy: spiculation and air bronchogram.*Methods and Materials For this retrospective study, low-dose chest CT scans for 406 malignant lung nodules were obtained. Five board-certified thoracic radiologists recorded the existence and confidence rate in a 5-point scale for spiculation and air bronchogram for each nodule. The ground truth (GT) for each feature was determined when at least three out of the five thoracic radiologists scored four or higher regarding the presence of each feature. A 3D patch-based convolutional neural network(CNN) model was used for the prediction of spiculation and air bronchogram separately from a single model. The input to the model was the concatenation of five 3D patches with various Hounsfield unit(HU) ranges to better capture the nodules' characteristics represented in different HU ranges. The nodules predicted as having any of the two features were categorized to 4X. The data was split into training and validation sets with a ratio of 80:20. The performance of each radiologist and the DL model were evaluated against the GT using Cohen ?.*Results The agreement for spiculation, air bronchogram, and 4X findings were 0.61±0.04, 0.54±0.23, and 0.53±0.21 between the radiologists and GT, and 0.47, 0.68, and 0.58 between DL and GT. DL exhibited comparable sensitivity (81.5% vs. 84.7±15.1%) and specificity (78.6% vs. 27.6±36.8%) to the radiologists. In addition, heatmaps based on the integrated gradient method demonstrated that the proposed model properly classified the nodular features based on the border characteristics.*Conclusions The proposed DL model showed comparable agreement to those of experienced radiologists in classification of 4X category findings (spiculation and air bronchogram). Furthermore, the high specificity of the DL model can be helpful to reduce unnecessary invasive diagnostic procedures.*Clinical Relevance/Application The robust DL model proposed in this study can assist to determine the presence of 4X features in lung cancer CT screening by providing visual explanation and consistent results.

RESULTS

The agreement for spiculation, air bronchogram, and 4X findings were 0.61±0.04, 0.54±0.23, and 0.53±0.21 between the radiologists and GT, and 0.47, 0.68, and 0.58 between DL and GT. DL exhibited comparable sensitivity (81.5% vs. 84.7±15.1%) and specificity (78.6% vs. 27.6±36.8%) to the radiologists. In addition, heatmaps based on the integrated gradient method demonstrated that the proposed model properly classified the nodular features based on the border characteristics.

CLINICAL RELEVANCE/APPLICATION

The robust DL model proposed in this study can assist to determine the presence of 4X features in lung cancer CT screening by providing visual explanation and consistent results.

CH03-D3 Pre-surgical Assessment Of Mediastinal Lymph Node Metastases In Stage Ia Non Small Cell Lung Cancers

Participants
Ye Qing Zhu, New York, New York (*Presenter*) Nothing to Disclose

PURPOSE

As the frequency of MLN metastases differs markedly by the cancer consistency on CT, and clinical staging determines the possible treatment choices, particularly surgery, we decided to assess the sensitivity and specificity of CT and FDG-PET for predicting MLN metastases in a prospectively clinical Stage IA NSCLC cohort.*Methods and Materials We reviewed all patients enrolled in the Mount Sinai Health System, prospective cohort between 2016 and 2020, who had pre-surgical FDG-PET and underwent surgery with mediastinal lymph node resection and/or pre-operative endobronchial ultrasound (EBUS) for a fist primary clinical Stage IA NSCLC= 30 mm in maximum diameter on pre-surgical CT. For each patient, the maximum short-axis diameter cutoff values for MLNs on the pre-surgical CT images was classified as: = 10.0 mm, 10.1-15.0 mm, 15.1-20.0 mm, and >20.0 mm. The highest SUVmax of any MLN for each patient were classified as: = 2.5, 2.6-3.0, 3.1-4.0 or >4.0.*Results Of the 470 patients, 58.1% (n=273) were women and the median age at time of surgery was 68 years (IQR: 63.0-74.0), 466 had MLN resections and 4 has EBUS alone. NSCLC consistency was solid in 81.7% (n=384), part-solid in 13.4% (n=63), and nonsolid in 4.9% (n=23). Median maximum diameter of the tumor on CT of solid, part-solid, or nonsolid NSCLCs was not significantly different (16.7 mm vs. 19.0 mm vs. 17.0 mm, p=0.10). Histology was adenocarcinoma for all 63 part-solid and 23 nonsolid NSCLCs. Cell-type among the 384 solid NSCLCs was adenocarcinoma for 272 (70.8%), squamous-cell for 49 (12.8%), typical carcinoids for 48 (12.5%), and other NSCLC cell-types for 15 (3.9%). Among the 470 patients, none with part-solid (n=63) or nonsolid (n=23) NSCLCs had MLN metastases. No solid NSCLC = 10 mm (n=47) in maximum diameter or diagnosed as typical carcinoid (n=48) had MLN metastases. Among the remaining 297 patients with solid NSCLCs 11-30 mm, 7 (2.4%) had MLN metastases. Area-under-the curve (AUC) for predicting MLN metastases in solid NSCLCs, using the CT maximum short-axis MLN diameter was 0.62 (95% CI: 0.44-0.81, p=0.18) and using the highest SUVmax of any MLN, AUC was 0.58 (95% CI: 0.39-0.78, p=0.41). Neither AUCs were significantly different from chance alone. Optimal

cutoff for prediction of MLN metastases was = 18.9 mm for CT maximum short-axis diameter [sensitivity 14.3% (95% CI: 0.0% - 57.9%); specificity 100.0% (95% CI:98.9%-100.0)] and for highest SUVmax was = 11.7 [sensitivity 14.3% (95% CI: 0.0% - 57.9%); specificity 99.7% (95% CI:98.3%-100.0)].*Conclusions CT and SUVmax had low sensitivity but high specificity for predicting MLN metastases in solid NSCLCs 11-30 mm.*Clinical Relevance/Application Clinical Stage IA NSCLCs=30 mm should be based on CT maximum tumor diameter and MLN maximum short-axis diameter=20 mm.

RESULTS

Of the 470 patients, 58.1% (n=273) were women and the median age at time of surgery was 68 years (IQR: 63.0-74.0), 466 had MLN resections and 4 has EBUS alone. NSCLC consistency was solid in 81.7% (n=384), part-solid in 13.4% (n=63), and nonsolid in 4.9% (n=23). Median maximum diameter of the tumor on CT of solid, part-solid, or nonsolid NSCLCs was not significantly different (16.7 mm vs. 19.0 mm vs. 17.0 mm, p=0.10). Histology was adenocarcinoma for all 63 part-solid and 23 nonsolid NSCLCs. Cell-type among the 384 solid NSCLCs was adenocarcinoma for 272 (70.8%), squamous-cell for 49 (12.8%), typical carcinoids for 48 (12.5%), and other NSCLC cell-types for 15 (3.9%). Among the 470 patients, none with part-solid (n=63) or nonsolid (n=23) NSCLCs had MLN metastases. No solid NSCLC = 10 mm (n=47) in maximum diameter or diagnosed as typical carcinoid (n=48) had MLN metastases. Among the remaining 297 patients with solid NSCLCs 11-30 mm, 7 (2.4%) had MLN metastases. Area-under-the-curve (AUC) for predicting MLN metastases in solid NSCLCs, using the CT maximum short-axis MLN diameter was 0.62 (95% CI: 0.44-0.81, p=0.18) and using the highest SUVmax of any MLN, AUC was 0.58 (95% CI: 0.39-0.78, p=0.41). Neither AUCs were significantly different from chance alone. Optimal cutoff for prediction of MLN metastases was = 18.9 mm for CT maximum short-axis diameter [sensitivity 14.3% (95% CI: 0.0% -57.9%); specificity 100.0% (95% CI:98.9%-100.0)] and for highest SUVmax was = 11.7 [sensitivity 14.3% (95% CI: 0.0% -57.9%); specificity 99.7% (95% CI:98.3%-100.0)].

CLINICAL RELEVANCE/APPLICATION

Clinical Stage IA NSCLCs=30 mm should be based on CT maximum tumor diameter and MLN maximum short-axis diameter=20 mm.

MK03-A1   **Deep Learning-based Prediction For Osteoporotic Compression Fracture In Lumbar Spine Radiographs: Can It Be Better Than FRAX?**

Participants
Jaewon Lee, Seoul, Korea, Republic Of (*Presenter*) Employee, VUNO Inc

PURPOSE

To evaluate the feasibility of osteoporotic compression fracture risk prediction using a convolutional neural network in a longitudinal cohort.*Methods and Materials A total of 1,595 patients were included for this study from the retrospective cohort including images and clinical information of 12,281 patients who took at least two lumbar spine radiographs(anteroposterior and lateral) from 2010 to 2015.Exclusion criteria were as follows: younger than 50 years old (n=4,980), compression fracture at the baseline (n=1,982), those who visited only once (n=2,899), those without lateral x-rays of neutral position (n=697), follow-up periods less than 6 months (n=113), and radiographs of poor image quality (n=439). As a result, 1,595 participants were eligible and divided into training/tuning (n=1416) and validation set (n=179).A convolutional neural network (CNN) based prediction algorithm was trained to predict hazard rates in follow-up studies given baseline radiographs and clinical information. A key-point detection network was trained to extract region of interest (ROI) patches corresponding to L1-L5 vertebral bodies, and the extracted ROIs were aligned vertically and horizontally using geometric transformations. Another CNN was then trained to predict osteoporotic fractures from ROI patches and clinical information.A Fracture Risk Assessment Tool (FRAX) and Cox proportional hazard (CoxPH) model predicting osteoporotic fracture risk using only the subject's clinical information were also assessed. Three model's prediction performance in Experiment A (using age, sex, and BMI for clinical information) and Experiment B (using age, sex, BMI, glucocorticoids, and secondary osteoporosis) were evaluated using the concordance index (C-Index).*Results During follow-up, fragility vertebral fractures occurred in 7.3 % (117/1595) participants. CNN-based prediction algorithm showed higher performance (C-Index) than FRAX and CoxPH in both experiment A (FRAX, 0.547; CoxPH, 0.553 [0.552, 0.555]; CNN, 0.610 [0.0.576, 0.644]) and B (FRAX 0.547; CoxPH, 0.594 CI [0.584, 0.604]; CNN, 0.612 CI [0.571, 0.653]).*Conclusions A CNN-based prediction algorithm using baseline image and clinical information outperformed FRAX and a Cox proportional hazard model in predicting osteoporotic fracture in lumbar spine radiographs in a longitudinal cohort.*Clinical Relevance/Application CNN-based prediction algorithms can potentially be used as an alternative or complementary tool to FRAX in predicting osteoporotic fracture in lumbar spine radiographs.

RESULTS

During follow-up, fragility vertebral fractures occurred in 7.3 % (117/1595) participants. CNN-based prediction algorithm showed higher performance (C-Index) than FRAX and CoxPH in both experiment A (FRAX, 0.547; CoxPH, 0.553 [0.552, 0.555]; CNN, 0.610 [0.0.576, 0.644]) and B (FRAX 0.547; CoxPH, 0.594 CI [0.584, 0.604]; CNN, 0.612 CI [0.571, 0.653]).

CLINICAL RELEVANCE/APPLICATION

CNN-based prediction algorithms can potentially be used as an alternative or complementary tool to FRAX in predicting osteoporotic fracture in lumbar spine radiographs.

MK03-A2   **Radial Multiplanar Reformatting Of Isotropic 3D Sequences Improves Diagnostic Accuracy For Ulnar-sided TFCC Lesions In Magnetic Resonance Arthrography Of The Wrist**

Participants
Henner Huflage, MD, Wuerzburg, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Triangular fibrocartilage complex (TFCC) injuries induce ulnar-sided wrist pain and can cause distal radioulnar joint instability. Due to its complex three-dimensional composition, diagnosis of TFCC lesions remains a challenging task even in MR arthrograms. The goal of this study was to assess the added diagnostic value of radial reformations of isotropic 3D MRI compared to standard planes after direct arthrography of the wrist.*Methods and Materials Ninety-three patients underwent fluoroscopy-guided arthrography of the wrist with subsequent MRI. Two radiologists analyzed two datasets for each MR arthrogram, with one set containing standard reconstructions of a T2-weighted 3D thin-slice sequence in axial, coronal and sagittal orientation, while the other set comprised an additional radial multiplanar reconstruction with the rotating center positioned at the ulnar styloid. Surgical reports (available in 35 patients) or radiological reports combined with clinical follow-up served as standard of reference. Diagnostic confidence and assessability of the central disc and ulnar-sided insertions were subjectively evaluated.*Results Injuries of the articular disc, styloid and foveal ulnar insertion were present in 20 (23.7%), 10 (10.8%) and 9 (9.7%) patients. Additional radial planes increased diagnostic accuracy for lesions of the styloid (0.83 vs. 0.90; p=0.016) and foveal (0.86 vs. 0.94; p=0.039) insertion, whereas no improvement was identified for alterations of the central cartilage disc. Readers' confidence (p<0.001) and assessability of the ulnar-sided insertions (p<0.001) were superior with ancillary radial reformatting available.*Conclusions Access to radial plane view of isotropic 3D sequences in MR arthrography improves diagnostic accuracy and confidence for ulnar-sided TFCC lesions.*Clinical Relevance/Application The reconstruction of radial planes in post-processing of isotropic 3D MRI requires little time and effort while providing substantial benefits for peripheral TFCC assessment.

RESULTS

Injuries of the articular disc, styloid and foveal ulnar insertion were present in 20 (23.7%), 10 (10.8%) and 9 (9.7%) patients. Additional radial planes increased diagnostic accuracy for lesions of the styloid (0.83 vs. 0.90; p=0.016) and foveal (0.86 vs. 0.94; p=0.039) insertion, whereas no improvement was identified for alterations of the central cartilage disc. Readers' confidence (p<0.001) and assessability of the ulnar-sided insertions (p<0.001) were superior with ancillary radial reformatting available.

CLINICAL RELEVANCE/APPLICATION

The reconstruction of radial planes in post-processing of isotropic 3D MRI requires little time and effort while providing substantial benefits for peripheral TFCC assessment.

MK03-A4   Osseous Tumor Reporting And Data System (OT-RADS) - Multi-reader Validation Study

Participants
Anurag Gupta, Dallas, Texas (*Presenter*) Nothing to Disclose

PURPOSE

To develop and validate an Osseous Tumor Reporting and Data System (OT-RADS) with the hypothesis that the proposed guideline is reliable and assists in separating benign from malignant osseous tumors with a good area under the curve that could outline further patient management.*Methods and Materials In this multi-reader cross-sectional validation study, an agreement was reached for OT-RADS categories based on previously described MRI features and consensus of expert musculoskeletal radiologists. WHO classification was used, and a wide spectrum of benign and malignant osseous tumors were evaluated. MRI categories were: OT-RADS 0 - incomplete imaging; OT-RADS I - negative; OT-RADS II - definitely benign; OT-RADS III - probably benign; OT-RADS IV - suspicious for malignancy or indeterminate; OT-RADS V - highly suggestive of malignancy; and OT-RADS VI - known biopsy-proven malignancy or recurrent malignancy in the tumor bed. Four blinded readers categorized each tumor according to OT-RADS classification. Intraclass correlation (ICC) and Conger's Kappa were used. Diagnostic performance measures including area under the receiver operating curve (AUC) were reported. OT-RADS was dichotomized as benign (I-III) and malignant (IV and V) for calculating sensitivity and specificity.*Results Inter-reader agreement for OT-RADS (ICC = 0.78) and binary distinction of benign versus malignant (kappa = 0.67) were good to excellent, while agreement for individual tumor signal characteristics were poor to fair (ICC = 0.25 - 0.36; kappa = 0.16 - 0.39). The sensitivities, specificities and AUC of the readers ranged from 0.93 - 1.0, 0.71 - 0.86, and 0.92 - 0.97, respectively.*Conclusions OT-RADS lexicon is reliable and helps stratify tumors into benign and malignant categories.*Clinical Relevance/Application OT-RADS can be practically used by radiologists to guide patient management, improve multi-disciplinary communications, and potentially impact outcomes. The OT-RADS classification will be a dynamic document, and changes can be made as more evidence becomes available.

RESULTS

Inter-reader agreement for OT-RADS (ICC = 0.78) and binary distinction of benign versus malignant (kappa = 0.67) were good to excellent, while agreement for individual tumor signal characteristics were poor to fair (ICC = 0.25 - 0.36; kappa = 0.16 - 0.39). The sensitivities, specificities and AUC of the readers ranged from 0.93 - 1.0, 0.71 - 0.86, and 0.92 - 0.97, respectively.

CLINICAL RELEVANCE/APPLICATION

OT-RADS can be practically used by radiologists to guide patient management, improve multi-disciplinary communications, and potentially impact outcomes. The OT-RADS classification will be a dynamic document, and changes can be made as more evidence becomes available.

GU03-A1   Comparison Of Bosniak Classification Of Cystic Renal Masses Version 2019 Assessed By CT And MRI

Participants
Jason Chan, Ottawa, Ontario (*Presenter*) Nothing to Disclose

PURPOSE

The Bosniak classification of Cystic Renal masses version 2019 (Bosniak.v2019) formally incorporates MRI. Studies evaluating this change are conflicting to date. This study explores the differences between Bosniak.v2019 and original Bosniak classification (Bosniak.original) comparing masses imaged with CT and MRI.*Methods and Materials IRB approved, cross-sectional study. 65 consecutively identified cystic masses imaged with CT and MRI between 2009-2019 were identified. Thirty-five masses had histologic diagnosis and 30 masses were classified as Bosniak.v2019 Class 2 and Class 2F by an expert radiologist (R1) and had minimum 5-year stability.Three radiologists (R2-R4) independently evaluated the cystic renal masses with CT, followed by MRI using Original.Bosniak followed by Bosniak.v2019 in two sessions separated by =two months. Radiologists also assessed for the presence and number of septa, septa/wall thickness, and presence and size of protrusions.*Results With MRI, there was an upward shift from Class 2 to Class 2F for both classification systems (Bosniak.original N=7, Bosniak.v2019 N=10) and from Class 2/2F to Class 3 only in the original classification system (N=2). A higher number of septa (p<0.001) and number of protrusions (p=0.034) were noted on MRI, with no differences in septa/wall thickness (p=0.067, 0.855) or protrusion size (p=0.467).For both CT and MRI, Bosniak.v2019 had improved specificity (79.0% [95%CI 71.0-87.0%] CT, 70% [62.0-77.0%] MRI) compared to Bosniak.original (63.0% [56.0-69.0%] CT, 66.0% [58.0-74.0%] MRI), with maintained sensitivity and higher overall accuracy. Inter-observer agreement was similar-to-slightly higher for Bosniak.v2019 (K=0.44 CT, 0.39 MRI) versus Bosniak.original (K=0.35 CT, 0.37 MRI).*Conclusions There are persistent differences comparing cystic masses imaged with CT and MRI in Bosniak version 2019 akin to the Original Classification. Overall, Bosniak.v2019 had improved specificity for cancer diagnosis with similar-to-slightly higher inter-observer agreement.*Clinical Relevance/Application Our study emphasizes important differences in imaging features and class assignments between CT and MRI using Bosniak classification systems, including version 2019.

RESULTS

With MRI, there was an upward shift from Class 2 to Class 2F for both classification systems (Bosniak.original N=7, Bosniak.v2019 N=10) and from Class 2/2F to Class 3 only in the original classification system (N=2). A higher number of septa (p<0.001) and number of protrusions (p=0.034) were noted on MRI, with no differences in septa/wall thickness (p=0.067, 0.855) or protrusion size (p=0.467).For both CT and MRI, Bosniak.v2019 had improved specificity (79.0% [95%CI 71.0-87.0%] CT, 70% [62.0-77.0%] MRI) compared to Bosniak.original (63.0% [56.0-69.0%] CT, 66.0% [58.0-74.0%] MRI), with maintained sensitivity and higher overall accuracy. Inter-observer agreement was similar-to-slightly higher for Bosniak.v2019 (K=0.44 CT, 0.39 MRI) versus Bosniak.original (K=0.35 CT, 0.37 MRI).

CLINICAL RELEVANCE/APPLICATION

Our study emphasizes important differences in imaging features and class assignments between CT and MRI using Bosniak classification systems, including version 2019.

GU03-A2   Clinical Applications Of High-resolution Photon-counting Detector CT For Urolithiasis

Participants
Andrea Ferrero, PhD, Rochester, Minnesota (*Presenter*) Nothing to Disclose

PURPOSE

Whole-body photon-counting-detector CT (PCD-CT) combined with advances in deep-learning medical imaging processing, promises to enable high-resolution (HR) CT in the abdomen at routine radiation dose. We sought to explore the benefit of HR-PCD-CT for patients with urinary stone disease (USD).*Methods and Materials An investigational dual-source PCD-CT scanner (NAEOTOM Alpha, Siemens Healthcare) was used to image 8 urinary stones of various compositions (mean size 9 mm, range 4.5-13.4 mm) in an anthropomorphic water tank, with each stone placed immediately adjacent to a silicone urinary stent (Coloplast). The phantom was scanned in HR mode at routine clinical dose (140 kV, 7 mGy), with routine clinical (QR40, 1 mm) and HR images (Qr76, 0.2 mm) reconstructed. Subsequently, five USD patients were recruited following their clinical CT exam and were scanned on the HR-PCD-CT at matched radiation dose. A deep-learning-based denoising algorithm for stone quantification was applied to the HR datasets to reduce noise while maintaining quantification accuracy. An in-house stone analysis software (qSAS 1.4) was used to automatically segment and quantify urinary stones in both ex vivo and in vivo datasets.*Results For the stent-adjacent stones in the ex vivo phantom study, accurate segmentation with stone-stent separation and stone quantification occurred in only 1 of 8 case at clinical resolution and in 4 of 8 cases at HR with denoising. For the patient studies, HR-PCD-CT acquisition combined with the deep-learning-based denoising algorithm allowed identification of two stones as mixed in composition, an observation that was not appreciated during the clinical scans. It also allowed identification of contiguous-appearing stone material on conventional scan as layering clustered tiny discrete stones. Another stone was determined to be subepithelial and was better characterized in the HR data, with a 75% reduction in stone volume compared to the clinical exam (3.9 mm3 vs 15 mm3), owing to reduced partial volume effects from improved spatial resolution.*Conclusions HR-PCD-CT demonstrates improved ability to identify mixed stones, tiny

clustered layering stones, and stones adjacent to stents. In order to leverage the high-resolution capability of PCD-CT, the use of advanced denoising algorithms is required.*Clinical Relevance/Application HR-PCD-CT has improved ability to characterize mixed stones, tiny clustered layering stones, and stones adjacent to stents compared to conventional CT, extending benefits of treatment planning and monitoring in USD patients.

RESULTS

For the stent-adjacent stones in the ex vivo phantom study, accurate segmentation with stone-stent separation and stone quantification occurred in only 1 of 8 case at clinical resolution and in 4 of 8 cases at HR with denoising. For the patient studies, HR-PCD-CT acquisition combined with the deep-learning-based denoising algorithm allowed identification of two stones as mixed in composition, an observation that was not appreciated during the clinical scans. It also allowed identification of contiguous-appearing stone material on conventional scan as layering clustered tiny discrete stones. Another stone was determined to be subepithelial and was better characterized in the HR data, with a 75% reduction in stone volume compared to the clinical exam (3.9 mm3 vs 15 mm3), owing to reduced partial volume effects from improved spatial resolution.

CLINICAL RELEVANCE/APPLICATION

HR-PCD-CT has improved ability to characterize mixed stones, tiny clustered layering stones, and stones adjacent to stents compared to conventional CT, extending benefits of treatment planning and monitoring in USD patients.

GU03-A3 Pelvic Organ Prolapse, What Fell Vs What Broke: Shifting Attention From Organ Descent To Identifying Failed Support Structures

Awards
Certificate of Merit

Participants
Katherine Bojicic, MD, Ann Arbor, Michigan (*Presenter*) Nothing to Disclose

TEACHING POINTS

- Current pelvic floor diagnostic strategies assess which organs have fallen. Using MRI, it is possible to identify the structural failures that result in prolapse.- This exhibit aims to refocus radiologists' attention to the structures that 'break', resulting in shifting anatomic relationships and functional loss.- The cardinal ligaments, perineal membrane, anterior vaginal wall, and levator ani are all key structures in pelvic floor integrity and are identifiable on pelvic MR.- Identifying anterior vaginal wall elongation, damage to the cardinal ligaments, and injuries of both the levator complex and perineal membrane are key to diagnosing the cause of specific types of pelvic organ prolapse, assisting clinicians in direction for treatment options.

TABLE OF CONTENTS/OUTLINE

IntroductionScaffolding of the pelvic floor: Cardinal ligaments; Perineal membrane; Anterior vaginal wall; LevatorPathology/structural damage: Cardinal ligament damage; Vaginal wall elongation; Levator injury; Perineal membrane injuryWhat do urogynecologists need from a radiology report? In the future, rather than measuring results (prolapse) which can be identified on clinical exam, radiologists will focus on identifying the structural damage underlying these changes.Current and future treatment options: As therapies become available for specific structural defects, it will be necessary to know whether a failure in that structure exists.Conclusion: Radiologists can have a future role in identifying the cause of prolapse, not just what organ fell.

GI04-C10   Fly-In: A Robust Visualization Approach For CT Colonography

Participants
Aly Farag, MS,PhD, Louisville, Kentucky (*Presenter*) Nothing to Disclose

PURPOSE

A CTC visualization methodology, known as Fly-In (FI), is introduced for examination of the luminal surface from abdominal CT scans of prepped patients. FI enables robust polyp detection and editing.*Methods and Materials FI involves a desk-like rig of virtual cameras centered on the centerline of reconstructed colon, providing 360 degrees visualization of a cylindrical region of interest (ROI) which, when projected, provides a "filet"-like display of the ROI. By moving the ROI along the centerline of the colon, radiologists are able to examine the luminal surface and detect colonic polyps. FI does not require two-pass (retrograde and antegrade) as in the Fly-Through method, and does not suffer from occlusions, especially at haustral folds. FI enables registration of prone and supine visualization and easier correspondence with the 2D CT slices. In addition, a novel camera transformation was incorporated to stabilize the virtual cameras movement, which yields a smooth image sequence in the ROI as visualization is performed. A font-end CTC system was created involving the pipe-line of CTC (Segmentation, 3D Reconstruction, Centerline extraction, Visualization and Polyp detection), which enabled empirical and clinical evaluation of FI.*Results Evaluation using 20 CTC patients' data was performed by two senior and board-certified radiologists who validated the accuracy of FI and provided crucial input for improving its performance with respect to CT workflow. A follow-up clinical evaluation was then conducted using 49 CTC patients by three senior board-certified radiologists. Thirty-six of the 49 patients (73%) had at least one 6-mm or larger abnormalities. A total of 57 polyps/lesions existed in the 36 cases. Two radiologists compared FI vs the TeraRecon system which provides a filet representation of the colon, the third radiologist read the CTC data using only FI. Radiologist 1 reported 72% sensitivity and 93% specificity using FI vs 81% sensitivity and 87% specificity using TeraRecon. Radiologist 2 reported 65% sensitivity and 81% specificity using FI vs 63% sensitivity and 81% specificity using TeraRecon. Radiologist 3 provided similar results using FI.*Conclusions FI visualization using a rig of virtual cameras which navigates inside the colon around the centerline, provides a natural and distortionless filet visualization of the luminal surface, and state of the art sensitivity and specificity for small-size polyp detection.*Clinical Relevance/Application Robust polyp detection is necessary for screening colorectal cancer (CRC), and synchronization of CTC and Optical Colonoscopy (OC), for their removal, holds best promise for combating CRC. FI visualization enables robust polyp detection, locally and on the cloud; thus easier to sync with OC.

RESULTS

Evaluation using 20 CTC patients' data was performed by two senior and board-certified radiologists who validated the accuracy of FI and provided crucial input for improving its performance with respect to CT workflow. A follow-up clinical evaluation was then conducted using 49 CTC patients by three senior board-certified radiologists. Thirty-six of the 49 patients (73%) had at least one 6-mm or larger abnormalities. A total of 57 polyps/lesions existed in the 36 cases. Two radiologists compared FI vs the TeraRecon system which provides a filet representation of the colon, the third radiologist read the CTC data using only FI. Radiologist 1 reported 72% sensitivity and 93% specificity using FI vs 81% sensitivity and 87% specificity using TeraRecon. Radiologist 2 reported 65% sensitivity and 81% specificity using FI vs 63% sensitivity and 81% specificity using TeraRecon. Radiologist 3 provided similar results using FI.

CLINICAL RELEVANCE/APPLICATION

Robust polyp detection is necessary for screening colorectal cancer (CRC), and synchronization of CTC and Optical Colonoscopy (OC), for their removal, holds best promise for combating CRC. FI visualization enables robust polyp detection, locally and on the cloud; thus easier to sync with OC.

GI04-C11   Portal Venous Phase Discordance Between Ceus And Mri: A Valuable Predictor Of Intrahepatic Cholangiocarcinoma?

Participants
Stephanie Wilson, MD, Calgary, Alberta (*Presenter*) Equipment support, Koninklijke Philips NV;Equipment support, Siemens AG;Equipment support, Samsung Electronics Co, Ltd;Research support, Samsung Electronics Co, Ltd;

PURPOSE

Accurate differentiation of intrahepatic cholangiocarcinoma (ICC) from hepatocellular carcinoma (HCC) is important given different management strategies and prognosis. On CEUS, performed with a purely intravascular microbubble contrast agent, ICC (along with other non-hepatocellular malignancies) shows arterial phase enhancement followed by marked and rapid washout. This pattern of enhancement on CEUS allows for the accurate diagnosis of ICC, and its differentiation from HCC. In addition, this enhancement is discordant with the classically described appearance of ICC on CT/MRI, where ICC shows progressive enhancement, owing to slow diffusion of interstitial contrast into the fibrous stroma of the tumor. This specific type of portal venous phase (PVP) discordance, characterized by marked, rapid washout on CEUS and sustained/progressive enhancement on CT and MRI was initially identified in cases of ICC and has since occasionally been observed with other pathologies. Our study aims to evaluate the incidence of this type of discordance in ICC and determine its utility as a diagnostic sign. Its relationship to other pathologies is also

explored.*Methods and Materials This retrospective IRB approved study recruited adult patients with a diagnosis of ICC from pathology records and weekly multidisciplinary hepatobiliary rounds. In addition, patients were recruited if our specifically defined type of PVP discordance was noted at CEUS examination. 64 patients were recruited. CEUS and CT/MRI examinations were reviewed by a non-blinded research assistant with consultation from primary investigators with CEUS and CT/MRI expertise. The enhancement characteristics in the arterial, portal venous and late phase were recorded. Data was analyzed to assess for the frequency of specific PVP discordance in cases of ICC. Final pathology for non-ICC lesions was reviewed.*Results PVP discordance as defined by marked rapid washout on CEUS and sustained/progressive enhancement on CT/MRI is identified in 43/51 cases of ICC (84%). The difference between the PVP appearance of ICC on CT/MRI and CEUS was significant (p<0.0001). Discordance was also identified in cases of lymphoma (n=5), sclerosed hemangioma (n=3), HCC (n=3) and metastases (n=2).*Conclusions Discordant portal venous phase imaging between CEUS and CT/MRI, whereby CEUS shows marked rapid washout and CT/MRI shows sustained/progressive enhancement, is a common observation in patients with ICC and occurs occasionally in other tumors. Recognition of this discordance aids in the diagnosis of ICC.*Clinical Relevance/Application Interpretation of CEUS in conjunction with MRI, particularly in cases of discordant imaging, improves diagnostic accuracy, reducing time to diagnosis and treatment.

RESULTS

PVP discordance as defined by marked rapid washout on CEUS and sustained/progressive enhancement on CT/MRI is identified in 43/51 cases of ICC (84%). The difference between the PVP appearance of ICC on CT/MRI and CEUS was significant (p<0.0001). Discordance was also identified in cases of lymphoma (n=5), sclerosed hemangioma (n=3), HCC (n=3) and metastases (n=2).

CLINICAL RELEVANCE/APPLICATION

Interpretation of CEUS in conjunction with MRI, particularly in cases of discordant imaging, improves diagnostic accuracy, reducing time to diagnosis and treatment.

GI04-C3   Accelerated Pancreatobiliary MRI For Surveillance In Patients With Pancreas Cystic Neoplasms

Participants
Jeong Hee Yoon, MD, Seoul, Korea, Republic Of (*Presenter*) Speaker, Bayer AG

PURPOSE

To establish an accelerated MRI protocol for pancreas cancer surveillance and test the performance for lesion characterization in participants with pancreas cystic neoplasms.*Methods and Materials This prospective study recruited thirty participants who were on follow-up for pancreas intraductal papillary mucinous neoplasm or newly diagnosed pancreas cyst of unknown character (= 10 mm) and scheduled for contrast-enhanced CT (CECT) or had a recent CECT. Accelerated MRI was performed at 3T which targeted 15min of table time, consisting of heavily T2WI, breath-hold 3D MRCP, two-point Dixon, dynamic T1WI and breath-hold DWI. In-room time and table time were measured. Seven radiologists independently reviewed the presence of high-risk stigmata and worrisome features in addition to the diagnostic confidence. The performance of accelerated MRI was compared with those of CECT and the non-contrast part of accelerated MRI (abbreviated MRI) using a composite reference standard.*Results Thirty participants (male = 17, mean age 67 ± 7 years) were enrolled and four had surgically or clinically diagnosed pancreas cancer in 29 participants with follow-up imaging or histologic results. The in-room time was 18.5 ± 2.6 min (range: 13.7 - 24.9 min) and table time was 13.9 ± 1.9 min (range: 10.7 - 17.5). The diagnostic performance did not show significant difference between accelerated MRI (area under the curve: 0.85), CECT (0.83) and abbreviated MRI (0.78, P = 0.23), with the highest diagnostic confidence of accelerated MRI (4.2 ± 0.1, P < 0.001). At accelerated MRI, the inter-observer agreement was fair to excellent for high-risk stigmata (? = 0.34 - 0.98).*Conclusions Accelerated MRI protocol allows the table time of 15 min which may be eligible for the cancer surveillance in patients at risk of developing pancreas cancer.*Clinical Relevance/Application This study shows an accelerated PB MRI can be achieved within 15 minutes of the table time. The fast acquisition may allow the indication of PB MRI for pancreas cancer surveillance.

RESULTS

Thirty participants (male = 17, mean age 67 ± 7 years) were enrolled and four had surgically or clinically diagnosed pancreas cancer in 29 participants with follow-up imaging or histologic results. The in-room time was 18.5 ± 2.6 min (range: 13.7 - 24.9 min) and table time was 13.9 ± 1.9 min (range: 10.7 - 17.5). The diagnostic performance did not show significant difference between accelerated MRI (area under the curve: 0.85), CECT (0.83) and abbreviated MRI (0.78, P = 0.23), with the highest diagnostic confidence of accelerated MRI (4.2 ± 0.1, P < 0.001). At accelerated MRI, the inter-observer agreement was fair to excellent for high-risk stigmata (? = 0.34 - 0.98).

CLINICAL RELEVANCE/APPLICATION

This study shows an accelerated PB MRI can be achieved within 15 minutes of the table time. The fast acquisition may allow the indication of PB MRI for pancreas cancer surveillance.

GI04-C6   Compressed Sensing Versus View-sharing Techniques For Triple Hepatic Arterial Phase Acquisition In Gadoxetic Acid-enhanced Liver MRI: Comparison Of Image Quality And Arterial Enhancing Lesion Detectability In HCC High-risk Patients

Participants
Jae Hyun Kim, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To determine whether triple arterial phase acquisition via compressed sensing (CS) technique can improve image quality and lesion detectability than View-sharing (VS) technique gadoxetic acid-enhanced magnetic resonance imaging (MRI) in patients at high-risk for hepatocellular carcinoma (HCC).*Methods and Materials A total of 387 high-risk patients who underwent gadoxetic acid-enhanced MRI, either CS (n = 225) or VS (n = 162) techniques were retrospective included. Among them, 121 patients had 183 arterial enhancing hepatic nodules (LR-4 or LR-5: 146, LR-3: 9, LR-1 or LR-2: 18, LR-M: 8, and LR-TR viable: 2). Two abdominal radiologists blindly assessed the presence or absence of proper late arterial phase (1 or 0) and image quality (1-4 Likert scales). The conspicuity (1-4) of lesions detected by reviewers was also evaluated. The ?2 test, Mann-Whitney U test, and generalized estimating equation were used for statistical analysis.*Results CS compared with VS demonstrated significantly improved overall image quality (mean 3.56 vs. 3.36 and 3.13 vs. 2.78, P = 0.0002 and <0.0001 in reviewers 1 and 2, respectively) and less motion artifact (mean 3.58 vs. 3.36 and 3.15 vs. 2.81, P = 0.0001 and <0.0001 for reviewers 1 and 2, respectively). However, CS compared with VS showed no significant difference in proper late arterial phase acquisition rate (95.1% vs. 94.4% and 92.9% vs. 93.8%, P = 0.77 and 0.72 for reviewers 1 and 2, respectively) and lesion conspicuity (mean 3.21 vs. 3.39 and 2.77 vs. 2.74, P =

0.27 and 0.34 for reviewers 1 and 2, respectively). Furthermore, there was no significant difference in pooled per-patient sensitivity (40.1% vs. 44.6%, P = 0.487) and specificity (94% vs. 97%, P = 0.185) for lesion detection between CS and VS techniques.*Conclusions Although applying CS technique for gadoxetic acid-enhanced MRI in high-risk patients significantly improved image quality compared with VS technique, there were no differences in proper late arterial phase acquisition rate, lesion detection performance, and lesion conspicuity between the two techniques.*Clinical Relevance/Application The CS technique could be helpful in improving the quality of arterial phase image in gadoxetic acid-enhanced MRI, but it might not have a significant effect on lesion detection in high-risk patients.

RESULTS

CS compared with VS demonstrated significantly improved overall image quality (mean 3.56 vs. 3.36 and 3.13 vs. 2.78, P = 0.0002 and <0.0001 in reviewers 1 and 2, respectively) and less motion artifact (mean 3.58 vs. 3.36 and 3.15 vs. 2.81, P = 0.0001 and <0.0001 for reviewers 1 and 2, respectively). However, CS compared with VS showed no significant difference in proper late arterial phase acquisition rate (95.1% vs. 94.4% and 92.9% vs. 93.8%, P = 0.77 and 0.72 for reviewers 1 and 2, respectively) and lesion conspicuity (mean 3.21 vs. 3.39 and 2.77 vs. 2.74, P = 0.27 and 0.34 for reviewers 1 and 2, respectively). Furthermore, there was no significant difference in pooled per-patient sensitivity (40.1% vs. 44.6%, P = 0.487) and specificity (94% vs. 97%, P = 0.185) for lesion detection between CS and VS techniques.

CLINICAL RELEVANCE/APPLICATION

The CS technique could be helpful in improving the quality of arterial phase image in gadoxetic acid-enhanced MRI, but it might not have a significant effect on lesion detection in high-risk patients.

GI04-C8   Reliability Of Lirads V.2018 And Easl Criteria In Small Liver Observations Using Extracellular And Hepatobiliary Contrast Agents. A Head-to Head Comparative Study.

Participants
Jordi Rimola, MD, Barcelona, Spain (*Presenter*) Consultant, Alimentiv Health Trust;Speaker, Takeda Pharmaceutical Company Limited;Consultant, Johnson & Johnson;Consultant, Boehringer Ingelheim GmbH;Grant, AbbVie Inc

PURPOSE

To assess the interreader agreement of LI-RADS v.2018 and EASL criteria for the diagnosis of hepatocellular carcinoma (HCC) with extracellular agents (ECA) and hepato-biliary contrast agents (HBA) enhanced MR imaging, and to determine the effect of ancillary features (AF) and reader expertise on LI-RADS categorization.*Methods and Materials 92 observations <3cm explored with both ECA and HBA-MRI acquired =1 month were reviewed by 9 independent readers. Representative images for each observation were presented in random order in a digital atlas. Readers assessed EASL criteria, LI-RADS v.2018 categories (with and without ancillary features [AF]) and LI-RADS major features for each observation. Intraclass correlation coefficients (ICC) were calculated for LI-RADS categorization and Cohen's kappa was assessed for major features and EASL criteria.*Results Kappa and ICC for EASL, LI-RADS category and LI-RADS re-categorization with AF were 0.72 (95%CI 0.63-0.8), 0.67 (0.62-0.70), and 0.65 (0.59-0.69) for ECA-MRI, and 0.69 (0.60-0.77), 0.67 (0.64-0.70) and 0.65 (0.61-0.68) for HBA-MRI, respectively. Kappa of ECA-MRI and HBA-MRI were 0.71 (0.42-1.0) and 0.68 (0.47 - 0.89) for non-rim arterial phase hyperenhancement; 0.5 (0.32-0.68) and 0.73 (0.61 - 0.85) for nonperipheral washout; and 0.57 (0.45-0.69) and 0.53 (0.40-0.66) for enhancing capsule. AF for LI-RADS categorization were applied in 17% (8.7-19.6%) and 28.3% (22.8-33.7%) of observations for ECA and HBA respectively (p-value=0.004). LI-RADS categorization adjusted by expertise was similar on both contrast agents 0.66 (0.62-0.7) and 0.67 (0.63-0.69) for ECA and HBA.*Conclusions Inter-reader agreement for EASL and LI-RADS categorization was substantial. No appreciable differences were observed between contrast agent, AF application or reader expertise.*Clinical Relevance/Application In this head-to-head comparison we identified a good reliability of both EASL and LIRADS categorization that justifies their use in clinical practice. However, according to our observations, the benefits of the use of subjective ancillary features are debatable.

RESULTS

Kappa and ICC for EASL, LI-RADS category and LI-RADS re-categorization with AF were 0.72 (95%CI 0.63-0.8), 0.67 (0.62-0.70), and 0.65 (0.59-0.69) for ECA-MRI, and 0.69 (0.60-0.77), 0.67 (0.64-0.70) and 0.65 (0.61-0.68) for HBA-MRI, respectively. Kappa of ECA-MRI and HBA-MRI were 0.71 (0.42-1.0) and 0.68 (0.47 - 0.89) for non-rim arterial phase hyperenhancement; 0.5 (0.32-0.68) and 0.73 (0.61 - 0.85) for nonperipheral washout; and 0.57 (0.45-0.69) and 0.53 (0.40-0.66) for enhancing capsule. AF for LI-RADS categorization were applied in 17% (8.7-19.6%) and 28.3% (22.8-33.7%) of observations for ECA and HBA respectively (p-value=0.004). LI-RADS categorization adjusted by expertise was similar on both contrast agents 0.66 (0.62-0.7) and 0.67 (0.63-0.69) for ECA and HBA.

CLINICAL RELEVANCE/APPLICATION

In this head-to-head comparison we identified a good reliability of both EASL and LIRADS categorization that justifies their use in clinical practice. However, according to our observations, the benefits of the use of subjective ancillary features are debatable.

GU03-B1   **CT-based Bosniak Classification Of Cystic Renal Lesions: Is The Version 2019 An Improvement On Version 2005?**

Participants
Jérémy Dana, MD, Clichy, France (*Presenter*) Nothing to Disclose

PURPOSE

To compare the diagnostic performance and inter-reader agreement of CT-based version 2019 with version 2005 of the Bosniak classification system.*Methods and Materials This retrospective study included patients with complex cystic renal lesions (CRL) between 2005 and 2018. The standard of reference was histopathology or 4-year imaging follow-up. The study cases were reviewed using a reading map and assigned to versions 2005 and 2019 Bosniak categories, independently, blinded to pathology results and imaging follow-up, by five reviewers (three senior and two junior). Final category was assigned if two of the three senior reviewers agreed. Diagnostic performance of versions 2005 and 2019 Bosniak classification system for distinguishing benign from malignant lesion was calculated by regrouping into positive (categories III-IV) or negative (categories I-IIF) diagnostic test results and reported metrics included sensitivity and specificity. Inter-reader agreement was calculated by Light's Kappa.*Results 149 CRL (139 patients) were included - 32 Bosniak I (0% malignancy), 40 Bosniak II (0%), 34 Bosniak IIF (8.8%), 15 Bosniak III (40%) and 28 Bosniak IV (85.7%) using 2005 version. Sensitivity and specificity of version 2005 was 0.89 and 0.91 versus 0.88 and 0.91 for version 2019. Fewer lesions were classified in categories IIF (15) and III (9) in version 2019 in favor of categories II and IV. However, 1 of the 3 malignant 2005 Bosniak IIF lesions was reclassified as 2019 Bosniak II and 1 of the malignant 2005 Bosniak III lesions was reclassified as 2019 Bosniak IIF. Inter-reader agreement was moderate to substantial for versions 2005 and 2019 between seniors (? = 0.61 vs 0.60) or juniors (? = 0.53 vs 0.58). It was slight to moderate for each evaluated criterion of version 2019, particularly for the measurement of the wall thickness (? = 0.36 between seniors and 0.16 between juniors).*Conclusions Diagnostic performance was comparable between version 2005 and 2019 but with fewer lesions in categories IIF and III in version 2019 resulting in fewer active surveillance. However, this lesser use of active surveillance presents a risk of underdiagnosing malignant lesions.*Clinical Relevance/Application 2019 Bosniak classification aims to improve grading of lesion complexity between categories IIF and III and reduce active surveillance but may present a risk of underdiagnosing malignant lesions.

RESULTS

149 CRL (139 patients) were included - 32 Bosniak I (0% malignancy), 40 Bosniak II (0%), 34 Bosniak IIF (8.8%), 15 Bosniak III (40%) and 28 Bosniak IV (85.7%) using 2005 version. Sensitivity and specificity of version 2005 was 0.89 and 0.91 versus 0.88 and 0.91 for version 2019. Fewer lesions were classified in categories IIF (15) and III (9) in version 2019 in favor of categories II and IV. However, 1 of the 3 malignant 2005 Bosniak IIF lesions was reclassified as 2019 Bosniak II and 1 of the malignant 2005 Bosniak III lesions was reclassified as 2019 Bosniak IIF. Inter-reader agreement was moderate to substantial for versions 2005 and 2019 between seniors (? = 0.61 vs 0.60) or juniors (? = 0.53 vs 0.58). It was slight to moderate for each evaluated criterion of version 2019, particularly for the measurement of the wall thickness (? = 0.36 between seniors and 0.16 between juniors).

CLINICAL RELEVANCE/APPLICATION

2019 Bosniak classification aims to improve grading of lesion complexity between categories IIF and III and reduce active surveillance but may present a risk of underdiagnosing malignant lesions.

GU01-B1   Multi-specialties Observer Performance Study For Bladder Cancer Treatment Response Assessment In CT Urography With And Without Computerized Decision Support

Participants
Di Sun, Ann Arbor, Michigan (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the impact of a computerized decision support system for bladder cancer treatment response assessment (CDSS-T) on physicians' performance in identifying patients with complete response after neoadjuvant chemotherapy for bladder cancer.*Methods and Materials With IRB approval, we collected the pre- and post-chemotherapy CTU scans of 123 patients (157 pre- and post-treatment lesion pairs). The pathological cancer stage after treatment was collected as reference standard for determining if a patient had complete response to treatment. Forty out of 157 lesion pairs were determined to have complete response (stage T0) after chemotherapy based on the standard. We have developed a CDSS-T system combining DL-CNN and radiomics features to identify cases with complete response. The CDSS-T has a specialized graphic user interface that allows the observer to compare the pre-post treatment CTU pairs side by side. Five abdominal radiologists, 4 radiology residents, 1 urologist, and 3 oncologists read all the cases in different randomized order and provided estimates of the likelihood of each lesion being stage T0 after treatment without and then with the CDSS-T aid. The multi-reader, multi-case (MRMC) receiver operating characteristic (ROC) methodology was used to analyze the observers' assessments. The area under the curve (AUC) and the statistical significance of the difference were calculated. AUC values were compared for observers from different specialties (radiologists, oncologists, and urologist).*Results For 9 radiologists, the AUC for estimation of T0 disease after treatment increased from 0.75 without CDSS-T to 0.77 with CDSS-T, with a significant difference (p = 0.014). For 3 oncologists, the AUC increased from 0.71 without CDSS-T to 0.76 with CDSS-T, with a significant difference (p = 0.004). For the single urologist, the AUC increased from 0.74 without CDSS-T to 0.76 with CDSS-T, without reaching significance (p = 0.244).*Conclusions Our study demonstrates that the CDSS-T system can improve the physicians' performance on the assessment of complete response to bladder cancer treatment, and there are differences in the effectiveness of CDSS-T on physicians from different specialties.*Clinical Relevance/Application CDSS-T has the potential to improve physicians' accuracy in bladder cancer treatment response assessment, which is vital for identifying non-responders and allowing them to seek alternative therapy.

RESULTS

For 9 radiologists, the AUC for estimation of T0 disease after treatment increased from 0.75 without CDSS-T to 0.77 with CDSS-T, with a significant difference (p = 0.014). For 3 oncologists, the AUC increased from 0.71 without CDSS-T to 0.76 with CDSS-T, with a significant difference (p = 0.004). For the single urologist, the AUC increased from 0.74 without CDSS-T to 0.76 with CDSS-T, without reaching significance (p = 0.244).

CLINICAL RELEVANCE/APPLICATION

CDSS-T has the potential to improve physicians' accuracy in bladder cancer treatment response assessment, which is vital for identifying non-responders and allowing them to seek alternative therapy.

IR04-B1   Clinical Outcomes Of Transjugular Intrahepatic Portosystemic Shunt With Ptfe-covered Stents After Liver Transplantation And Technical Results In Split And Whole Liver Graft Recipients

Participants
Luigi Maruzzelli, MD, Palermo, Italy (*Presenter*) Nothing to Disclose

PURPOSE

To assess the clinical outcomes of transjugular intrahepatic portosystemic shunt (TIPS) creation using PTFE-covered stents in liver transplant (LT) recipients and to analyze the technical result of TIPS creation in split grafts (SG) compared with whole liver grafts (WG).*Methods and Materials Single-center, retrospective study, analyzing LT patients who underwent TIPS using a PTFE-covered stent. Clinical and technical variables were analyzed. Survival curves were constructed using the Kaplan-Meier method.*Results Between 2004 and 2018, TIPS was created using a PTFE-covered stent in 44 LT patients at a median of 43 months (range, 17 days - 16 years) after LT. TIPS indications were refractory ascites (RA) in 30 patients (68%), variceal bleeding in 8 patients (18%), others in 6 (14%). Eight patients (18%) received a SG such as right extended liver lobe (n = 4), right liver lobe (n = 2) and left lateral segment (n = 2). Thirty-six patients (82%) received a WG. Pre-TIPS median MELD score was 12 (range, 6 - 22). Ultimate technical success rate was 100% in both groups: after an initial technical failure, in one WG recipient (3%) a second attempt was successfully accomplished. An unconventional approach (combined transjugular/percutaneous transhepatic or transplenic access) was needed in 2 WG (6%) and 2 SG recipients (25%). One procedure-related death occurred in the WG group. Overall, during a median follow up of 22 months (range 4 days - 12 years), 15 patients (50%) in RA group did not require post-TIPS paracentesis and 5 patients (17%) underwent only one paracentesis, while in the VB group rebleeding occurred in 3 patients (37.5%) because of stent dysfunction. Fourteen patients (32%) underwent TIPS revision. Overt hepatic encephalopathy occurred in 13 patients (29.5%). Three patients (6.8%) required re-transplantation at 25, 27, and 56 months after TIPS. Patient survival at 6 months, 1 year, and 3 years was 75%, 62%, and 45%, respectively.*Conclusions Although technically demanding, the feasibility and safety of TIPS creation in split liver grafts is comparable to that of whole grafts. TIPS creation using PTFE-covered stents represents a viable option to treat portal hypertensive complications in LT recipients.*Clinical Relevance/Application Results from this study may help to refine the management of LT patients with recurrent portal hypertensive complications encouraging physicians to consider TIPS creation as treatment option in both SG and WG recipients.

RESULTS

Between 2004 and 2018, TIPS was created using a PTFE-covered stent in 44 LT patients at a median of 43 months (range, 17 days - 16 years) after LT. TIPS indications were refractory ascites (RA) in 30 patients (68%), variceal bleeding in 8 patients (18%), others in 6 (14%). Eight patients (18%) received a SG such as right extended liver lobe (n = 4), right liver lobe (n = 2) and left lateral segment (n = 2). Thirty-six patients (82%) received a WG. Pre-TIPS median MELD score was 12 (range, 6 - 22). Ultimate technical success rate was 100% in both groups: after an initial technical failure, in one WG recipient (3%) a second attempt was successfully accomplished. An unconventional approach (combined transjugular/percutaneous transhepatic or transplenic access) was needed in 2 WG (6%) and 2 SG recipients (25%). One procedure-related death occurred in the WG group. Overall, during a median follow up of 22 months (range 4 days - 12 years), 15 patients (50%) in RA group did not require post-TIPS paracentesis and 5 patients (17%) underwent only one paracentesis, while in the VB group rebleeding occurred in 3 patients (37.5%) because of stent dysfunction. Fourteen patients (32%) underwent TIPS revision. Overt hepatic encephalopathy occurred in 13 patients (29.5%). Three patients (6.8%) required re-transplantation at 25, 27, and 56 months after TIPS. Patient survival at 6 months, 1 year, and 3 years was 75%, 62%, and 45%, respectively.

CLINICAL RELEVANCE/APPLICATION

Results from this study may help to refine the management of LT patients with recurrent portal hypertensive complications encouraging physicians to consider TIPS creation as treatment option in both SG and WG recipients.

IR04-B2   Intra-articular Application Of Sluijter-teixera Poisson Pulsed Radiofrequency In Symptomatic Patients With Knee Osteoarthritis: Focus Upon Clinical Efficacy And Safety

Participants
Nikolaos Arkoudis, MD,MSc, Athens, Greece (*Presenter*) Nothing to Disclose

PURPOSE

To retrospectively evaluate the effectiveness of intra-articular application of Sluijter-Teixera Poisson pulsed radiofrequency (STP PRF) in knee osteoarthritis symptomatic patients with chronic pain refractory to conservative therapies.*Methods and Materials Institutional database research of two centers identified 39 cases of knee osteoarthritis patients treated with intra-articular STP PRF. Pain prior, one week, one, three, six and 12 months post STP PRF was compared by means of a numeric visual scale (NVS) questionnaire. Cardiovascular and Interventional Radiological Society of Europe (CIRSE) classification system was used for complications reporting. Mean patient age was 71.59±11.99 years, mean body mass index was 30.23±4.69 and male/female ratio was 9/30.*Results Mean baseline pain score was 8.31 ± 1.70 NVS units. This was reduced to a mean value of 0.90 ± 1.50 NVS units one week post-RF, 1.08 ± 1.53 at one month, 1.54 ± 1.88 at three months, 2.33 ± 2.17 at six months, and 3.23 ± 2.23 at 12

months of follow-up (p<0.01). Pain decrease of more than 4 NVS units was noticed in 35/39 knees (89.7%) at first week, 36/39 knees (92.3%) at first month, 35/39 knees (89.7%) at three months, 32/39 knees (82.1%) at six months and 25/39 knees (64.1%) at one year. There was no recurrence during the follow-up. No complication was observed.*Conclusions Percutaneous, intra-articular application of STP PRF is an effective and safe technique for chronic pain reduction in patients with knee osteoarthritis. Results seem to be reproducible and long lasting with significant patient satisfaction at 12 months follow-up.*Clinical Relevance/Application The present study demonstrates that intra-articular application of pulsed RF constitutes a safe and effective technique for pain palliation in knee osteoarthritis.

RESULTS

Mean baseline pain score was 8.31 ± 1.70 NVS units. This was reduced to a mean value of 0.90 ± 1.50 NVS units one week post-RF, 1.08 ± 1.53 at one month, 1.54 ± 1.88 at three months, 2.33 ± 2.17 at six months, and 3.23 ± 2.23 at 12 months of follow-up (p<0.01). Pain decrease of more than 4 NVS units was noticed in 35/39 knees (89.7%) at first week, 36/39 knees (92.3%) at first month, 35/39 knees (89.7%) at three months, 32/39 knees (82.1%) at six months and 25/39 knees (64.1%) at one year. There was no recurrence during the follow-up. No complication was observed.

CLINICAL RELEVANCE/APPLICATION

The present study demonstrates that intra-articular application of pulsed RF constitutes a safe and effective technique for pain palliation in knee osteoarthritis.

IR04-B3   Combined Transarterial Embolization And Percutaneous Sclerotherapy For Refractory And Non-resectable Aneurysmal Bone Cysts

Participants
Max Masthoff, MD, Muenster, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate safety, outcome and quality of life after combined transarterial embolization and percutaneous sclerotherapy for refractory and non-resectable aneurysmal bone cysts (ABCs).*Methods and Materials In this retrospective single center study n=16 consecutive patients (f=9, m=7; age: 17 (6-25) years) undergoing combined transarterial embolization and percutaneous sclerotherapy for refractory and non-resectable ABCs were included. 9/16 patients had history of previous therapies, all of them with no treatment response. Median follow-up was 27.3 months (range 6.7-47.5 months). Imaging data was assessed regarding volume of viable lesion (volumetry of contrast enhancing tissue), grade of mineralization (five-point Likert-scale) and fluid-fluid levels (four-point Likert-scale) of ABCs. Quality of life was analyzed using Musculoskeletal Tumor Society (MSTS) Score and 36-Item Short Form Survey (SF-36) health questionnaire.*Results No adverse events were observed after interventional procedures. All patients showed either partial or complete response to treatment. Mean viable lesion volume significantly decreased compared to baseline. Grade of mineralization and grade of fluid-fluid levels significantly improved compared to baseline. MSTS and SF-36 showed a significant quality of life improvement leaving most patients without relevant constraints. 14/16 patients did not need further ABC therapy. No patient showed ABC recurrence.*Conclusions Combined treatment of refractory and non-resectable ABCs by transarterial embolization and percutaneous sclerotherapy showed good response in treated patients regarding a decrease in lesion size, fostered bone mineralization and significant improvement of patients' quality of life.*Clinical Relevance/Application Combined transarterial embolization and percutaneous sclerotherapy is a minimal-invasive, safe and effective treatment option for refractory and non-resectable ABCs.

RESULTS

No adverse events were observed after interventional procedures. All patients showed either partial or complete response to treatment. Mean viable lesion volume significantly decreased compared to baseline. Grade of mineralization and grade of fluid-fluid levels significantly improved compared to baseline. MSTS and SF-36 showed a significant quality of life improvement leaving most patients without relevant constraints. 14/16 patients did not need further ABC therapy. No patient showed ABC recurrence.

CLINICAL RELEVANCE/APPLICATION

Combined transarterial embolization and percutaneous sclerotherapy is a minimal-invasive, safe and effective treatment option for refractory and non-resectable ABCs.

IR04-B4   Evaluation Of A Deep Learning-based Noise Reduction Algorithm For Use During CT-guided Ablation Procedures

Participants
Christopher Favazza, PhD, Rochester, Minnesota (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate deployment feasibility and efficacy of a deep convolution neural network (DCNN) denoising algorithm to improve images containing metal devices during CT-guided ablation procedures.*Methods and Materials CT image data (Philips Big Bore) containing either cryoablation or microwave needles from 35 soft tissue ablation procedures were collected and reconstructed with 3 different iterative reconstruction algorithms (iDose, IMR strength of 1 and IMR strength of 3). Additionally, iDose images were denoised with an in-house DCNN, yielding a total of 4 sets of images/patient. Three radiologists performed a blinded review and scored each individual dataset for overall image quality, noise texture, metal artifact, and local tissue/iceball conspicuity (scale 1-5). Pairwise comparisons of reader-averaged scores between image sets was performed using a Wilcoxon signed rank test. Finally, the DCNN was deployed to the image production chain for use during ablation procedures, in which iDose images are: (1) automatically transferred to a GPU-based server hosting the DCNN, (2) denoised and (3) automatically transferred to the radiologist image review tool. Denoising times were assessed and compared with IMR reconstruction times as means ± standard deviations.*Results Denoised images were scored significantly higher than iDose images for image quality, noise texture and tissue/iceball conspicuity (all p<1e-04) and scored significantly higher than IMR images across all metrics, including metal artifact appearance (all p<6.4e-03). IMR(1) scores were significantly higher than iDose for noise texture only (p=4e-4); IMR(3) image quality scores were significantly worse than iDose (p=0.03). IMR reconstructions required an average of 349±95ms/image, as compared to 177±68ms/image for iDose reconstructions. Timing measurements showed that denoising added 58±22ms/image to the iDose reconstructions.*Conclusions Application of a DCNN to denoise image data acquired during CT-guided ablations significantly improves image quality over standard and more sophisticated iterative reconstruction algorithms, while requiring less processing time than IMR reconstructions.*Clinical Relevance/Application A DCNN can denoise images during CT-guided ablations with modest time penalty and could be used to improve image quality, reduce dose, or enable low-kV imaging for improved contrast-enhanced

imaging intraprocedurally.

RESULTS

Denoised images were scored significantly higher than iDose images for image quality, noise texture and tissue/iceball conspicuity (all p<1e-04) and scored significantly higher than IMR images across all metrics, including metal artifact appearance (all p<6.4e-03). IMR(1) scores were significantly higher than iDose for noise texture only (p=4e-4); IMR(3) image quality scores were significantly worse than iDose (p=0.03). IMR reconstructions required an average of 349±95ms/image, as compared to 177±68ms/image for iDose reconstructions. Timing measurements showed that denoising added 58±22ms/image to the iDose reconstructions.

CLINICAL RELEVANCE/APPLICATION

A DCNN can denoise images during CT-guided ablations with modest time penalty and could be used to improve image quality, reduce dose, or enable low-kV imaging for improved contrast-enhanced imaging intraprocedurally.

PH03-C1   Dual-task Convolutional Neural Network Based Virtual Non-calcium Imaging For Bone Marrow Diseases Detection In Dual Energy Muscular Skeletal CT

Participants
Hao Gong, PhD, Rochester,, Minnesota (*Presenter*) Nothing to Disclose

PURPOSE

Virtual non-calcium (VNCa) images derived from dual energy CT (DECT) can be used to detect bone marrow diseases (e.g. post-traumatic edema, multiple myeloma). However, current techniques are limited in diagnostic image quality, due to amplified noise / artifacts. To overcome the limitation, we have developed a dual task convolutional neural network (CNN) based material decomposition technique to generate VNCa images.*Methods and Materials The CNN used an in-house-designed bifurcated architecture to simultaneously perform two tasks: material decomposition and classification. The classification branch shared features with material decomposition branch, meanwhile provided auxiliary regularization at output layer. CNN parameters were optimized with two customized loss functions: material decomposition - two fidelity terms in material maps and DECT data domain, and regularization terms for structure consistency and texture validity; classification - cross entropy. CNN training used image patches of tissue mimicking phantom materials (e.g. hydroxyapatite (HA), adipose, etc.). Numerical phantom materials with various mass densities were simulated to boost training sample diversity. The trained CNN was tested with phantom images at routine (17.2mGy) and lower dose (8.5mGy), and patients with suspected multiple myeloma, with all data acquired from a clinical DECT. In phantom study, bias and variance of material decomposition accuracy was gauged with normalized mean absolute error (NMAE). Patient images were evaluated by a fellowship-trained MSK radiologist for diagnostic image quality in terms of noise, artifact, and lesion conspicuity compared the presented method with a commercial technique over patient exam.*Results CNN generalized well over testing phantom materials with unseen mass densities and real anatomy. In phantom study, CNN consistently yielded high material decomposition accuracy at both dose levels: NMAE of testing HA (400 & 800 mg/cc) < 6%, and NMAE of testing soft tissues (e.g. lung, blood, & liver) < 3%. In patient exam, CNN yielded much less image noise (~50% reduction) and artifacts than commercial technique. There is improved conspicuity of intramedullary and cortical myeloma lesions on the CNN images compared to the commercial product.*Conclusions The presented dual task CNN has demonstrated accurate VNCa images with reduced noise and artifacts, and improve lesion conspicuity compared to commercial solution, enabling potential improvement in bone marrow diseases detection.*Clinical Relevance/Application Diagnostic acceptability of commercial VNCa is limited by amplified noise / artifacts. Our method can potentially improve the quality and clinical adoption of VNCa in diagnosis of bone marrow diseases.

RESULTS

CNN generalized well over testing phantom materials with unseen mass densities and real anatomy. In phantom study, CNN consistently yielded high material decomposition accuracy at both dose levels: NMAE of testing HA (400 & 800 mg/cc) < 6%, and NMAE of testing soft tissues (e.g. lung, blood, & liver) < 3%. In patient exam, CNN yielded much less image noise (~50% reduction) and artifacts than commercial technique. There is improved conspicuity of intramedullary and cortical myeloma lesions on the CNN images compared to the commercial product.

CLINICAL RELEVANCE/APPLICATION

Diagnostic acceptability of commercial VNCa is limited by amplified noise / artifacts. Our method can potentially improve the quality and clinical adoption of VNCa in diagnosis of bone marrow diseases.

PH03-C10   Clinical Pitfalls In The Selection Of Grids In Digital Radiography: Image Artifacts Produced By X-ray Scatter Rejection Grids Of Various Grid Line Frequencies Due To The Interaction Of The Grid Line Frequency With The Pixel Pitch.

Participants
Joseph Meier, PhD, Madison, Wisconsin (*Presenter*) Nothing to Disclose

PURPOSE

Anti-scatter grids are used in x-ray imaging to improve image contrast by the removal of scattered radiation that adds a relatively uniform haze to the image. Grid specifications must be carefully selected to best address exam type, SID, alignment accuracy, etc. One specification that is typically misunderstood and incorrectly selected is the line frequency of the grid septa. This talk addresses the artifacts encountered by the wrong selection of grid line frequency and methods for proper grid selection to avoid these artifacts, which can manifest as moiré or beating patterns in the image.*Methods and Materials A Carestream Health DRX-Evolution digital detector was used with pixel spacing of 0.139 x 0.139 mm, corresponding to a Nyquist frequency of 3.60 mm-1 (91.4 inch-1). Focused grids with nominal grid frequencies from 60 to 215 lines per inch (lpi), were imaged with the grid placed directly on top of the detector. The images were assessed visually for grid line artifacts and analyzed using a 2D Fourier transform (2DFT) to identify the spatial frequencies of these artifacts. These frequencies were direct imaging of the grid lines when below the Nyquist frequency, and imaged as aliased frequencies when above the Nyquist frequency.*Results Using the 2DFT analysis we were able to identify the direct imaging of the grid lines for the 4 lowest frequency grids. For the 3 highest frequency grids, the grid line frequency appeared in the image as a lower frequency alias of the grid frequency. All grids contained some identifiable frequencies

in the images that were below 2.0 mm-1, which would be difficult to remove with grid suppression software. In most of the grids these low frequencies were strong enough to be apparent in clinical images, making these grids unsuitable for optimal clinical use. To help in the proper selection of grid frequencies, we have developed a table indicating the best range of grid line frequencies that can be selected for different image receptor pixel sizes, with or without the use of grid suppression software.*Conclusions This work shows that the choice of a grid cannot be based solely on having a grid line frequency greater than the detector Nyquist frequency, or by relying on a grid line suppression algorithm to remove the artifacts produced by the interaction between the grid frequency and pixel spacing of the detector. Severe aliasing artifacts, that cannot be corrected with grid line suppression algorithms, can appear when using grids with improper line frequencies.*Clinical Relevance/Application To avoid clinically relevant artifacts, careful methods must be used to select the correct grid line frequency for a specific pixel spacing of the digital image receptor.

RESULTS

Using the 2DFT analysis we were able to identify the direct imaging of the grid lines for the 4 lowest frequency grids. For the 3 highest frequency grids, the grid line frequency appeared in the image as a lower frequency alias of the grid frequency. All grids contained some identifiable frequencies in the images that were below 2.0 mm-1, which would be difficult to remove with grid suppression software. In most of the grids these low frequencies were strong enough to be apparent in clinical images, making these grids unsuitable for optimal clinical use. To help in the proper selection of grid frequencies, we have developed a table indicating the best range of grid line frequencies that can be selected for different image receptor pixel sizes, with or without the use of grid suppression software.

CLINICAL RELEVANCE/APPLICATION

To avoid clinically relevant artifacts, careful methods must be used to select the correct grid line frequency for a specific pixel spacing of the digital image receptor.

PH03-C2   An Ultra-Low-Dose, Stationary, Tomographic Molecular Breast Imaging System Using Depth-Of-Interaction Sensitive CZT Detectors

Participants
Alexander Cherlin, PhD, Durham, United Kingdom (*Presenter*) Nothing to Disclose

PURPOSE

Molecular Breast Imaging (MBI) has been shown to have high sensitivity in cancer detection, even in patients with dense breast tissue. However, long imaging time and radiation dose that is higher than mammography impede its wide adoption. Improved lesion detection has been demonstrated using tomography, but it usually involves complex motion mechanics. Kromek is developing an ultra-low-dose stationary tomographic MBI system with at least the same sensitivity for lesion detection as planar MBI, but with the patient dose similar to mammography.*Methods and Materials The proposed system is comprised of CZT detectors with 2x2 sub-pixelisation and depth of interaction (DOI) capability, combined with densely packed multi-pinhole collimators. It allows tomographic image reconstruction but results in significant multiplexing. De-multiplexing algorithms have been developed to mitigate the adverse multiplexing artefacts by taking advantage of DOI. GATE simulations were used to evaluate the feasibility of the design and to compare it to a published planar MBI camera performance. The first prototype has been built at Kromek with 2x2 array of 7.3 mm thick CZT detectors with 2 mm pixels and a 3D printed tungsten collimator. It is being evaluated using an "activity-painting" setup incorporating an XYZ motorised stage assembly and a point 57Co source.*Results The reconstructed images from an array of simulated lesions at 1.5 cm depth in the phantom demonstrate a significant improvement in contrast and axial resolution obtained by using the DOI. Analysis of contrast to noise ratios confirmed that the administered activity could be decreased by at least a factor of 5 compared to the normal activity used in planar MBI. At the reduced dose, 100% of the simulated lesions reached a detection threshold on the proposed system compared to only 50% for the planar MBI. The first imaging results taken with the "activity-painting" setup demonstrated that the tomographic resolution is better than 7 mm in the direction normal to the detector plane. More complex "activity-painted" phantoms are currently being used to quantify the performance improvement of the prototype.*Conclusions Our results demonstrate that design of a stationary MBI system with the targeted radiation dose reduction is feasible. The next steps will include full evaluation of the image quality and the dose reduction followed by optimisation and construction of a larger scale prototype.*Clinical Relevance/Application The reduction of patient dose and scanning time will encourage the widespread adoption of MBI, providing a very quick and effective tool for cancer screening of patients with dense breast tissue. The added advantage of the tomographic system is the 3D localisation which could aid biopsy and cancer staging.

RESULTS

The reconstructed images from an array of simulated lesions at 1.5 cm depth in the phantom demonstrate a significant improvement in contrast and axial resolution obtained by using the DOI. Analysis of contrast to noise ratios confirmed that the administered activity could be decreased by at least a factor of 5 compared to the normal activity used in planar MBI. At the reduced dose, 100% of the simulated lesions reached a detection threshold on the proposed system compared to only 50% for the planar MBI. The first imaging results taken with the "activity-painting" setup demonstrated that the tomographic resolution is better than 7 mm in the direction normal to the detector plane. More complex "activity-painted" phantoms are currently being used to quantify the performance improvement of the prototype.

CLINICAL RELEVANCE/APPLICATION

The reduction of patient dose and scanning time will encourage the widespread adoption of MBI, providing a very quick and effective tool for cancer screening of patients with dense breast tissue. The added advantage of the tomographic system is the 3D localisation which could aid biopsy and cancer staging.

PH03-C4   Comparison Of Peak Skin Dose And Dose Map Obtained With A Real-time Software And Radiochromic Films On Phantom And In Patients Undergoing Abdominal Embolizations

Joel Greffier, PhD, Nimes, France (*Presenter*) Nothing to Disclose

PURPOSE

To compare the peak skin dose (PSD) and dose map calculated by the Dose Tracking System (DTS) software and measured with radiochromic films on 13 phantom configurations and in patients undergoing abdomen-pelvis embolizations.*Methods and Materials The PSD measured by radiochromic films (PSDFilm) or calculated by the DTS software (PSDDTS) were compared on 13 simple and complex configurations and in patients who underwent abdomen-pelvis embolization between September 2020 and April 2021. The

statistical concordance between PSDFilm and PSDDTS was computed using the Lin's concordance correlation coefficient and the clinical concordance using the Bland and Altman graphic; values were compared using the paired Mann-Whitney-Wilcoxon test.*Results Among 93 eligible consecutive patients, 53 were excluded (forgotten/non-centered films, late DTS use?) and 40 patients were included (32 men, 73.0±14.6 years). On phantom, the median difference between PSDFilm and PSDDTS was -9% (-10%; -3%; p<0.05). This result was confirmed in patients, with a median difference of -5% (-10%; 0%; p<0.05), a median PSDFilm of 756 (390; 1094) mGy and 768 (421; 1076) mGy for PSDDTS. The concordance between PSDFilm and PSDDTS was strong both on the phantom (0.928 [0.840; 0.968]) and in patients (0.986 [0.977; 0.992]). Bland and Altman plots showed that the PSDDTS was underestimated compared to PSDFilm by approximately -36 mGy [-68; -4]. Similar dose maps were found with DTS and films.*Conclusions The real-time DTS software allows to compute the PSD with accuracy and generate an adequate dose map. The PSDDTS was weakly underestimated compared to the PSDFilm requiring the use of a correction factor for the PSDDTS as to avoid lacking follow up for some patients.*Clinical Relevance/Application The magnitude and location of maximum peak skin dose (PSD) need to be assessed, for complex interventional procedures in order to improve the therapeutic follow-up of patients at risk of skin injuries.

RESULTS

Among 93 eligible consecutive patients, 53 were excluded (forgotten/non-centered films, late DTS use?) and 40 patients were included (32 men, 73.0±14.6 years). On phantom, the median difference between PSDFilm and PSDDTS was -9% (-10%; -3%; p<0.05). This result was confirmed in patients, with a median difference of -5% (-10%; 0%; p<0.05), a median PSDFilm of 756 (390; 1094) mGy and 768 (421; 1076) mGy for PSDDTS. The concordance between PSDFilm and PSDDTS was strong both on the phantom (0.928 [0.840; 0.968]) and in patients (0.986 [0.977; 0.992]). Bland and Altman plots showed that the PSDDTS was underestimated compared to PSDFilm by approximately -36 mGy [-68; -4]. Similar dose maps were found with DTS and films.

CLINICAL RELEVANCE/APPLICATION

The magnitude and location of maximum peak skin dose (PSD) need to be assessed, for complex interventional procedures in order to improve the therapeutic follow-up of patients at risk of skin injuries.

PH03-C6 Deep Silicon-based Photon Counting CT: A Virtual Clinical Study For Assessing Perceptual Benefits Of Improved Spatial Resolution Across Multiple Anatomies

Participants
Shobhit Sharma, MSc, BEng, Durham, North Carolina (*Presenter*) Nothing to Disclose

PURPOSE

To assess the perceptual quality of deep silicon-based photon-counting CT (Si-PCCT) with improved spatial resolution performance over conventional CT across multiple anatomies in lungs, liver, head-and-neck, and inner auditory canal.*Methods and Materials High resolution computational human models (0.1 mm voxel size) representing diverse anatomies and pathologies of interest (lesions in the liver and lungs, mastoids in inner auditory canal, and stenosis in carotid artery) were integrated with a simulation platform for CT (DukeSim) modeling the scanner-specific geometry and components of a prospective Si-PCCT system. The simulation process involved incorporating energy-dependent response and crosstalk characteristics of the Si detector (pixel size: 0.2-0.4 mm in x, 0.5-0.7 mm in z), energy-binning of photon counts, addition of Poisson noise, generation of energy-summed grayscale images, and correcting for effects of beam hardening. The human models were "imaged" using helical scans (120 kV, pitch 1) with the largest pixel size (0.4 mm in x, 0.7 mm in z) at clinically representative dose levels. Corresponding images for an energy-integrating CT (ECT) system (Revolution CT, GE Healthcare) (pixel size: 1.1 mm in both x and z) were also simulated using the same platform. The images from the two systems were reconstructed using matched FOV, image size, slice thickness, and kernel, which were then reviewed by four experienced radiologists to evaluate differences in the appearance of clinically relevant diagnostic features across the modeled pathologies.*Results Images for Si-PCCT offered improved visualization of details over ECT across all anatomies. The lung images offered enhanced low contrast visualization and improved representation of fine details such as the secondary pulmonary lobules and lesion boundary. The liver images displayed improved appearance of noise texture, better low contrast visualization, and enhanced visualization of the lesion and portal vein. The head-and-neck images offered enhanced visualization for both soft plaque and a high contrast calcified plaque. The inner auditory canal images offered improved visualization of the mastoid geometry.*Conclusions The assessment revealed superior perceptual quality of Si-PCCT over ECT across a variety of clinical applications. The higher spatial resolution offered by Si-PCCT resulted in improved visualization of fine details and desirable noise textures due to reduced noise aliasing across all imaged anatomies.*Clinical Relevance/Application To effectively launch Si-PCCT for clinical use, its performance needs to be assessed in a task-specific manner. In absence of a prototype system, virtual studies help ascertain the potential clinical utility of the new technology.

RESULTS

Images for Si-PCCT offered improved visualization of details over ECT across all anatomies. The lung images offered enhanced low contrast visualization and improved representation of fine details such as the secondary pulmonary lobules and lesion boundary. The liver images displayed improved appearance of noise texture, better low contrast visualization, and enhanced visualization of the lesion and portal vein. The head-and-neck images offered enhanced visualization for both soft plaque and a high contrast calcified plaque. The inner auditory canal images offered improved visualization of the mastoid geometry.

CLINICAL RELEVANCE/APPLICATION

To effectively launch Si-PCCT for clinical use, its performance needs to be assessed in a task-specific manner. In absence of a prototype system, virtual studies help ascertain the potential clinical utility of the new technology.

PH03-C7 Metal Artifact Reduction In Head And Neck Cone Beam CT Using Synthetic Paired Images With And Without Artifacts Through Generative Adversarial Networks

Participants
JiHeon Jeong, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To train better metal artifact reduction (MAR) model with generative adversarial network (GAN) using with synthetic paired dataset with or without artifact.*Methods and Materials Metal free CT scans of 110 patients from Yonsei Severance Dental Hospital were enrolled. First, we randomly drew artificial metal using tooth segmentation in 447 CT images, which was reconstructed into CT images with metal artifacts in Figure 1 using Radon transform.Two doctors of dental surgery (DDSs) were requested to evaluate the quality of these image pairs with or without metal artifacts.Next, we trained high-quality MAR model with Pix2PixHD GAN, which can

translate from CT images with metal artifact into those with no artifact. To increase the stability of learning and reduce checkerboard artifacts in Figure 2 which is a chronic problem during convolution transpose`s upsampling process, DiffAugment, spectral normalization, and convolution with pixel shuffle were used. Sixty pairs of images with or without metal artifact (30 vs 30) of an external test set were translated into images without metal artifact. Structural similarity index measure (SSIM), peak signal-to-noise ratio (PSNR), root mean squared error (RMSE), and visual scoring on MAR quality of these images were evaluated. Wilcoxon test was performed.*Results Visual scoring of two DDSs on the gold-standard pair images were 4.55 and 4.57. Both SSIM and PSNR are increased by about 10% compared to those of the original model, and checkerboard artifact no longer appeared in all images. SSIM, PSNR and RMSE of original model with or without artifact was 0.97, 35.53, and 0.02 HU and, 0.99, 46.34, and 0.01 HU, respectively. Those of our model was 0.98, 38.37 and 0.02 HU and 1.00, 50.25, and 0.01 HU. All of the measures in our model are significantly better (Wilcoxson rank sum test). In addition, visual scorings on the quality of the original were 1.88 and 2.58 and our models were 2.98 and 3.65. Also, visual scroring in our model is significantly better (Wilcoxson rank sum test)*Conclusions Our Supervised GAN based MAR shows significantly better than the original, which could be useful in actual clinical setting.*Clinical Relevance/Application This work could lead for human readers to better diagnose CBCT images and for image processing algorithm including segmentation and classification to be better performed.

RESULTS

Visual scoring of two DDSs on the gold-standard pair images were 4.55 and 4.57. Both SSIM and PSNR are increased by about 10% compared to those of the original model, and checkerboard artifact no longer appeared in all images. SSIM, PSNR and RMSE of original model with or without artifact was 0.97, 35.53, and 0.02 HU and, 0.99, 46.34, and 0.01 HU, respectively. Those of our model was 0.98, 38.37 and 0.02 HU and 1.00, 50.25, and 0.01 HU. All of the measures in our model are significantly better (Wilcoxson rank sum test). In addition, visual scorings on the quality of the original were 1.88 and 2.58 and our models were 2.98 and 3.65. Also, visual scroring in our model is significantly better (Wilcoxson rank sum test)

CLINICAL RELEVANCE/APPLICATION

This work could lead for human readers to better diagnose CBCT images and for image processing algorithm including segmentation and classification to be better performed.

PH03-C9   Technical Performance Metrics Compared In The New Generation Of Small Pixel Size Detectors For General Radiography

Participants
Hilde Bosmans, PhD, Leuven, Belgium (*Presenter*) Stockholder, Qaelum NV

PURPOSE

To establish whether new small pixel detectors with different design and technology for general radiography applications have improved technical image quality performance.*Methods and Materials Seven CsI-based flat panel detectors named A to G, with pixel size 175µm (A175) down to 76µm (G76) were evaluated at IEC RQA3 beam quality. Modulation transfer function (MTF) was measured along with detective quantum efficiency (DQE) at a detector air kerma (DAK) of 2.38µGy. Threshold contrast (CT) for 250µm diameter discs was measured using the TO20 test object at 70 kV, 1mm Cu added filter at DAK levels of 1.10µGy, 2.28µGy and 5.88µGy. Four observers scored the images. A Fourier non-prewhitening with eye filter (NPWE) detectability index (d') for a disc signal spectrum of a 250µm circular disc was calculated at the three DAK levels. Detector E124 was used as a reference and a t-test applied to determine whether CT was for each detector significantly different.*Results Spatial frequency for an MTF value of 0.1 for detectors A to G was: 3.21mm-1 for A175, 3.79mm-1 for B150, 3.59 for C148, 3.85 mm-1 for D125, 3.63 mm-1 for E124, 4.51 mm-1 for F100, 4.70 mm-1 for G76, indicating better MTF performance for the smaller pixel detectors (F100 and G76). DQE at 0.5mm-1 ranged from 0.46 to 0.62, with an average of 0.52, and was highest for detector F100. DQE at 2.5 mm-1 was 0.08 for detector A175, 0.27 for B150, 0.21 for C148, 0.27 for D125, 0.24 for E124, 0.34 for F100 and 0.31 for G76, indicating low performance for A175 and highest DQE for F100. A linear correlation was found between Log(CT) and log(d'), with R2 = 0.96. No significant difference in CT at 2.28µGy was found in comparison to reference detector E124, with two exceptions: threshold contrast was significantly worse for detector C148 and significantly better for F100. Improved MTF performance for the smaller pixel detectors did not directly translate into improved CT performance for 250µm circular details. DQE, even at low spatial frequencies (0.5 mm-1), has an important influence on small detail detection.*Conclusions DQE had a stronger influence on small detail detectability than pixel size.*Clinical Relevance/Application The use of small pixel flat panel detectors for general radiographic applications does not guarantee improved small detail detectability compared to the flat panel detectors currently in use.

RESULTS

Spatial frequency for an MTF value of 0.1 for detectors A to G was: 3.21mm-1 for A175, 3.79mm-1 for B150, 3.59 for C148, 3.85 mm-1 for D125, 3.63 mm-1 for E124, 4.51 mm-1 for F100, 4.70 mm-1 for G76, indicating better MTF performance for the smaller pixel detectors (F100 and G76). DQE at 0.5mm-1 ranged from 0.46 to 0.62, with an average of 0.52, and was highest for detector F100. DQE at 2.5 mm-1 was 0.08 for detector A175, 0.27 for B150, 0.21 for C148, 0.27 for D125, 0.24 for E124, 0.34 for F100 and 0.31 for G76, indicating low performance for A175 and highest DQE for F100. A linear correlation was found between Log(CT) and log(d'), with R2 = 0.96. No significant difference in CT at 2.28µGy was found in comparison to reference detector E124, with two exceptions: threshold contrast was significantly worse for detector C148 and significantly better for F100. Improved MTF performance for the smaller pixel detectors did not directly translate into improved CT performance for 250µm circular details. DQE, even at low spatial frequencies (0.5 mm-1), has an important influence on small detail detection.

CLINICAL RELEVANCE/APPLICATION

The use of small pixel flat panel detectors for general radiographic applications does not guarantee improved small detail detectability compared to the flat panel detectors currently in use.

NR04-C2   Short-term Gadolinium Elimination Kinetics For Gadoteridol, Gadoterate Meglumine And Gadobutrol, Following Repeated Intravenous Administration To Rats.

Participants
Simona Bussi, BMedSc, Colleretto Giacosa, Italy (*Presenter*) Employee, Bracco Group

PURPOSE

To compare gadolinium (Gd) levels in rat tissues at 1, 2, 3 and 5 weeks after repeated intravenous administration of macrocyclic gadolinium-based contrast agents (GBCAs).*Methods and Materials One-hundred eighty male Sprague-Dawley rats were randomized to three exposure groups to receive 20 intravenous injections of gadoteridol, gadoterate meglumine or gadobutrol at a dose of 0.6 mmol/kg over 5 weeks (cumulative dose of 12 mmol/kg). Animals were sacrificed 1, 2, 3 or 5 weeks after the last injection (15 animals per group per timepoint) and tissues harvested for Gd determination by inductively coupled plasma-mass spectrometry (ICP-MS).*Results Gd levels in cerebellum, cerebrum and skin were significantly (p=0.01) lower after administration of gadoteridol than after administration of gadoterate and gadobutrol at all timepoints, and decreased more rapidly over time. The mean cerebellum Gd concentrations after administration of gadoteridol, gadoterate and gadobutrol decreased from 0.693, 0.878 and 1.011 nmol Gd/g tissue, respectively, at 1 week to 0.144, 0.282 and 0.297 nmol Gd/g tissue, respectively, at 5 weeks after injection (Figure 1). Similar findings were noted for the cerebrum (decreases from 0.675, 0.860 and 0.843 nmol Gd/g tissue at 1 week to 0.129, 0.311 and 0.309 nmol Gd/g tissue at 5 weeks, respectively) and skin (2.939, 9.744 and 8.799 nmol Gd/g tissue at 1 week to 0.305, 0.525 and 0.518 nmol Gd/g tissue at 5 weeks, for gadoteridol, gadoterate and gadobutrol, respectively). Conversely, significantly (p< 0.01) higher Gd levels were noted in blood after gadoteridol than after gadoterate at all timepoints and after gadobutrol at 1, 2 and 3 weeks after injection.*Conclusions Our study confirms that gadoteridol is eliminated more rapidly than gadoterate and gadobutrol in the first days and weeks after administration in rats. Gd levels in cerebellum, cerebrum and skin were significantly (p=0.01) lower after administration of gadoteridol at all timepoints investigated and decreased more rapidly over the course of the study.*Clinical Relevance/Application Lower levels of Gd in the first 5 weeks after administration to rats are seen with gadoteridol than with gadoterate and gadobutrol, confirming that this GBCA is eliminated more rapidly in this species.

RESULTS

Gd levels in cerebellum, cerebrum and skin were significantly (p=0.01) lower after administration of gadoteridol than after administration of gadoterate and gadobutrol at all timepoints, and decreased more rapidly over time. The mean cerebellum Gd concentrations after administration of gadoteridol, gadoterate and gadobutrol decreased from 0.693, 0.878 and 1.011 nmol Gd/g tissue, respectively, at 1 week to 0.144, 0.282 and 0.297 nmol Gd/g tissue, respectively, at 5 weeks after injection (Figure 1). Similar findings were noted for the cerebrum (decreases from 0.675, 0.860 and 0.843 nmol Gd/g tissue at 1 week to 0.129, 0.311 and 0.309 nmol Gd/g tissue at 5 weeks, respectively) and skin (2.939, 9.744 and 8.799 nmol Gd/g tissue at 1 week to 0.305, 0.525 and 0.518 nmol Gd/g tissue at 5 weeks, for gadoteridol, gadoterate and gadobutrol, respectively). Conversely, significantly (p< 0.01) higher Gd levels were noted in blood after gadoteridol than after gadoterate at all timepoints and after gadobutrol at 1, 2 and 3 weeks after injection.

CLINICAL RELEVANCE/APPLICATION

Lower levels of Gd in the first 5 weeks after administration to rats are seen with gadoteridol than with gadoterate and gadobutrol, confirming that this GBCA is eliminated more rapidly in this species.

NR04-C3   Prediction Of Parkinson Tremor Improvement After Mrgfus Thalamotomy Using Pretherapeutic Functional Connectivity Of Tractography-based Ventral Intermediate Nucleus

Participants
Yongqin Xiong, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

Parkinson disease (PD) tremor is one of the most common tremors, causing significant disability. Magnetic resonance-guided focused ultrasound (MRgFUS) thalamotomy of ventral intermediate nucleus (Vim) is a novel minimally invasive treatment for tremor. This study aimed to explore whether pretherapeutic resting-state functional connectivity of tractography-based Vim (T-VIM) predicts tremor improvement after MRgFUS thalamotomy in PD.*Methods and Materials Data were collected from nine participants with PD, who underwent unilateral MRgFUS thalamotomy. T-VIM was defined by tracking the pyramidal and medial lemniscus tracts using diffusion tractography. Lesioning area (L-VIM) was delineated on the post 24-hour T1-weighted images. The overlapping volume and center distance between L-VIM and T-VIM were calculated and correlated with post 12-months tremor improvement. The relationship between the pretherapeutic functional connectivity of T-VIM or L-VIM and tremor improvement were investigated using both ROI connectivity analysis and whole-brain seed-to-voxel connectivity analysis.*Results The overlapping volume between T-VIM and L-VIM was positively correlated with tremor improvement (r = 0.788, P = 0.012). The center distance was negatively correlated with tremor improvement ratio (r = -0.696, P = 0.037). Pretherapeutic functional connectivity of T-VIM with ipsilateral sensorimotor cortex (r = 0.876, P = 0.002), subthalamic nucleus (r = 0.700, P = 0.036) and visual area (r = 0.911, P = 0.001) significantly correlated with tremor improvement, with greater connectivity relating to greater tremor improvement. For L-VIM functional connectivity analysis, L-VIM - ipsilateral sensorimotor cortex functional connectivity was correlated with tremor improvement (r = 0.752,P = 0.019).*Conclusions T-VIM method may improve clinical responses of MRgFUS thalamotomy. The pretherapeutic resting-state functional connectivity T-VIM with ipsilateral sensorimotor cortex, subthalamic nucleus and visual area might predict tremor improvement after MRgFUS thalamotomy in PD, although this should be validated by prospective studies with larger number of patients.*Clinical Relevance/Application The method of directly targeting Vim using tractography may improve tremor responses of MRgFUS thalamotomy in PD. The pretherapeutic resting-state functional connectivity T-VIM might predict tremor improvement after MRgFUS thalamotomy in PD.

RESULTS

The overlapping volume between T-VIM and L-VIM was positively correlated with tremor improvement (r = 0.788, P = 0.012). The center distance was negatively correlated with tremor improvement ratio (r = -0.696, P = 0.037). Pretherapeutic functional connectivity of T-VIM with ipsilateral sensorimotor cortex (r = 0.876, P = 0.002), subthalamic nucleus (r = 0.700, P = 0.036) and visual area (r = 0.911, P = 0.001) significantly correlated with tremor improvement, with greater connectivity relating to greater tremor improvement. For L-VIM functional connectivity analysis, L-VIM - ipsilateral sensorimotor cortex functional connectivity was correlated with tremor improvement (r = 0.752,P = 0.019).

CLINICAL RELEVANCE/APPLICATION

The method of directly targeting Vim using tractography may improve tremor responses of MRgFUS thalamotomy in PD. The pretherapeutic resting-state functional connectivity T-VIM might predict tremor improvement after MRgFUS thalamotomy in PD.

NR04-C4   Intracranial Abnormalities And Epilepsy In Patients With Parry-Romberg Syndrome

Participants
Cynthia De la Garza Ramos, MD, Jacksonville, Florida (*Presenter*) Nothing to Disclose

PURPOSE

Parry-Romberg syndrome (PRS) is a rare disorder characterized by progressive hemifacial atrophy affecting the skin and underlying subcutaneous tissues. Concomitant intracranial abnormalities have been reported, frequently resulting in epilepsy, but the incidence and spectrum of intracranial involvement is not well established. This study aimed to characterize the frequency and severity of the most common intracranial abnormalities in PRS and determine associations with epilepsy.*Methods and

Materials This is a single-center, retrospective review of patients diagnosed with PRS from 2000-2020. MRI studies were reviewed by two board-certified neuroradiologists for intracranial abnormalities. Degree of hemispheric atrophy, white matter disease (WMD), hemorrhage, and leptomeningeal enhancement were graded as none, mild, moderate, or severe. Other abnormalities were also qualitatively reported. Findings were considered potentially PRS-related when occurring asymmetrically on side affected by PRS. Categorical variables were compared using the Chi-square or Fischer's exact test, as appropriate.*Results Eighty-six patients were identified, with a median age at PRS diagnosis of 20 years. Hemifacial involvement was left-sided in 44 (52%) cases. Thirty-six (41%) had intracranial abnormalities, and 27 (31.4%) were ipsilateral to the hemifacial atrophy, 7 (8.1%) contralateral, and 2 (2.3) bilateral. Nineteen (22%) had epilepsy, of which 18 (95%) had intracranial abnormalities. Fifteen (83%) of epileptic patients had abnormalities ipsilateral to facial hemiatrophy, therefore considered likely related to PRS. Neuroimaging findings were present in 18 (27%) patients in the non-epilepsy group. Unilateral WMD was the predominant finding in both epilepsy (47%) and non-epilepsy (22%) patients. When comparing between groups, WMD and hemispheric atrophy had a higher incidence and severity in epilepsy patients (p<0.001). Hemorrhage was also found to be more severe in the epilepsy group (p=0.026).*Conclusions Lateralized brain abnormalities are common in PRS patients, with a much higher incidence and greater severity in those with epilepsy. The most common findings in both groups are WMD and hemispheric atrophy, while hemorrhage is uncommon in those without epilepsy.*Clinical Relevance/Application Recognition of the incidence and spectrum of brain abnormalities related to PRS is vital for radiologists. Such asymmetric findings can be mistaken for other etiologies, such as Rasmussen encephalitis, leading to an erroneous diagnosis.

RESULTS

Eighty-six patients were identified, with a median age at PRS diagnosis of 20 years. Hemifacial involvement was left-sided in 44 (52%) cases. Thirty-six (41%) had intracranial abnormalities, and 27 (31.4%) were ipsilateral to the hemifacial atrophy, 7 (8.1%) contralateral, and 2 (2.3) bilateral. Nineteen (22%) had epilepsy, of which 18 (95%) had intracranial abnormalities. Fifteen (83%) of epileptic patients had abnormalities ipsilateral to facial hemiatrophy, therefore considered likely related to PRS. Neuroimaging findings were present in 18 (27%) patients in the non-epilepsy group. Unilateral WMD was the predominant finding in both epilepsy (47%) and non-epilepsy (22%) patients. When comparing between groups, WMD and hemispheric atrophy had a higher incidence and severity in epilepsy patients (p<0.001). Hemorrhage was also found to be more severe in the epilepsy group (p=0.026).

CLINICAL RELEVANCE/APPLICATION

Recognition of the incidence and spectrum of brain abnormalities related to PRS is vital for radiologists. Such asymmetric findings can be mistaken for other etiologies, such as Rasmussen encephalitis, leading to an erroneous diagnosis.

NR04-C5 Machine Learning-based Prediction Of Pseudoprogression In High Grade Gliomas

Participants
Burak Akkurt, MD, Muenster, Germany (Presenter) Nothing to Disclose

PURPOSE

Differentiation of post-treatment pseudoprogression from true progression in patients with high grade glioma (HGG) remains a diagnostic challenge and often requires hybrid imaging and/or invasive biopsies. A reliable and non-invasive differentiation between these two entities would be highly desirable. In this study we evaluate the prognostic value of Radiomics in HGG for the assessment of pseudoprogression development after multimodal therapy.*Methods and Materials We retrospectively screened 193 patients with histologically-proven HGG that presented to our tertiary referral center between 2015 and 2020. After exclusion of patients with missing or non-diagnostic preoperative imaging, clinical data and/ or histopathology, 131 patients remained for further analysis. Of the 131 included patients, 64 patients had a histopathological proven progress and 68 patients had a mixed or pure pseudoprogression (58 females, 44 %).Segmentation of the T1 TSE GD enhancing parts of the tumor was manually performed by experienced neuroradiologists using the 3D Slicer software. For computation of Radiomics features the open source PyRadiomics plugin was used. In order to prevent overfitting, 20 % of the data was reserved as a validation data set. Data preprocession involved Yeo-Johnson- and Z-Transformation followed by a bagged-tree classifier with 10-fold cross validation and a 95% correlation matrix (Figure 1) for dimension reduction. The resulting 25 Radiomics features were used in a machine learning classifier based on Generalized Boosted Regression Modeling (GBM).The final variables were: "diag.Image.orig.Mean","orig.shape.Elongation","diag.Image.intpol.Mean","diag.Mask.orig.VoxelNum","diag.Image.orig.Max.","orig.glcm.ClusterShade","orig.ngtdm.Strength" and "orig.fst.ord.RobustMeanAbsoluteDeviation".*Results Based on the test dataset the GBM classifier was able to predict a pseudoprogression development with a positive predictive value of 80%, a negative predictive value of 73,3% and an accuracy of 76%. The AUC ROC showed a value of 0.81 (Figure 2).*Conclusions The Radiomics approach shows promising results for pseudoprogression prediction in HGG and may add value to post treatment imaging after multimodal therapy.*Clinical Relevance/Application Differentiation of pseudoprogression from true progression in high grade glioma after multimodal therapy

RESULTS

Based on the test dataset the GBM classifier was able to predict a pseudoprogression development with a positive predictive value of 80%, a negative predictive value of 73,3% and an accuracy of 76%. The AUC ROC showed a value of 0.81 (Figure 2).

CLINICAL RELEVANCE/APPLICATION

Differentiation of pseudoprogression from true progression in high grade glioma after multimodal therapy

NR04-C6 Automated Detection Of Large Vessel Occlusion Using Relative Vessel Density: One Year Experience In A Multihospital Integrated Delivery Network

Participants
Warren Chang, MD,MBA, Pittsburgh, Pennsylvania (Presenter) Nothing to Disclose

PURPOSE

Several new techniques have emerged for automated detection of anterior circulation large vessel occlusion (LVO) by quantifying MCA territory relative vessel density (RVD) compared to the contralateral side, including RAPID-CTA, which may allow faster triage and decreased time to mechanical thrombectomy. We present our one year experience in a multihospital health system on the accuracy of RAPID-CTA for LVO detection in patients with stroke symptoms and its effect on treatment time and clinical outcomes.*Methods and Materials The study was supervised by the local institutional review board. 1203 patients presenting with stroke symptoms receiving CTAs with RAPID-CTA analysis were included. RAPID CTA examinations were considered positive at RVD < 60% (red or yellow color) and negative at RVD >60%. Radiology exams were considered positive if LVO (ICA/M1 or M2 occlusion) or high grade stenosis were documented in the radiology report. All positive cases were reviewed by a second reader with 100% concordance. The consensus expert reads were used as the gold standard and sensitivity, specificity, PPV (positive predictive value) and NPV (negative predictive value) were calculated.Patients eligible for mechanical thrombectomy were transported to a comprehensive stroke center for treatment. CTA to groin puncture time was calculated during one year time intervals before and after RAPID-CTA installation for patients undergoing mechanical thrombectomy. 90 day Modified Rankin Scores were obtained for patients undergoing treatment in each cohort.*Results 126 patients had M1/ICA occlusion, 71 had M2 occlusion, and 134 had high grade stenosis of the ICA or MCA. RAPID-CTA had sensitivities of 90%, 82%, and 82%, specificities of 82%, 85%, and 95%, PPV of 37%, 52%.,and 87% and NPV of 99%, 96%, and 93% in the detection of M1 occlusion, LVO, or high grade stenosis/LVO, respectively.CTA to groin puncture time was significantly lower after deployment of RAPID-CTA (93 minutes vs 68 minutes, p<0.05).Average 90 day mRS was lower in the RAPID CTA group with a higher percentage of patients with functional independence (mRS = 2), although the data was not statistically significant.*Conclusions RAPID CTA had high accuracy for detection of high grade stenosis or LVO in patients presenting with stroke symptoms. After implementation of RAPID-CTA, time to treatment was significantly lower and clinical outcomes were improved, including both average modified Rankin score and percentage of patients demonstrating functional independence.*Clinical Relevance/Application RAPID CTA demonstrated high accuracy for the detection of high grade stenosis or LVO in patients presenting with stroke symptoms, significantly decreased time from imaging to treatment, and improved clinical outcomes.

RESULTS

126 patients had M1/ICA occlusion, 71 had M2 occlusion, and 134 had high grade stenosis of the ICA or MCA. RAPID-CTA had sensitivities of 90%, 82%, and 82%, specificities of 82%, 85%, and 95%, PPV of 37%, 52%.,and 87% and NPV of 99%, 96%, and 93% in the detection of M1 occlusion, LVO, or high grade stenosis/LVO, respectively.CTA to groin puncture time was significantly lower after deployment of RAPID-CTA (93 minutes vs 68 minutes, p<0.05).Average 90 day mRS was lower in the RAPID CTA group with a higher percentage of patients with functional independence (mRS = 2), although the data was not statistically significant.

CLINICAL RELEVANCE/APPLICATION

RAPID CTA demonstrated high accuracy for the detection of high grade stenosis or LVO in patients presenting with stroke symptoms, significantly decreased time from imaging to treatment, and improved clinical outcomes.

NR04-C8 Evaluation Ofdeep Learning-based Computer Aided Diagnostic System In Measuring The Intracerebral Hemorrhagevolumein Clinical Practice

Participants
Jiandong Lai, Ankang, China (Presenter) Nothing to Disclose

PURPOSE

To explore and validate the performance of deep learning-based computer aided diagnostic system (DL-CAD) in measuring the intracerebral hemorrhage (ICH) volume in clinical practice.*Methods and Materials One hundred and eighty patients at different ICH stages were retrospectively collected, in particular, 60 cases for each stage, including hyperacute, acute, and subacute stages. The ICH volume of each patient was measured by DL-CAD, two residents using the ABC/2 method, and two senior physicians using the computer assisted volumetric analysis (CAVA) method. The measuring time-consumptions were recorded and the results from the CAVA method were used as gold standard. The volumetric measurement consistency between the two residents was studied, and the absolute percentage error (APE) of DL-CAD approach and the ABC/2 method was calculated and compared. A paired sample t test was used for normally distributed data; otherwise the Wilcoxon signed rank test would be used. P <0.05 was considered statistically significant.*Results Statistically significant differences were found between the two residents in measuring the volume of ICH at all stages when using ABC/2 method. For ICH at hyperacute, acute, and subacute stages, the APE of DL-CAD approach and ABC/2 method was 3.891±4.806%, 6.776±6.567%, 8.561±7.630% and 14.809±10.936%, 14.132±11.276%,17.412±14.484%, respectively, showing statistically significant differences between them (P<0.05). Additionally, no significant difference was observed between the measured values of DL-CAD and the gold standard (P> 0.05). In terms of time-consumption, the average volumetric measurement time of DL-CAD for ICH at hyperacute, acute, and subacute stages were 53.77±0.89s, 53.39±0.80s, and 53.60±0.47s, respectively, which were significantly lower than the ones of the ABC/2 method (95.43±17.60s, 116.86±38.40s, and 112.73±43.71s, respectively, P<0.05) and CAVA method (282.43±103.85s, 270.40±63.17s, and 232.37±93.13s, respectively, P<0.05).*Conclusions For ICH at any stage studied above, DL-CAD was able to measure its volume more accurately and more quickly than the traditional ABC/2 method.*Clinical Relevance/Application comparing with the traditional ABC/2 method, DL-CAD can automatically measure the volume of ICH at all stages more accurately and efficiently. By reducing the human errors and the measurement time, the DL-CAD is of important application value in clinical work.

RESULTS

Statistically significant differences were found between the two residents in measuring the volume of ICH at all stages when using ABC/2 method. For ICH at hyperacute, acute, and subacute stages, the APE of DL-CAD approach and ABC/2 method was 3.891±4.806%, 6.776±6.567%, 8.561±7.630% and 14.809±10.936%, 14.132±11.276%,17.412±14.484%, respectively, showing statistically significant differences between them (P<0.05). Additionally, no significant difference was observed between the measured values of DL-CAD and the gold standard (P> 0.05). In terms of time-consumption, the average volumetric measurement time of DL-CAD for ICH at hyperacute, acute, and subacute stages were 53.77±0.89s, 53.39±0.80s, and 53.60±0.47s, respectively, which were significantly lower than the ones of the ABC/2 method (95.43±17.60s, 116.86±38.40s, and 112.73±43.71s, respectively, P<0.05) and CAVA method (282.43±103.85s, 270.40±63.17s, and 232.37±93.13s, respectively, P<0.05).

CLINICAL RELEVANCE/APPLICATION

comparing with the traditional ABC/2 method, DL-CAD can automatically measure the volume of ICH at all stages more accurately and efficiently. By reducing the human errors and the measurement time, the DL-CAD is of important application value in clinical work.

GI03-B10   Volumetric Pancreas Segmentation On CT With A Convolutional Neural Network (CNN): Comparison Of Accuracy And Efficiency Versus NVIDIA Module In 3D Slicer® In The Context Of Inter-reader Variability Of Expert Manual Segmentation

Participants
Hala Khasawneh, MD, Rochester, Minnesota (*Presenter*) Nothing to Disclose

PURPOSE

Accurate & efficient pancreas segmentation is necessary for translation of pancreas morphometrics and radiomics for applications such as early detection of pancreas cancer & opportunistic detection of diabetes. Our purpose was to compare the accuracy & time of volumetric pancreas segmentation with our previously published automated CNN vs the boundary-points based NVIDIA segmentation module in 3D Slicer® in the context of inter-reader variability of expert manual segmentation.*Methods and Materials CNN-derived & Slicer® NVIDIA module-derived pancreas segmentations on a curated cohort of 89 abdomen CTs (portal venous phase, slice thickness =3.75 mm) with normal pancreas were independently corrected [corrected AI (cAI) and corrected NVIDIA (cNVIDIA)] by two radiologists (R1 and R2). Both R1 & R2 also independently performed manual pancreas segmentations on each CT using "Fill between Slices" tool on Slicer®. Segmentation time for each CT was recorded and compared between the 3 sets (cAI, cNVIDIA and manual). Manual segmentation by the radiologist with more experience (R1) was ground truth (GT) for calculation of Dice-Sorenson coefficient (DSC) and Jaccard coefficient (JC).*Results When compared with GT segmentations of R1, manual segmentations by R2 had mean (SD) DSC 0.83 (0.03) and JC 0.70 (0.05). CNN-derived automated segmentation had DSC 0.78 (0.06) and JC 0.64 (0.07). DSC and JC were identical for both readers for cAI [DSC: 0.80 (0.04); JC:0.67 (0.06)] and cNVIDIA [DSC: 0.82 (0.04); JC 0.70 (0.06)]. Compared to pancreatic volumes derived from GT [68.42 cc (35.6)], all other methods tended to over-segment the pancreas but the differences in volumes were non-inferior (p<0.05). Mean (SD) automated segmentation time for AI (with CPU) was 1.2 (0.3) minutes. Time for cAI, cNVIDIA, and manual method tended to be longer for R2 than R1 (R1: 1.22 (0.55), 3.27 (1.44) and 2.26 (0.49) minutes; R2: 1.57 (1.36), 3.50 (2.35) & 4.38 (1.46) minutes, respectively). Even after accounting for corrections of automated AI segmentations, there was significant time savings with AI compared to both manual (R1 46%; R2 64%; p<0.0001) & cNVIDIA (R1 63%; R2 55%; p-value <0.0001) sets.*Conclusions CNN-derived pancreas segmentation is accurate and has performance comparable to inter-reader variability. It delivers substantial time savings compared with both manual & NVIDIA module even after accounting for review of initial output of automated segmentations & with more pronounced effect for relatively inexperienced reader.*Clinical Relevance/Application AI-powered volumetric pancreas segmentation offers an accurate and scalable discovery tool for potential clinical translation of insights from quantitative pancreas imaging for endocrine and exocrine pancreas diseases.

RESULTS

When compared with GT segmentations of R1, manual segmentations by R2 had mean (SD) DSC 0.83 (0.03) and JC 0.70 (0.05). CNN-derived automated segmentation had DSC 0.78 (0.06) and JC 0.64 (0.07). DSC and JC were identical for both readers for cAI [DSC: 0.80 (0.04); JC:0.67 (0.06)] and cNVIDIA [DSC: 0.82 (0.04); JC 0.70 (0.06)]. Compared to pancreatic volumes derived from GT [68.42 cc (35.6)], all other methods tended to over-segment the pancreas but the differences in volumes were non-inferior (p<0.05). Mean (SD) automated segmentation time for AI (with CPU) was 1.2 (0.3) minutes. Time for cAI, cNVIDIA, and manual method tended to be longer for R2 than R1 (R1: 1.22 (0.55), 3.27 (1.44) and 2.26 (0.49) minutes; R2: 1.57 (1.36), 3.50 (2.35) & 4.38 (1.46) minutes, respectively). Even after accounting for corrections of automated AI segmentations, there was significant time savings with AI compared to both manual (R1 46%; R2 64%; p<0.0001) & cNVIDIA (R1 63%; R2 55%; p-value <0.0001) sets.

CLINICAL RELEVANCE/APPLICATION

AI-powered volumetric pancreas segmentation offers an accurate and scalable discovery tool for potential clinical translation of insights from quantitative pancreas imaging for endocrine and exocrine pancreas diseases.

GI03-B12   Artificial Intelligence In Crohn's Disease Imaging: From Concept To Clinical Application

Awards
Certificate of Merit

Participants
Mahmoud M. Al-Hawary, MD, Ann Arbor, Michigan (*Presenter*) Nothing to Disclose

TEACHING POINTS

• Review machine learning (ML) methods and techniques to develop automated Crohn's disease (CD) features extraction• Review efficacy and feasibility of models with traditional predictors in assessing qualitative and quantitative features with examples • Review bias, explainable AI and challenges in application of ML models in bowel imaging

TABLE OF CONTENTS/OUTLINE

1. Overview of defined qualitative imaging features in CD with clinical implications 2. Explore concept of ML applications with

emphasis on supervised shallow machine learning methods (Random Forest) and deep learning methods (convoluted Neural network). 3. Discuss inherent challenges in bowel analysis using machine learning 4. Step wise approach to machine learning methods in CD- Identify cohort, data acquisition and cleanup; split data into training, validation and test; establish criteria for ground truth and labelling; define your problem (classification or regression) based on your data and outcome (binary, ordinal, continuous, longitudinal or time series); understand which model works best on your data; evaluate model performance 5. Extraction of hidden (explainable) features (Radiomics/texture analysis) towards quantitative assessment - a path towards personalized/precision medicine 6. Case examples 7. Conclusion: ML in CD may have the potential to improve reproducibility and efficiency in qualitative imaging features with a capability to extract hidden quantitative features that can impact treatment plan and patient related outcome

GI03-B3   The Experiment Research Of Ivim-dwi And 3d-asl Quantitative Parameters To Evaluate Regulating Mettl14 On Xenograft Growth And Angiogenesis In Nude Mice With Human Colorectal Cancer Cells

Participants
Zhongyuan Zhang, hefei, China (*Presenter*) Nothing to Disclose

PURPOSE

To explore the feasibility of intravoxel incoherent motion diffusion weighted imaging (IVIM-DWI) and three-dimensional arterial spin labeling (3D-ASL) perfusion imaging technique dynamically evaluating the regulation of METTL14 on the cell proliferation and angiogenesis of subcutaneous xenograft in nude mice of human colorectal cancer.*Methods and Materials Divided into experimental group (Mettl14 knockdown group) and control group and 10 mice in each group, 20 5-week-old nude mice were used to established xenograft models. After that these mice carrying subcutaneous tumor preoperatively underwent plain MRI for IVIM-DWI and 3D-ASL examinations. IVIM-DWI quantitative parameters (ADC, D, D*, f) and 3D-ASL parameters(blood flow, BF)value were measured and optimal maps were reconstructed. Correlation analysis was conducted between all parameters and subcutaneous tumor volume, mass, Ki-67 and CD34 staining indices.*Results Compared with control group, the volume and mass of subcutaneous xenograft in the experimental group were much greater, with statistically significant differences (t value was 5.312, 5.535, P <0.05). Besides, the values of ADC and D in the experimental group were lower than those in the control group, while D*, F and BF values were higher than the counterpart, and the differences were statistically significant (t values were -2.802, -4.311, 4.992, 4.141 and 6.498, respectively, all P <0.05). Ki-67 and CD34 immunohistochemical results showed that the proliferation index and the MVD count of xenograft in the experimental group was significantly higher than that in the control group, and the difference was statistically significant (t value 9.387, 7.3, P <0.05). Pearson correlation analysis showed that D* and BF values of the experimental group were positively correlated with MVD count, xenograft volume and weight (P<0.05), while ADC values and D values were negatively correlated with Ki67 proliferation index, xenograft tumor volume and weight (P<0.05).*Conclusions The microcirculation and molecular diffusion movement of water of xenografts in nude mice can be evaluated quantitatively via IVIM-DWI and 3D-ASL technology, reflecting the microvascular formation and cell density of tumor tissues, noninvasively monitoring the regulation of METTL14 on the growth of xenograft of human CRC cells. Therefore, IVIM-DWI and 3D-ASL can be used as a useful tool for tumor experimental research.*Clinical Relevance/Application Quantitative parameters of IVIM-DWI and 3D-ASL can noninvasively monitor the regulation of metTL14 on the growth of subcutaneous transplanted tumor in nude mice with human colorectal cancer.

RESULTS

Compared with control group, the volume and mass of subcutaneous xenograft in the experimental group were much greater, with statistically significant differences (t value was 5.312, 5.535, P <0.05). Besides, the values of ADC and D in the experimental group were lower than those in the control group, while D*, F and BF values were higher than the counterpart, and the differences were statistically significant (t values were -2.802, -4.311, 4.992, 4.141 and 6.498, respectively, all P <0.05). Ki-67 and CD34 immunohistochemical results showed that the proliferation index and the MVD count of xenograft in the experimental group was significantly higher than that in the control group, and the difference was statistically significant (t value 9.387, 7.3, P <0.05). Pearson correlation analysis showed that D* and BF values of the experimental group were positively correlated with MVD count, xenograft volume and weight (P<0.05), while ADC values and D values were negatively correlated with Ki67 proliferation index, xenograft tumor volume and weight (P<0.05).

CLINICAL RELEVANCE/APPLICATION

Quantitative parameters of IVIM-DWI and 3D-ASL can noninvasively monitor the regulation of metTL14 on the growth of subcutaneous transplanted tumor in nude mice with human colorectal cancer.

GI03-B7   Evaluation Of The Quantitative Prediction Study Of Extracorporeal Shock Wave Lithotripsy For The Treatment Of Pancreatic Duct Stones Based On Energy Spectrum CT Effective Atomic Number Measurement Technology

Participants
Qingyu Ji, Baotou, China (*Presenter*) Nothing to Disclose

PURPOSE

The effective atomic number analysis of pancreatic duct stones (PDS) was performed by energy spectral plain computed tomography (CT) to find potential predictors of extracorporeal shock wave lithotripsy (ESWL) for the treatment of PDS.*Methods and Materials Fifty-six patients with chronic pancreatitis and pancreatic duct stones (stone diameter 0.5cm-1.2cm) were enrolled. Before and after ESWL treatment, energy spectrum plain scan CT was performed. All patients were treated with ESWL using an electromagnetic lithotripter. According to the effective atomic number (EAN) and mean stone density (MSD), the stone clearance rate (SCR) was obtained. The patients were divided into three groups, and the thresholds were respectively >90%, 50-90% and <50% of SCR. Factors include EAN and MSD. These factors were analyzed with ESWL, and their impact on SCR was evaluated through univariate and multivariate analysis. The diagnostic threshold of the independent predictive index was further calculated, and the relationship with SCR and ESWL was analyzed by drawing a trend line.*Results Both EAN and MSD can be the important predictors of ESWL for PDS (p <0.05), but the prediction effect of EAN is better than MSD (AUC is 0.915, 0.812, p <0.001). PDS patients with EAN higher than the cut-off value of 1.52e+3 but relatively low SCR (average 44.87 vs 89.57%) require more courses of ESWL treatment.*Conclusions The EAN obtained by energy spectrum CT plain scan can be an independent predictor of ESWL treatment of PDS patients. Using a cut-off value of 1.52e+3, patients with low stone EAN are good candidates for ESWL treatment of PDS.*Clinical Relevance/Application The study of the composition of pancreatic duct stones through energy spectrum CT, and the evaluation before and after extracorporeal shock wave lithotripsy combined with endoscopic treatment of pancreatic duct stones, instead of traditional imaging methods, more accurate analysis of the composition of pancreatic duct stones in patients with pancreatic duct stones. Optimize the lithotripsy plan, and guide clinicians to formulate "individualized treatment plan" according

to the patient's condition, pay attention to early diagnosis and treatment, so that patients can obtain better clinical effects.

RESULTS

Both EAN and MSD can be the important predictors of ESWL for PDS (p <0.05), but the prediction effect of EAN is better than MSD (AUC is 0.915, 0.812, p <0.001). PDS patients with EAN higher than the cut-off value of 1.52e+3 but relatively low SCR (average 44.87 vs 89.57%) require more courses of ESWL treatment.

CLINICAL RELEVANCE/APPLICATION

The study of the composition of pancreatic duct stones through energy spectrum CT, and the evaluation before and after extracorporeal shock wave lithotripsy combined with endoscopic treatment of pancreatic duct stones, instead of traditional imaging methods, more accurate analysis of the composition of pancreatic duct stones in patients with pancreatic duct stones. Optimize the lithotripsy plan, and guide clinicians to formulate "individualized treatment plan" according to the patient's condition, pay attention to early diagnosis and treatment, so that patients can obtain better clinical effects.

CA02-B3   **Heartaches Of A Different Kind: Comprehensive Review Of Infections**

Awards
Certificate of Merit

Participants
Sevcan Turk, MD, Ann Arbor, Michigan (*Presenter*) Nothing to Disclose

TEACHING POINTS

-Infections have a broad spectrum of imaging appearance based on the pathogen (viral, bacterial, fungal, and parasitic) and site of primary involvement (myocardium, pericardium, endocardium).-Cross-sectional imaging is commonly utilized for the evaluation of infections, particularly cardiac MR in the setting of suspected myocarditis and FDG PET in prosthetic valve endocarditis. Similarly, CT can play an important role in the assessment of complications like thromboembolism, pseudoaneurysms, and prosthetic valve endocarditis.-Role of imaging in cardiac infections has become particularly important during the current COVID pandemic. Understanding the value of MR in diagnosis and management is important.-Awareness of common as well as uncommon cardiac infections and their complications can help direct appropriate care. After reviewing this exhibit, the reader will become familiar with the spectrum of cardiac infections and the role of different qualitative and quantitative imaging parameters in the diagnosis.

TABLE OF CONTENTS/OUTLINE

1. Overview of imaging characteristics of a spectrum of common as well as rare cardiac infections: Viral (including SARS-CoV 2, HIV), Bacterial (ranging from common infections like Streptococcus, Staphylococcus to rarer entities like Mycobacterium tuberculosis), Fungal, Parasitic: e.g. Echinococcus, Chagas. 2. Learn the role of state of the art imaging with emphasis on qualitative and quantitative imaging parameters (e.g. T1 and T2 mapping). 3. Review of acute and chronic complications.

GU02-A3   The Gamut Of Extratesticular Scrotal Masses: An Anatomic Approach To Differential Diagnosis

Awards
Identified for RadioGraphics
Certificate of Merit

Participants
Rocio Marquez, MD, Chicago, Illinois (*Presenter*) Nothing to Disclose

TEACHING POINTS

The purpose of this exhibit is to: 1. Discuss the gamut of extratesticular (ET) masses which are common lesions that may be clinically significant and can pose diagnostic and management dilemmas 2. Review scrotal anatomy 3. Recognize mimics of paratesticular masses 4. Outline the differential diagnoses of ET masses defined by specific anatomic compartments 5. Describe imaging findings of benign ET lesions 6. Illustrate findings suggestive of malignant ET lesions and suggestions for management 7. Delineate conditions in which US findings are diagnostic and those in which MRI can serve an adjunctive role.

TABLE OF CONTENTS/OUTLINE

1-Introduction 2-Review of ET Scrotal Anatomy 3-Mimics of Paratesticular Masses (torsion knot, focal epididymitis/abscess, hematoma) 4-Benign ET Masses By Anatomical Compartment a)Skin (cysts, abscess, hematoma) b)Tunica (fibrous pseudotumor, mesothelioma) c)Testis (polyorchidism, appendage) d)Rete Testis (epididymal cyst, spermatocele, sperm cell granuloma, cystadenoma) e)Epididymis (adenomatoid tumor, cystadenoma, epidermoid) f)Spermatic Cord (lipoma, liposarcoma, metastases) g)Paratesticular (mesenchymal lesions, hernia) 5-Malignant ET Masses (sarcomas, lymphoma, metastases, amongst others) 6-Problem-solving role of MRI 7-Conclusions

VA02-B1   **Factors Affecting The Incidence Of The Thoracic Aortic Aneurysm Dissection Or Rupture: Initial Diameter And Patient Age**

Participants
Rokas Liubauskas, MD, Boston, Massachusetts (*Presenter*) Nothing to Disclose

PURPOSE

In patients with thoracic aortic aneurysm (TAA), the decision of surgical or endovascular repair relies primarily on its diameter. A threshold of 5.5cm is recommended for patients with a degenerative aneurysm, but the majority of acute aortic events occur below this threshold. Association between patients' age and the diameter of the TAA at the time of diagnosis and incidence of aortic aneurysm rupture (AAR) and acute aortic dissection (AAD) was investigated.*Methods and Materials Single-center IRB-approved study of patients with a TAA who underwent computed tomography (CT) that included thoracic imaging between October 4th, 2002 and February 18th, 2021. Patient demographic data and the diameter of the TAA at the time of diagnosis (initial TAA diameter) were recorded from online medical records. For this study, Rupture or dissection of TAA was defined as an aortic event. Association between patients' age and the initial TAA diameter and incidence of aortic events was investigated. Mann-Whitney test, t-test, and logistic regression were used to investigate the association of age and the initial diameter with AAR and AAD.*Results 6269 patients were included. 4102 (65%) patients were male, median age 71 (IQR 63-80, range 20-104). The median initial TAA diameter was 44.4 mm (IQR 40-46). The overall aortic event rate was 4.5% (282/6269). Younger age and larger initial diameter were associated with a higher rate of AAR or AAD (both p<0.0001). Patients with the initial TAA diameter 45 mm or greater experienced an aortic event rate of 4%. There was a trend of aortic event rate increasing with the initial TAA diameter increasing and plateauing at the diameter of 55 mm or greater at the rate of 13%. There was a trend of decreasing aortic event rate with increasing age, declining from more than 10% to 2%. Patients younger than 40 years old had an event rate of 10.7%. Patients 40 years old and older had an event rate of 4.4%. The highest event rate was demonstrated in the age group of 30-40 years old (11.8%). Age was demonstrated to affect the event rate independently from the initial aortic diameter.*Conclusions Patients with the diameter of the TAA 45 mm or greater suffer an aortic event more often than those with smaller aneurysms. There is also a tendency of younger patients to experience an aortic event more often than the older patients, peaking at the age 30-40 years old.*Clinical Relevance/Application The diameter of the thoracic aortic aneurysm and age, jointly and independently affect the rate of thoracic aneurysm rupture and dissection and should be taken into consideration when planning surgical or endovascular repair.

RESULTS

6269 patients were included. 4102 (65%) patients were male, median age 71 (IQR 63-80, range 20-104). The median initial TAA diameter was 44.4 mm (IQR 40-46). The overall aortic event rate was 4.5% (282/6269). Younger age and larger initial diameter were associated with a higher rate of AAR or AAD (both p<0.0001). Patients with the initial TAA diameter 45 mm or greater experienced an aortic event rate of 4%. There was a trend of aortic event rate increasing with the initial TAA diameter increasing and plateauing at the diameter of 55 mm or greater at the rate of 13%. There was a trend of decreasing aortic event rate with increasing age, declining from more than 10% to 2%. Patients younger than 40 years old had an event rate of 10.7%. Patients 40 years old and older had an event rate of 4.4%. The highest event rate was demonstrated in the age group of 30-40 years old (11.8%). Age was demonstrated to affect the event rate independently from the initial aortic diameter.

CLINICAL RELEVANCE/APPLICATION

The diameter of the thoracic aortic aneurysm and age, jointly and independently affect the rate of thoracic aneurysm rupture and dissection and should be taken into consideration when planning surgical or endovascular repair.

NPM05-A1 **Diversity, Equity And Inclusion: Analysis Of IMG Applicants Experience In The 2020 Diagnostic Radiology Residency Match**

Participants
Melina Hosseiny, MD, Los Angeles, California (*Presenter*) Nothing to Disclose

PURPOSE

1) analyze the proportion of the Diagnostic Radiology (DR) residency positions filled by International Medical School Graduates (IMG), American Medical School Graduates (AMG MD), and Doctor of Osteopathic Medicine (DO) applicants, 2) compare these values with other specialties and 3) analyze DR residency match results for IMGs in each state.*Methods and Materials The official published data of national residency match program (NRMP) for the 2020 Main Residency Match were accessed and reviewed from NRMP website (https://www.nrmp.org/main-residency-match-data/). The proportions of DR residency positions filled by US citizen and non-US citizen IMGs were compared with the overall match results for all applicants and all specialties. Match data were reviewed state-wise to assess the distribution of IMGs ranked into DR residency spots.*Results Overall, 990 PGY2 and 123 PGY1 DR residency positions were offered, of which 967 PGY2 and 116 PGY1 spots were filled. Of filled PGY2 spots, the proportion of AMG MD, DO, non-US IMGs and US IMG applicants were 72.1%,14.8%, 8%, and 5.1%, respectively. The share of IMG applicants from the filled DR spots was lower compared to the average of all specialties. (Fig. 1a) Among applicants who ranked DR as their only choice , 60.4% of non-US and 67.9% of US IMGs were matched, compared to a match rate of 97.8% for AMG MD and 97% for DO applicants whose only choice for specialty was DR. (Fig. 1b)At state-wise level, the ratio of matched IMGs/total DR residency spots was highest at AZ (62.5%, 5/8) followed by MI (38%, 8/21), MA (25%, 15/60), FL (25%, 13/52) and NY (19.1%, 26/136). There were 19 states who did not have any IMGs match into their DR Residency spots. Of these, NC (28), GA (23), VA (21) had the highest number of eligible DR residency spots.*Conclusions IMGs filled 14.8% of the DR residency positions in 2020 main residency match, compared to 21.7% of total residency positions filled by IMGs in all specialties. Overall, AZ, MI, MA, FL and NY were the most IMG-friendly states, while in 19 states with DR residency spots, no IMG applicants were matched. The findings have implications on the goals of diversity, equity and inclusion in the Diagnostic Radiology specialty.*Clinical Relevance/Application Less proportion of DR residency spots were filled by IMG applicants compared to the proportion for all specialties. This proportion heavily varies between different states and influences the diversity of the physician population in DR.

RESULTS

Overall, 990 PGY2 and 123 PGY1 DR residency positions were offered, of which 967 PGY2 and 116 PGY1 spots were filled. Of filled PGY2 spots, the proportion of AMG MD, DO, non-US IMGs and US IMG applicants were 72.1%,14.8%, 8%, and 5.1%, respectively. The share of IMG applicants from the filled DR spots was lower compared to the average of all specialties. (Fig. 1a) Among applicants who ranked DR as their only choice , 60.4% of non-US and 67.9% of US IMGs were matched, compared to a match rate of 97.8% for AMG MD and 97% for DO applicants whose only choice for specialty was DR. (Fig. 1b)At state-wise level, the ratio of matched IMGs/total DR residency spots was highest at AZ (62.5%, 5/8) followed by MI (38%, 8/21), MA (25%, 15/60), FL (25%, 13/52) and NY (19.1%, 26/136). There were 19 states who did not have any IMGs match into their DR Residency spots. Of these, NC (28), GA (23), VA (21) had the highest number of eligible DR residency spots.

CLINICAL RELEVANCE/APPLICATION

Less proportion of DR residency spots were filled by IMG applicants compared to the proportion for all specialties. This proportion heavily varies between different states and influences the diversity of the physician population in DR.

NPM05-A2 **Sterotactic Radiation Therapy In Oligometastatic Cancers: A Long-term Cost-effectiveness Evaluation**

Participants
Dirk Mehrens, MD, Munich, Germany (*Presenter*) Nothing to Disclose

PURPOSE

In certain malignancies, patients with oligometastatic disease benefit from radical ablative or surgical treatment. The SABR-COMET trial demonstrated a survival benefit for oligometastatic patients randomized to local stereotactic ablative radiation (SABR) compared to patients receiving standard care (SC) alone. Our aim was to determine the cost-effectiveness of SABR for oligometastatic cancer patients over a long-term horizon.*Methods and Materials A decision model based on partitioned survival simulations estimated costs and quality-adjusted life years (QALY) associated with both strategies in a United States setting from a health care perspective. Analyses were performed over the trial duration of six-years as well as a long-term horizon of 16 years. Model input parameters were based on the SABR-COMET trial data as well as best available and most recent data provided in the published literature. A discount of 3% for costs was implemented in the analysis. All costs were adjusted to 2019 US Dollars according to United States Consumer Price Index. SABR costs were reported with an average of $11,700 per treatment. Deterministic sensitivity analyses were performed. Incremental costs, effectiveness, and cost-effectiveness ratios (ICER) were calculated. The willingness-to-pay (WTP) threshold was set to $100,000/QALY.*Results Based on increased overall and progression-free survival, the SABR group showed 0.78 incremental QALYs over the trial duration and 1.34 incremental QALYs for long-term analysis. Treatment with SABR led to a marginal increase in costs compared to SC alone (SABR: $304,656; SC: $303,523

of 6 years; ICER $1,446/QALY and SABR: $402,888; SC: $350,708 for long term analysis; ICER $38,874/QALY). Therapy with SABR remained cost-effective until unit costs of $88,969 over the trial duration (i.e. 7.6 times the average cost). Sensitivity analysis identified a strong model impact for cost parameters of oligo- and polymetastatic disease states.*Conclusions Our analysis suggests that local treatment with SABR adds QALYs for patients with certain oligometastatic cancers and represents an intermediate- and long-term cost-effective treatment strategy.*Clinical Relevance/Application SABR is increasingly used as a therapy for oligometastatic disease. Based on this cost-effectiveness analysis, further investments in local ablative treatments for oligometastatic patients appear justified.

RESULTS

Based on increased overall and progression-free survival, the SABR group showed 0.78 incremental QALYs over the trial duration and 1.34 incremental QALYs for long-term analysis. Treatment with SABR led to a marginal increase in costs compared to SC alone (SABR: $304,656; SC: $303,523 of 6 years; ICER $1,446/QALY and SABR: $402,888; SC: $350,708 for long term analysis; ICER $38,874/QALY). Therapy with SABR remained cost-effective until unit costs of $88,969 over the trial duration (i.e. 7.6 times the average cost). Sensitivity analysis identified a strong model impact for cost parameters of oligo- and polymetastatic disease states.

CLINICAL RELEVANCE/APPLICATION

SABR is increasingly used as a therapy for oligometastatic disease. Based on this cost-effectiveness analysis, further investments in local ablative treatments for oligometastatic patients appear justified.

Abstract Archives of the RSNA, 2021

Sub-Events

SDP-BR-1 **Ultrafast Dynamic Contrast-enhanced Breast MRI: Association With Pathologic Complete Response In Neoadjuvant Treatment Of Breast Cancer**

Participants
Ji Hee Kim, Goyang, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this study was to investigate whether pretreatment kinetic features from ultrafast dynamic contrast enhanced (DCE)-MRI are associated with pathologic complete response (pCR) in patients with invasive breast cancer and according to immunohistochemistry (IHC) subtype.*Methods and Materials Between August 2018 and June 2019, 256 consecutive breast cancer patients (mean age, 50.2 years; range, 25-86 years) who underwent both ultrafast and conventional DCE-MRI and surgery following neoadjuvant chemotherapy were included. DCE-MRI kinetic features were obtained from pretreatment MRI data. Time-to-enhancement, maximal slope (MS), and volumes at U1 and U2 (U1, time point at which the lesion starts to enhance; U2, subsequent time point after U1) were derived from ultrafast MRI. To identify factors associated with pCR, logistic regression analysis was performed.*Results Overall, 41.4% of all patients achieved pCR. None of the kinetic features were associated with pCR when including all cancers. Among ultrafast DCE-MRI kinetic features, a higher MS (OR, 0.982; P = 0.040) was associated with pCR at univariate analysis in hormone receptor (HR)-positive cancers. In triple-negative cancers, a higher volume ratio U1/U2 was associated with pCR at univariate (OR, 11.787; P = 0.006) and multivariate analysis (OR, 14.811; P = 0.005). Among conventional DCE-MRI kinetic features, higher peak enhancement (OR, 0.993; P = 0.031) and a higher percentage of washout (OR, 0.904; P = 0.039) was associated with pCR only in HR-positive cancers at univariate analysis.*Conclusions A higher volume ratio of U1/U2 derived from ultrafast DCE-MRI was independently associated with pCR in triple-negative invasive breast cancer.*Clinical Relevance/Application Ultrafast DCE-MRI can aid in pCR prediction. Especially, a tailored approach of applying different parameters according to IHC subtype would be beneficial.

RESULTS

Overall, 41.4% of all patients achieved pCR. None of the kinetic features were associated with pCR when including all cancers. Among ultrafast DCE-MRI kinetic features, a higher MS (OR, 0.982; P = 0.040) was associated with pCR at univariate analysis in hormone receptor (HR)-positive cancers. In triple-negative cancers, a higher volume ratio U1/U2 was associated with pCR at univariate (OR, 11.787; P = 0.006) and multivariate analysis (OR, 14.811; P = 0.005). Among conventional DCE-MRI kinetic features, higher peak enhancement (OR, 0.993; P = 0.031) and a higher percentage of washout (OR, 0.904; P = 0.039) was associated with pCR only in HR-positive cancers at univariate analysis.

CLINICAL RELEVANCE/APPLICATION

Ultrafast DCE-MRI can aid in pCR prediction. Especially, a tailored approach of applying different parameters according to IHC subtype would be beneficial.

SDP-BR-10 **An Independent Evaluation Of A Breast Artificial Intelligence Product As A Stand-alone Reader On A Dataset Representative Of Two Uk Breast Screening Centres**

Participants
Lucy Warren, PhD, Guildford, United Kingdom (*Presenter*) Institutional Research Grant, Alphabet Inc

PURPOSE

To independently evaluate the stand-alone performance of a breast AI product on multi-centre UK breast screening data.*Methods and Materials An evaluation of a CE marked breast AI product (Lunit INSIGHT MMG, Seoul, South Korea) was performed independently from the vendor. Images from 30,000 women from the OPTIMAM image database (OMI-DB) formed a dataset representative of all women attending two UK breast screening centres in 2016. OMI-DB is continually updated with subsequent images and clinical information for the women collected. This allowed the inclusion of a representative number of prior images to interval and screen-detected cancers in the dataset. Images from OMI-DB have been shared with many AI developers. The vendor has had access to a subset of OMI-DB. These women were not used in this evaluation. The vendor did not have access to the product during the evaluation. The study aimed at assessing non-inferiority of the AI product (at an operating point defined prior to study) to first, second and consensus human readers. A positive case was defined as a woman diagnosed with a screen-detected cancer within 39 months or interval cancer within 36months of the screening mammogram. McNemar methods compared the AI product and human performance, with a non-inferiority range of 5 percentage points.*Results The AI was non-inferior to first and second human readers and consensus in terms of sensitivity and specificity, within a non-inferiority range of 5 percentage points. The sensitivity (95% confidence interval in brackets) of the AI product was 7.6 (3.7, 11.5), 2.9 (-0.6, 6.4) and 4.4 (0.9, 7.9) percentage points higher than first, second and consensus human readers respectively. The specificity of the AI product was 0.7 (0.3, 1.1), 1.2 (0.8, 1.6) and 3.6 (3.2, 3.9) percentage points lower than first, second and consensus human readers respectively. The disagreement between first human reader and AI product was 11%, significantly higher than the 4% disagreement between first and second human readers. This may be due to the AI product and human recalling different types of cases. The AI recalled 88% of screen-detected cancers, 34% priors to interval cancer and 23% prior to screen-detected cancer. The second human

reader recalled 97% of screen-detected cancers, 15% of priors to interval cancer and 11% of priors to screen-detected cancer. The impact of this after consensus needs to be investigated further.*Conclusions This study demonstrated that the breast AI product was non-inferior to human readers in terms of specificity and sensitivity, within a 5 percentage point non-inferiority range.*Clinical Relevance/Application Independent evaluation of CE marked breast AI product on representative multi-centre data from UK breast screening programme.

RESULTS

The AI was non-inferior to first and second human readers and consensus in terms of sensitivity and specificity, within a non-inferiority range of 5 percentage points. The sensitivity (95% confidence interval in brackets) of the AI product was 7.6 (3.7, 11.5), 2.9 (-0.6, 6.4) and 4.4 (0.9, 7.9) percentage points higher than first, second and consensus human readers respectively. The specificity of the AI product was 0.7 (0.3, 1.1), 1.2 (0.8, 1.6) and 3.6 (3.2, 3.9) percentage points lower than first, second and consensus human readers respectively. The disagreement between first human reader and AI product was 11%, significantly higher than the 4% disagreement between first and second human readers. This may be due to the AI product and human recalling different types of cases. The AI recalled 88% of screen-detected cancers, 34% priors to interval cancer and 23% prior to screen-detected cancer. The second human reader recalled 97% of screen-detected cancers, 15% of priors to interval cancer and 11% of priors to screen-detected cancer. The impact of this after consensus needs to be investigated further.

CLINICAL RELEVANCE/APPLICATION

Independent evaluation of CE marked breast AI product on representative multi-centre data from UK breast screening programme.

SDP-BR-11 Utility Of A Full Waveform Inversion Reconstruction Algorithm For Speed-of-sound Images On Ultrasound Computed Tomography For Breast Cancer

Participants
Fumi Kato, Sapporo, Japan (*Presenter*) Research Grant, Hitachi, Ltd;Research Grant, FUJIFILM Holdings Corporation;

PURPOSE

Ultrasound computed tomography (USCT) can generate speed-of-sound images (SSI) with a ring-shaped transducer array surrounding the breast in a water tank. High-resolution (HR)-SSI is obtained using a full waveform inversion reconstruction algorithm. Breast cancer (BC) may be more distinguishable from background parenchyma (BP) on HR-SSI. We evaluated the visibility and speed-of-sound value (SSV) of BC on SSI.*Methods and Materials BC patients (pts) who were scheduled to receive surgery between August and December 2018 and between August 2019 and March 2020 were eligible for the study for scanning with prototype USCT. Thirty-four lesions in 30 pts were included and received USCT. Six lesions in five pts were excluded due to being outside of the scanned area. Moreover, one lesion in one pt was excluded due to poor image quality. Finally, 27 lesions in 24 pts were analyzed.Visibility of BC on C-SSI and HR-SSI by reference to magnetic resonance (MR) images was evaluated using a 5-point scoring (1; invisible, 2; probably invisible, 3; not sure, 4; probably visible, 5; visible) by two radiologists (R1 and R2) independently, and compared using Wilcoxon signed ranks test. SSV of BC and BP on C-SSI and HR-SSI were measured and compared using paired samples t-test. The ratio of SSV of BC to BP was compared between C-SSI and HR-SSI using paired samples t-test. The correlation between SSV and apparent diffusion coefficient (ADC) value on MR imaging was investigated using Spearman's correlation coefficients.*Results By R1, all lesions (100%) were visible (score 4 or 5) on HR-SSI, and 12 lesions (44.4%) on C-SSI. By R2, 26 lesions (96.3%) were visible on HR-SSI and seven lesions (25.9%) on C-SSI. Scores for visibility by both radiologists on HR-SSI were significantly higher than those on C-SSI (p < 0.0001).SSV of BC was significantly higher than that of BP both on C-SSI and HR-SSI. The ratio of SSV of BC to BP on HR-SSI was significantly higher than that on C-SSI (p = 0.0009). There was no significant correlation between SSV and ADC value.*Conclusions HR-SSI provides better visibility of BC than C-SSI, and the SSV of BC is higher than BP.*Clinical Relevance/Application A full waveform inversion reconstruction algorithm for speed-of-sound imaging provides a high-resolution image and good visibility of breast cancer on ultrasound computed tomography.

RESULTS

By R1, all lesions (100%) were visible (score 4 or 5) on HR-SSI, and 12 lesions (44.4%) on C-SSI. By R2, 26 lesions (96.3%) were visible on HR-SSI and seven lesions (25.9%) on C-SSI. Scores for visibility by both radiologists on HR-SSI were significantly higher than those on C-SSI (p < 0.0001).SSV of BC was significantly higher than that of BP both on C-SSI and HR-SSI. The ratio of SSV of BC to BP on HR-SSI was significantly higher than that on C-SSI (p = 0.0009). There was no significant correlation between SSV and ADC value.

CLINICAL RELEVANCE/APPLICATION

A full waveform inversion reconstruction algorithm for speed-of-sound imaging provides a high-resolution image and good visibility of breast cancer on ultrasound computed tomography.

SDP-BR-12 The Performance Of Quantitative And Volumetric Enhancement Measurement To Assess Tumor Response In Patients With Breast Cancer After Early Neoadjuvant Chemotherapy

Participants
Jie Ding, Yinchuan, China (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the feasibility of quantitative enhancing lesion volume (ELV) for evaluating the responsiveness of breast cancer patients to early neoadjuvant chemotherapy (NAC) using dynamic contrast- enhanced magnetic resonance imaging (DCE-MRI).*Methods and Materials Seventy-five women with breast cancer underwent DCE-MRI before and after NAC. Lesions were assessed by ELV, response evaluation criteria in solid tumors 1.1 (RECIST 1.1), and total lesion volume (TLV). The diagnostic and pathological predictive performances of the methods were compared and color maps were compared with pathological results.*Results ELV identified 29%, 67%, and 4% of cases with partial response, stable disease, and progressive disease, respectively. There was no significant difference in evaluation performances among the methods. The sensitivity, specificity, positive predictive value, negative predictive value (NPV), and accuracy of ELV for predicting pathologic response were 72%, 92%, 81.8%, 86.8%, and 85.3%, respectively, with the highest sensitivity, NPV, and accuracy of the three methods. The area under the receiver operating characteristic curve was also highest for ELV. Pre- and post- NAC color maps reflecting tumor activity were consistent with pathological necrosis.*Conclusions ELV may help evaluate the responsiveness of breast cancer patients to NAC, and may provide a good tumor-response indicator through the ability to indicate tumor viability.*Clinical Relevance/Application ELV is a more effective method to assess breast tumor therapy response after early NAC.

RESULTS

ELV identified 29%, 67%, and 4% of cases with partial response, stable disease, and progressive disease, respectively. There was no significant difference in evaluation performances among the methods. The sensitivity, specificity, positive predictive value, negative predictive value (NPV), and accuracy of ELV for predicting pathologic response were 72%, 92%, 81.8%, 86.8%, and 85.3%, respectively, with the highest sensitivity, NPV, and accuracy of the three methods. The area under the receiver operating characteristic curve was also highest for ELV. Pre- and post- NAC color maps reflecting tumor activity were consistent with pathological necrosis.

CLINICAL RELEVANCE/APPLICATION

ELV is a more effective method to assess breast tumor therapy response after early NAC.

SDP-BR-14 The Performance Of Automated Breast Ultrasound Versus Hand-held Ultrasound In The Visualization And Characterization Of Axillary Lymph Node In Recent Diagnosed Breast Cancer Patients.

Participants
Sung Kim, MD, Sungnam-si, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

This study aimed to evaluate automated breast ultrasound (ABUS) and compare it to handheld ultrasound (HHUS) in the visualization and characterization of axillary lymph nodes (LNs) in recently diagnosed breast cancer patients.*Methods and Materials We retrospectively reviewed the medical records of 388 women (396 cancers) with recently diagnosed breast cancer (aged 53.0 ± 11.1 years) who underwent ABUS and HHUS examinations from September 2017 to May 2018. The findings of ABUS and HHUS were reviewed and compared using pathologic results as a reference. Their diagnostic performances in predicting axillary LN metastasis and heavy nodal (=3 LNs) metastasis were analyzed. The agreement between ABUS and HHUS was estimated using percent agreement and ? statistic.*Results Among the 396 breast cancers, 109 had axillary LN metastases (84 in N1, 17 in N2, and 8 in N3) and 35 had =3 LN metastases. Of the 396 ipsilateral axillae of breast cancer sites, 257 axillae (64.9%) had an axillary LN (average 1.4 ± 0.8, median 1, range 1-8) based on ABUS. Among the 139 axillae with no visualized LNs on ABUS, 12 had axillary LN metastases (8.6%; all in N1; one LN metastasis: 11, two LN metastases: 1). ABUS and HHUS showed ultrasonographically suspicious LNs in 63 (24.5%, 63/257) and 60 (15.2%, 60/396) axillae, respectively. The sensitivity, specificity, positive predictive value, negative predictive value, and accuracy of ABUS in predicting axillary LN metastases were 45.0, 95.1, 77.8, 82.0, and 81.3%, respectively, and those of HHUS were 42.2, 95.1, 76.7, 81.3, and 80.6%, respectively; while those of ABUS in predicting heavy nodal metastases were 71.4, 89.5, 39.7, 97.0, and 88.2%, and those of HHUS were 65.7, 89.8, 38.3, 96.4, and 87.9%, respectively (p > 0.05). The overall agreement between HHUS and ABUS in the included LNs of 257 axillae was 94.9%; kappa = 0.86.*Conclusions Although over one-third of axillae in recently diagnosed breast cancer site LN were not visualized on ABUS, ABUS could be used in the characterization of axillary LN. Moreover, in all heavy nodal metastasis cases, LNs were visualized on ABUS*Clinical Relevance/Application 1. ABUS showed axillary LNs in 64.9% of the recently diagnosed breast cancer patients. 2. Of the ABUS that did not visualize the axillary LNs of recently diagnosed breast cancer patients, 8.6% showed only one or two axillary LN metastasis. 3. The ABUS and HHUS findings of axillary LN showed almost perfect agreement.

RESULTS

Among the 396 breast cancers, 109 had axillary LN metastases (84 in N1, 17 in N2, and 8 in N3) and 35 had =3 LN metastases. Of the 396 ipsilateral axillae of breast cancer sites, 257 axillae (64.9%) had an axillary LN (average 1.4 ± 0.8, median 1, range 1-8) based on ABUS. Among the 139 axillae with no visualized LNs on ABUS, 12 had axillary LN metastases (8.6%; all in N1; one LN metastasis: 11, two LN metastases: 1). ABUS and HHUS showed ultrasonographically suspicious LNs in 63 (24.5%, 63/257) and 60 (15.2%, 60/396) axillae, respectively. The sensitivity, specificity, positive predictive value, negative predictive value, and accuracy of ABUS in predicting axillary LN metastases were 45.0, 95.1, 77.8, 82.0, and 81.3%, respectively, and those of HHUS were 42.2, 95.1, 76.7, 81.3, and 80.6%, respectively; while those of ABUS in predicting heavy nodal metastases were 71.4, 89.5, 39.7, 97.0, and 88.2%, and those of HHUS were 65.7, 89.8, 38.3, 96.4, and 87.9%, respectively (p > 0.05). The overall agreement between HHUS and ABUS in the included LNs of 257 axillae was 94.9%; kappa = 0.86.

CLINICAL RELEVANCE/APPLICATION

1. ABUS showed axillary LNs in 64.9% of the recently diagnosed breast cancer patients. 2. Of the ABUS that did not visualize the axillary LNs of recently diagnosed breast cancer patients, 8.6% showed only one or two axillary LN metastasis. 3. The ABUS and HHUS findings of axillary LN showed almost perfect agreement.

SDP-BR-15 Improve Preoperative Evaluation Of Axillary Lymph Node Involvement With Combination Of Grayscale And Contrast Enhanced Ultrasound In Clinical Node Negative Early Breast Cancer

Participants
Zihan Niu, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the diagnostic value of contrast-enhanced ultrasound (CEUS) combined with grayscale ultrasound for preoperative diagnosis of ALN metastatic involvement in patients with early-stage breast cancer and negative clinical palpation.*Methods and Materials A total of clinically node-negative early breast cancer 232 patients with 235 axillae were enrolled in this study. All patients underwent preoperative conventional US and CEUS examinations. The CEUS enhanced patterns were analyzed and further classified into four patterns, including homogeneous, featured inhomogeneous, focal defect, and no enhancement. The diagnostic value of conventional US and CEUS for the diagnosis of ALN tumor burden (ALN+(>=3) v.s. ALN+(1-2)) and ALN status (ALN+ v.s. ALN-) were evaluated. Moreover, at 3:2 ratio, 155 and 80 axillae were divided as the modeling and external validation groups. Two nomograms combined with gray-scale US and CEUS were constructed for the diagnosis of ALN status.*Results The ALN-, ALN+(1-2) and ALN+(=3)were observed in 164, 48, and 23 axillae, respectively. The identification rate of CEUS was 97.9%. Of them, 96.4% SLN with homogeneous enhancement and 92.5% SLN with special enhancement showed ALN-. And 99.2% with the above two patterns showed ALN+(1-2). Compared with the conventional US, the CEUS showed a higher AUC (tumor burden: 0.773 v.s 0.715, ALN metastasis: 0.815 v.s. 0.681) and NPV (tumor burden: 99.19% v.s. 97.48%, ALN metastasis: 94.31% v.s. 84.03%) for ALN status. Moreover, the nomogram further increased the diagnostic efficiency while keeping high NPV in both ALN tumor burden(AUC:0.828, NPV:97.92%) and ALN metastasis(AUC:0.857, NPV:94.74%) in the validation group.1111MicrosoftInternetExplorer402DocumentNotSpecified7.8 &7;Normal0*Conclusions The combination of CEUS and gray-scale US as a novel method could improve the diagnostic performance while keeping the high NPV for the diagnosis of ALN metastatic

status for clinically negative ALN in early breast cancer.*Clinical Relevance/Application This study further classified the enhancement patterns of SLN and explore the value of different US characteristics for ALN status diagnosis. Compared with the conventional US, CEUS further improved the negative prediction value of ALN status. Moreover, this study first developed and validated the nomogram based on nodal imaging methods combined with the gray-scale US and CEUS and showed high NPV and stable efficiency. The application of CEUS combined with the gray-scale US provides valuable information for the preoperative diagnosis of ALN status, and it might be helpful to the select the subgroups patients who would safely exempt for SLNB and/or ALN in early breast cancer patients with negative palpation ALN.

RESULTS

The ALN-, ALN+(1-2) and ALN+(=3)were observed in 164, 48, and 23 axillae, respectively. The identification rate of CEUS was 97.9%. Of them, 96.4% SLN with homogeneous enhancement and 92.5% SLN with special enhancement showed ALN-. And 99.2% with the above two patterns showed ALN+(1-2). Compared with the conventional US, the CEUS showed a higher AUC (tumor burden: 0.773 v.s 0.715, ALN metastasis: 0.815 v.s. 0.681) and NPV (tumor burden: 99.19% v.s. 97.48%, ALN metastasis: 94.31% v.s. 84.03%) for ALN status. Moreover, the nomogram further increased the diagnostic efficiency while keeping high NPV in both ALN tumor burden(AUC:0.828, NPV:97.92%) and ALN metastasis(AUC:0.857, NPV:94.74%) in the validation group.1111MicrosoftInternetExplorer402DocumentNotSpecified7.8 &7;Normal0

CLINICAL RELEVANCE/APPLICATION

This study further classified the enhancement patterns of SLN and explore the value of different US characteristics for ALN status diagnosis. Compared with the conventional US, CEUS further improved the negative prediction value of ALN status. Moreover, this study first developed and validated the nomogram based on nodal imaging methods combined with the gray-scale US and CEUS and showed high NPV and stable efficiency. The application of CEUS combined with the gray-scale US provides valuable information for the preoperative diagnosis of ALN status, and it might be helpful to the select the subgroups patients who would safely exempt for SLNB and/or ALN in early breast cancer patients with negative palpation ALN.

SDP-BR-16   The Impact Of Slice Thickness On The Interpretation Of Digital Breast Tomosynthesis

Participants
Yen Zhi Tang, MBBS,FRCR, Hamilton, Ontario (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the impact of slice thickness on the diagnostic accuracy and recall rates of Digital Breast Tomosynthesis (DBT).*Methods and Materials In this retrospective study, two readers (breast radiologist and fellow) interpreted 150 DBT studies performed between October 2017-November 2020, 125 normal cases and 25 with pathology-proven cancer. The DBT studies were randomized and reviewed independently by the two reader, who were blinded to the histopathology. DBT studies were reviewed using the standard protocol (1-mm slices with no overlap along with synthetic 2D-mammography (SM)). The presence/absence of an abnormality and a BIRADS score was recorded by each reader. After a 4-week washout period, the same DBT studies were interpreted using an experimental protocol (10-mm slabs with 5-mm overlap and SM). The results were then compared in terms of diagnostic accuracy and recall rates. Interobserver and intraobserver agreement was calculated (Cohen's Kappa). For diagnostic accuracy, the reference standard was histopathology or a normal follow-up mammogram at 2 years.*Results The cohort characteristics are listed in Table 1. Reader 1 had 97.6% intraobserver agreement (Cohen's Kappa [? 0.95] and reader 2 had 96.4% intraobserver agreement [? 0.92] when assessing the standard and experimental protocols. There was 90.5% agreement between reader 1 and 2 for the standard protocol [? 0.80]. There was 90.9% agreement between reader 1 and 2 for the experimental protocol [? 0.81]. Of the 25 DBT studies with pathology-proven cancer, one cancer was missed by both readers using both protocols.*Conclusions The diagnostic accuracy and recall rates were similar between the standard and experimental DBT protocols, demonstrating excellent interobserver and intraobserver agreement. This suggests that 10-mm thick slabs can be used in place of the 1-mm thin slices in the interpretation of DBT.*Clinical Relevance/Application Thick slab DBT reconstructions may be used in place of thin slice images with no effect on the diagnostic accuracy of DBT. The reduction in the number of images to be reviewed will improve efficiency and decrease interpretation time.

RESULTS

The cohort characteristics are listed in Table 1. Reader 1 had 97.6% intraobserver agreement (Cohen's Kappa [? 0.95] and reader 2 had 96.4% intraobserver agreement [? 0.92] when assessing the standard and experimental protocols. There was 90.5% agreement between reader 1 and 2 for the standard protocol [? 0.80]. There was 90.9% agreement between reader 1 and 2 for the experimental protocol [? 0.81]. Of the 25 DBT studies with pathology-proven cancer, one cancer was missed by both readers using both protocols.

CLINICAL RELEVANCE/APPLICATION

Thick slab DBT reconstructions may be used in place of thin slice images with no effect on the diagnostic accuracy of DBT. The reduction in the number of images to be reviewed will improve efficiency and decrease interpretation time.

SDP-BR-17   Clinical Outcomes And Imaging Features Of Microinvasive Carcinoma And Ductal Carcinoma In Situ: A Matched Cohort Study

Participants
Ga Young Yoon, MD, Gangwon-do, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the differences in clinical outcomes between microinvasive carcinoma (mIC) and ductal carcinoma in situ (DCIS) and compare imaging features of two diseases by using mammography, US and MRI.*Methods and Materials This retrospective study was approved by the institutional review board. Between January 2011 and December 2013, 516 women with mIC or DCIS confirmed by surgery were included. Patients were matched with propensity score matching to compare recurrence-free survival (RFS). RFS were compared using Cox proportional hazards model. Imaging features were also compared between two groups.*Results Among 516 women, 219 mIC and 297 DCIS tumors were identified. After matching, 132 women were allocated into each group. The mean follow-up duration was 80.2 months. In the matched cohort, no statistically significant association was observed between DCIS and mIC group of total recurrence (hazard ratio [HR]: 1.737; 95% confidence interval [CI]: 0.755-3.994; P = 0.194), local-regional recurrence (HR: 3.359; CI: 0.914-12.344, P = 0.068), or contralateral recurrence (HR: 0.992; CI: 0.295-2.88, P = 0.888). Non-mass lesions at US (P = 0.004), moderate or marked background parenchymal enhancement (P = 0.039), higher peak enhancement (P = 0.021) at MRI were more commonly seen in mIC group than in the DCIS group.*Conclusions Microinvasive carcinomas are distinct

from DCIS in terms of imaging features but are similar to DCIS in terms of clinical outcomes.*Clinical Relevance/Application Microinvasive carcinomas are distinct from DCIS in terms of imaging features but are similar to DCIS in terms of clinical outcomes. Our results suggest that mIC might be treated and followed up as DCIS.

RESULTS

Among 516 women, 219 mIC and 297 DCIS tumors were identified. After matching, 132 women were allocated into each group. The mean follow-up duration was 80.2 months. In the matched cohort, no statistically significant association was observed between DCIS and mIC group of total recurrence (hazard ratio [HR]: 1.737; 95% confidence interval [CI]: 0.755-3.994; P = 0.194), local-regional recurrence (HR: 3.359; CI: 0.914-12.344, P = 0.068), or contralateral recurrence (HR: 0.992; CI: 0.295-2.88, P = 0.888). Non-mass lesions at US (P = 0.004), moderate or marked background parenchymal enhancement (P = 0.039), higher peak enhancement (P = 0.021) at MRI were more commonly seen in mIC group than in the DCIS group.

CLINICAL RELEVANCE/APPLICATION

Microinvasive carcinomas are distinct from DCIS in terms of imaging features but are similar to DCIS in terms of clinical outcomes. Our results suggest that mIC might be treated and followed up as DCIS.

SDP-BR-18   Comparison Of Reader Performance Of Synthesized Mammograms Versus Original Digital Mammograms Alone And In Combination With Tomosynthesis Images

Participants
Takayoshi Uematsu, MD, PhD, Nagaizumi, Japan (*Presenter*) Research collaboration, FUJIFILM Holdings Corporation;

PURPOSE

To assess reader performance when synthesized mammograms (SM) versus original full-field digital mammograms (DM) are used alone or in combination with digital tomosynthesis images (Tomo).*Methods and Materials A fully crossed, mode-balanced multicase (n = 388), multireader (n = 4), retrospective observer performance study was performed by using deidentified images acquired from one institution with institutional review board approved protocols, during which each patient signed informed consent. The cohort included 84 cases of biopsy-proven cancer, 83 cases of biopsy-proven benign lesions, and 221 normal or benign cases (Breast Imaging Reporting and Data System [BI-RADS] score of 1 or 2) with negative 1-year follow-up results. Accuracy of sequentially reported probability of malignancy ratings and five-category forced BI-RADS ratings was evaluated by using areas under the receiver operating characteristic curve (AUCs) in the random-reader analysis.*Results Probability of malignancy based mean AUCs for SM and DM images alone was 0.902 and 0.871, respectively (P = .002). Mean AUC for SM with Tomo and DM with Tomo was 0.909 and 0.895, respectively (P = .082). In terms of the reader specific AUCs, all four readers performed better with SM alone versus DM alone, and three readers performed better with combined SM and Tomo. Similar results were obtained by using a nonparametric analysis of forced BI-RADS ratings. The mean interpretation time was 42.37 seconds for SM and 41.36 seconds for DM. The mean interpretation time with combined Tomo and SM (91.87 seconds) was 7.21 seconds shorter compared with DM with Tomo (99.08 seconds) (P < .001).*Conclusions SM alone is superior to DM alone and SM in combination with Tomo is comparable in performance to DM in combination with Tomo. SM may replace DM in both screening and clinical setting.*Clinical Relevance/Application Two-dimensional synthesized mammograms alone or in combination with tomosynthesis can be used as an acceptable replacement for directory acquired full-field digital mammograms in both screening and clinical setting.

RESULTS

Probability of malignancy based mean AUCs for SM and DM images alone was 0.902 and 0.871, respectively (P = .002). Mean AUC for SM with Tomo and DM with Tomo was 0.909 and 0.895, respectively (P = .082). In terms of the reader specific AUCs, all four readers performed better with SM alone versus DM alone, and three readers performed better with combined SM and Tomo. Similar results were obtained by using a nonparametric analysis of forced BI-RADS ratings. The mean interpretation time was 42.37 seconds for SM and 41.36 seconds for DM. The mean interpretation time with combined Tomo and SM (91.87 seconds) was 7.21 seconds shorter compared with DM with Tomo (99.08 seconds) (P < .001).

CLINICAL RELEVANCE/APPLICATION

Two-dimensional synthesized mammograms alone or in combination with tomosynthesis can be used as an acceptable replacement for directory acquired full-field digital mammograms in both screening and clinical setting.

SDP-BR-19   Intraductal Mass And Complex Cystic And Solid Mass On Breast Ultrasound: Are They Dangerous?

Participants
Andrei Alves de Queiroz, MD, Sao Paulo, Brazil (*Presenter*) Nothing to Disclose

PURPOSE

We aimed to analyze intraductal masses (IM) and complex cystic and solid masses (CCSM) detected by ultrasound and submitted to ultrasound guided biopsy, describing its malignancy rate, the association with papillary lesions and other diagnosis.*Methods and Materials Methods: We reviewed the database of the breast imaging department in our tertiary hospital and retrieved data from all ultrasound-guided breast biopsies from January 1, 2019 until December 31,2020. Lymph node biopsies and fine needle aspiration were excluded. Data retrieved included age, lesion characteristics (size and ultrasound characteristics) and method for tissue sample: core biopsy (CB) or vacuum assisted biopsy (VAB). Pathology was determined assessing the pathology reports. All ultrasound findings were re-classified according to ACR-BIRADS® lexicon by two breast imaging specialists with 8+ years of experience and over 15.000 ultrasounds performed. All statistics were done using R software. T student test, Fisher exact test and chi square test were used when appropriated.*Results A total of 483 breast lesions were submitted to ultrasound guided biopsy. The mean age was 47.7 years. CB was performed in 363 (75.2%) lesions and VAB in 120 (24.8%). Forty-nine lesions (10.1%) were IM or CCSM. The mean age was significantly higher compared to patients without these lesions (51.1 vs 47.3, p=0.03). There was no difference on mass size (1.26 vs 1.56, p=0.08). VAB was the choice for these masses in 57.1%, which is significantly higher (p<0.001) than for other lesions (21.2%). Papilloma without atypia was the most common specified pathology (24.5%), but miscellaneous and unspecified benign findings represented 51.0%. Breast malignancy was less common in IM or CCSM when compared with other lesions, (6.1% vs 23.0%; p=0.01). In total, 52.2% of breast papilloma were IM or CCSM.*Conclusions Intraductal mass and complex cystic and solid mass comprehend 10.1% of biopsied lesions of the breast, it is correlated with breast papilloma, and VAB was the sampling-method of choice. Although lower estimated malignancy (6.1%) than other lesions, it still in the ACR-BIRADS® 4 category.*Clinical Relevance/Application This study shows that intraductal mass or complex cystic and solid mass are frequently submitted to vaccum assisted biopsy and it they are related to breast papillomas

RESULTS

A total of 483 breast lesions were submitted to ultrasound guided biopsy. The mean age was 47.7 years. CB was performed in 363 (75.2%) lesions and VAB in 120 (24.8%). Forty-nine lesions (10.1%) were IM or CCSM. The mean age was significantly higher compared to patients without these lesions (51.1 vs 47.3, p=0.03). There was no difference on mass size (1.26 vs 1.56, p=0.08). VAB was the choice for these masses in 57.1%, which is significantly higher (p<0.001) than for other lesions (21.2%). Papilloma without atypia was the most common specified pathology (24.5%), but miscellaneous and unspecified benign findings represented 51.0%. Breast malignancy was less common in IM or CCSM when compared with other lesions, (6.1% vs 23.0%; p=0.01). In total, 52.2% of breast papilloma were IM or CCSM.

CLINICAL RELEVANCE/APPLICATION

This study shows that intraductal mass or complex cystic and solid mass are frequently submitted to vaccum assisted biopsy and it they are related to breast papillomas

SDP-BR-2   Non-mass Enhancement At Breast MR Imaging: The Added Value Of Radiomics Signature

Participants
Yan Li, MD,MD, Wuhan, China (*Presenter*) Nothing to Disclose

PURPOSE

To assess the additional value of radiomics signature to patients for differentiating benign from malignant non-mass enhancement lesions (NMEs) at breast MR imaging.*Methods and Materials The discriminative model was developed in a primary cohort that consisted of 232 patients with 247 NMEs at breast dynamic contrast-enhanced magnetic resonance imaging (DCE-MRI), and data was collected from December 2017 to October 2020. Radiomic features were extracted from DCE images at the very early phase (90 seconds) after contrast media injection. The least absolute shrinkage and selection operator (LASSO) regression model was applied for dimensionality reduction, feature selection, and radiomics signature building. We used multivariable logistic regression analysis to develop a clinical conventional discriminative model at first, and added the radiomics signature into the clinical model and developed a radiomics nomogram. The performance of the clinical model and radiomics nomogram was assessed. The internal validation was evaluated. An independent validation cohort consisted of 72 consecutive patients from November 2020 to April 2021.*Results The clinical model, which contained discriminative factors including the time-intensity curve (TIC) types and MR-reported Axillary Lymph Nodes (ALN) status, showed a high sensitivity of 0.942 (95%CI, 0.906 to 0.974) and a low specificity of 0.589 (95%CI, 0.464 to 0.714). Consisted of 6 selected features, the radiomics signatures was significantly associated with malignancy (P<0.001 for both primary and validation cohorts). Finally, the individual radiomics nomogram, which contained factors including TIC types and radiomics signatures, showed good discrimination, with an acceptable sensitivity of 0.869 (95%CI, 0.816 to 0.916) and improved specificity of 0.839(95%CI, 0.750 to 0.929), and good calibration. We applied the nomogram to the validation cohort and still reached good discrimination, with a sensitivity of 0.820 (95%CI, 0.700 to 0.920) and 0.864 (95%CI,0.682 to 1.000) and good calibration. The radiomics nomogram was clinically helpful demonstrated by decision curve analysis.*Conclusions Our study added radiomics signatures into the conventional clinical model and developed a radiomic nomogram including radiomics signatures and TIC types, which could be helpfully applied to differentiate benign NMEs from malignant NMEs for patients with suspicious lesions at breast MR imaging.*Clinical Relevance/Application Adding radiomics signatures into the conventional clinical model could help to differentiate benign NMEs from malignant NMEs for patients with suspicious lesions at breast MR imaging, especially improving the specificity, which may decrease the negative biopsy rates.

RESULTS

The clinical model, which contained discriminative factors including the time-intensity curve (TIC) types and MR-reported Axillary Lymph Nodes (ALN) status, showed a high sensitivity of 0.942 (95%CI, 0.906 to 0.974) and a low specificity of 0.589 (95%CI, 0.464 to 0.714). Consisted of 6 selected features, the radiomics signatures was significantly associated with malignancy (P<0.001 for both primary and validation cohorts). Finally, the individual radiomics nomogram, which contained factors including TIC types and radiomics signatures, showed good discrimination, with an acceptable sensitivity of 0.869 (95%CI, 0.816 to 0.916) and improved specificity of 0.839(95%CI, 0.750 to 0.929), and good calibration. We applied the nomogram to the validation cohort and still reached good discrimination, with a sensitivity of 0.820 (95%CI, 0.700 to 0.920) and 0.864 (95%CI,0.682 to 1.000) and good calibration. The radiomics nomogram was clinically helpful demonstrated by decision curve analysis.

CLINICAL RELEVANCE/APPLICATION

Adding radiomics signatures into the conventional clinical model could help to differentiate benign NMEs from malignant NMEs for patients with suspicious lesions at breast MR imaging, especially improving the specificity, which may decrease the negative biopsy rates.

SDP-BR-20   Is Chest CT Scan Still Not Good Enough For Predicting Axillary Response To Neoadjuvant Chemotherapy In Patients With Clinically Node Positive Breast Cancer

Participants
Myoung Won Song, HWASUN GUN, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

According to ACR appropriateness criteria, US is the primary method for assessment of residual axillary lymph node (LN) metastasis after neoadjuvant chemotherapy (NAC), although other imaging modalities such as breast MRI and CT can show extensive visualization of the axilla and enable to node-to-node comparison. We investigated whether chest CT scan, which has been constantly advanced during the decades but depreciated in evaluating axillary nodal disease burden, can predict residual axillary LN metastasis after NAC in patients with node-positive breast cancer.*Methods and Materials In this retrospective pilot study, women with clinically node-positive breast cancer who were treated with NAC following surgery between January 2019 and December 2019 were included. Clinically-positive node was defined to have one of followings: palpability at physical examination; suspicious imaging features; or biopsy-proven malignancy. We defined the suspicious CT features of axillary LNs as follows: eccentric cortex, loss of fatty hilum, round shape (long/short axis ratio of <1.6), complete or partial tumoral replacement of node, and irregular margins or perinodal infiltration. Univariable and multivariable logistic regression analyses were performed to evaluate the independent predictors of residual axillary LN metastasis.*Results A total of 94 women were included (mean age = 51.7 years). The axillary pathologic complete response (pCR) rate was 56.4% (53 of 94). Independent predictors of residual axillary LN metastasis were luminal A breast cancer based on immunohistochemical (IHC) staining, primary tumor size reduction less than 30% at MRI, eccentric cortical thickness more than 2.5mm and the total numbers of suspicious LNs (= 2) on post-NAC chest CT scan (all, p < 0.05). The

area under the receiver operating characteristic (AUC) with using CT parameters was 0.650 (95% confidence interval: 0.518, 0.781). When adding the information about IHC subtype and tumor reduction at MRI, the AUC increased as 0.790 (95% confidence interval: 0.682, 0.898).*Conclusions Conventional chest CT features, while informative, could not be used as a reliable parameter alone to predict residual axillary nodal metastasis after NAC. However, our findings suggest that the combined use of CT features and other clinical and radiological data might provide better information regarding the nodal burden before surgery.*Clinical Relevance/Application In case of no routine use of post-NAC/preoperative axillary US, chest CT features of axillary LN with other clinical/radiological data could pick up the slack for predicting residual axillary LN metastasis. The quantitative (radiomics) feature analysis and deep learning approach based on CT are currently under investigation.

RESULTS

A total of 94 women were included (mean age = 51.7 years). The axillary pathologic complete response (pCR) rate was 56.4% (53 of 94). Independent predictors of residual axillary LN metastasis were luminal A breast cancer based on immunohistochemical (IHC) staining, primary tumor size reduction less than 30% at MRI, eccentric cortical thickness more than 2.5mm and the total numbers of suspicious LNs (= 2) on post-NAC chest CT scan (all, $p < 0.05$). The area under the receiver operating characteristic (AUC) with using CT parameters was 0.650 (95% confidence interval: 0.518, 0.781). When adding the information about IHC subtype and tumor reduction at MRI, the AUC increased as 0.790 (95% confidence interval: 0.682, 0.898).

CLINICAL RELEVANCE/APPLICATION

In case of no routine use of post-NAC/preoperative axillary US, chest CT features of axillary LN with other clinical/radiological data could pick up the slack for predicting residual axillary LN metastasis. The quantitative (radiomics) feature analysis and deep learning approach based on CT are currently under investigation.

SDP-BR-21 Quantitative Dual Energy CT (DECT) For Predicting Immunohistochemical Biomarkers In Breast Cancer.

Participants
Jumanah Altwalah, MBBS, Riyadh, Saudi Arabia (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the possibility of quantitative parameters derived from DECT to detect breast cancer and discriminate immunohistochemical (IHC) biomarkers of invasive breast cancer.*Methods and Materials This retrospective study included a total of 49 patients (49.3 ± 10.5 years) with biopsy-proven breast cancer who had contrast enhanced DECT as initial staging from August 2017 to November 2020. The DECT quantitative parameters, including Iodine Concentration, normalized iodine concentration (NIC), fat percentage, the relative electron density (Rho), and the effective atomic number (Zeff), were obtained from the images of the tumor tissue, metastatic lymph nodes, breast tissue and normal lymph nodes. The breast tumors were classified according to their histopathology.*Results A total of 52 tumors were found on DECT for 49 patients. Iodine Concentration, NIC, Rho and Z values all showed significant difference between normal breast tissue and primary tumor (p < 0.001 for all). The AUC for ROC curves were 0.99 (CI 0.99 - 1), 0.98 (CI 0.96 - 1), 0.742 (CI 0.66 - 0.82) and 0.98 (CI 0.96 - 0.99) for Iodine Concentration, NIC, Rho and Zeff respectively. An Iodine Concentration Cut-off value of 1.5 mg/ml or greater was able to detect breast tumor with a Sensitivity and Specificity of 100% (CI 93.2% - 100%) and 98.1% (CI 93.26% - 99.66%) respectively. Iodine Concentration values were also able to discriminate between metastatic and normal lymph nodes (p < 0.0001) with an AUC for the ROC curve of 0.88 (CI 0.82 - 0.95). A value of 1.75 mg/ml or lower provided a Sensitivity and Specificity of 94.74% (CI 75.36% - 99.73%) and 70.19% (CI 60.81% - 78.14%) respectively. A Spearman Correlation analysis failed to demonstrate any significant correlation between the Iodine concentration or NIC results and any of the IHC biomarkers (ER, PR, HER2, Ki-67) or SBR Grade. There was moderate negative correlation between Tumor Fat percentage and Ki-67 expression (r = -0.76, p = 0.006) and moderate correlation with PR expression (r = 0.68, p = 0.02). Rho showed moderate correlation with Ki-67 expression (r = 0.69, p = 0.016). Zeff showed moderate to weak negative correlation with ER expression (r = -0.65, p = 0.026).*Conclusions DECT quantitative parameters can reliably detect breast cancer and metastatic lymph nodes. Some DECT parameters showed correlation to IHC biomarkers. However, the remaining DECT parameters do not show a significant correlation with any of the IHC biomarkers at this time. A larger study population is needed to validate the results.*Clinical Relevance/Application DECT has a role in predicting metastatic lymph nodes which could reduce the need for their removal and associated complications. DECT may have a role in predicting IHC biomarkers which could help treatment planning.

RESULTS

A total of 52 tumors were found on DECT for 49 patients. Iodine Concentration, NIC, Rho and Z values all showed significant difference between normal breast tissue and primary tumor (p < 0.001 for all). The AUC for ROC curves were 0.99 (CI 0.99 - 1), 0.98 (CI 0.96 - 1), 0.742 (CI 0.66 - 0.82) and 0.98 (CI 0.96 - 0.99) for Iodine Concentration, NIC, Rho and Zeff respectively. An Iodine Concentration Cut-off value of 1.5 mg/ml or greater was able to detect breast tumor with a Sensitivity and Specificity of 100% (CI 93.2% - 100%) and 98.1% (CI 93.26% - 99.66%) respectively. Iodine Concentration values were also able to discriminate between metastatic and normal lymph nodes (p < 0.0001) with an AUC for the ROC curve of 0.88 (CI 0.82 - 0.95). A value of 1.75 mg/ml or lower provided a Sensitivity and Specificity of 94.74% (CI 75.36% - 99.73%) and 70.19% (CI 60.81% - 78.14%) respectively. A Spearman Correlation analysis failed to demonstrate any significant correlation between the Iodine concentration or NIC results and any of the IHC biomarkers (ER, PR, HER2, Ki-67) or SBR Grade. There was moderate negative correlation between Tumor Fat percentage and Ki-67 expression (r = -0.76, p = 0.006) and moderate correlation with PR expression (r = 0.68, p = 0.02). Rho showed moderate correlation with Ki-67 expression (r = 0.69, p = 0.016). Zeff showed moderate to weak negative correlation with ER expression (r = -0.65, p = 0.026).

CLINICAL RELEVANCE/APPLICATION

DECT has a role in predicting metastatic lymph nodes which could reduce the need for their removal and associated complications. DECT may have a role in predicting IHC biomarkers which could help treatment planning.

SDP-BR-22 Yield Of Flow Cytometry In Addition To Cytology For Lymph Node Sampling In Patients With Incidental Axillary Adenopathy Without A Concurrent Diagnosis Of Primary Breast Malignancy

Participants
Roberto Lo Gullo, MD, New York, New York (*Presenter*) Nothing to Disclose

PURPOSE

Non-specific lymphadenopathy is increasingly being reported especially given COVID-19 vaccination campaign and is a diagnostic

dilemma especially in oncology patients where it raises concern for malignancy. When axillary lymphadenopathy persists, biopsy is performed to rule out malignancy. Fine needle aspiration (FNA) with flow cytometry (FC) can confidently rule out lymphoma although FC may be costly and requires additional sampling. We hypothesized that FNA with cytology alone without ancillary techniques is sufficient to assess non-specific axillary lymphadenopathy and rule out lymphoproliferative disease*Methods and Materials In this IRB-approved retrospective study, 222 eligible patients who underwent screening or diagnostic axillary ultrasound yielding unilateral lymphadenopathy without concurrent diagnosis of breast cancer and who had subsequent image-guided axillary FNA and flow cytometry were included. Diagnostic accuracy, sensitivity, specificity, positive and negative predictive value (PPV and NPV) were reported for FNA with cytology alone, and FC alone and in combination. Discordance rate between FNA cytology and FC was also assessed. Discordant cases (FNA positive for malignancy but FC negative, or vice versa) were evaluated with histology performed on core biopsy or surgical excision or follow up*Results Overall diagnostic sensitivity, specificity, PPV, NPV, and diagnostic accuracy were 88%, 92%, 77%, 96%, and 91%, for FNA alone, 98%, 98%, 92%, 99%, and 98%, for FC alone and 100%, 92%, 79%, 100%, and 94% for combined FNA/FC. Overall discordance rate between FNA and FC was 7% (16/222). 7/16 (44%) patients with discordant FNA/FC results were diagnosed with lymphoma. 6/7 patients had positive flow cytometry but negative FNA, 1 patient had suspicious FNA but negative FC. The one patient who was misdiagnosed on FC had Hodgkin lymphoma. 9/16 (56%) patients with discordant results had benign findings. All 9 patients had suspicious FNA and negative FC; benign etiology was confirmed with histology by means of core biopsy in 3 patients, follow up greater that 3 years in 4 patients, and 2/6 were lost at follow up*Conclusions With an overall diagnostic accuracy of 91%, FNA with cytology alone. FC is sufficient to screen patients with indeterminate and incidental lymphadenopathy. Flow cytometry could be initially deferred in patients with low pretest probability of lymphoma*Clinical Relevance/Application FNA with cytology is an accurate first-line standalone diagnostic procedure for assessing incidental nonspecific axillary lymphadenopathy in the breast cancer screening population. A positive/suspicious FNA result can be used to triage specimens for flow cytometry and/or tissue biopsy to characterize hematologic malignancy

RESULTS

Overall diagnostic sensitivity, specificity, PPV, NPV, and diagnostic accuracy were 88%, 92%, 77%, 96%, and 91%, for FNA alone, 98%, 98%, 92%, 99%, and 98%, for FC alone and 100%, 92%, 79%, 100%, and 94% for combined FNA/FC. Overall discordance rate between FNA and FC was 7% (16/222). 7/16 (44%) patients with discordant FNA/FC results were diagnosed with lymphoma. 6/7 patients had positive flow cytometry but negative FNA, 1 patient had suspicious FNA but negative FC. The one patient who was misdiagnosed on FC had Hodgkin lymphoma. 9/16 (56%) patients with discordant results had benign findings. All 9 patients had suspicious FNA and negative FC; benign etiology was confirmed with histology by means of core biopsy in 3 patients, follow up greater that 3 years in 4 patients, and 2/6 were lost at follow up

CLINICAL RELEVANCE/APPLICATION

FNA with cytology is an accurate first-line standalone diagnostic procedure for assessing incidental nonspecific axillary lymphadenopathy in the breast cancer screening population. A positive/suspicious FNA result can be used to triage specimens for flow cytometry and/or tissue biopsy to characterize hematologic malignancy

SDP-BR-23   Added Value Of Mammography Or Tomosynthesis To Breast Cancer Detection In Women Undergoing Breast MR For Screening - A Systematic Meta-analysis

Participants
Toni Vomweg, Koblenz, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Most research on breast MRI screening investigates its use as a supplement to mammography, and/or includes cohorts of women pre-selected to have normal mammograms. In view of the superior performance of breast MRI for screening, there is reason to re-address the role of mammography in women who have access to breast MRI. We performed a meta-analysis to investigate the published evidence on the additional cancer yield of mammography or DBT (Mx/DBT) in women undergoing breast MRI for screening.*Methods and Materials The Web of Science was searched for studies on the use of breast MRI for screening where participants had undergone mammography or DBT and breast MRI for screening, and where the cancer detection rates were analyzed separately. We recorded the number of participants and screening rounds, their individual level of risk, and stage of cancers detected (invasive vs. DCIS).*Results A total 9 studies were identified; 7 on high-risk (37,964 screening rounds), and 2 studies on average risk (3,185 screening rounds). The mean overall cancer detection rate (CDR) was 20.4 per 1000 screens. Of the total 672 cancers observed in the cohorts, 47 (6.9%) were only detected by Mx/DBT. Thus, additional Mx/DBT increased CDR only marginally compared to the use of MRI alone, from 19.1 per 1000 (with MRI alone) to 20.4 per 1000 (MRI plus Mx/DBT). Stratified by personal risk, the contribution of Mx/DBT to CDR was similarly low in women at high risk (from 21.3 to 22.9 per 1000 screens) as in average risk (from 11.4 to 11.7 per 1000). Among cancers detected by Mx/DBT alone, i.e. in addition to MRI, DCIS was over-represented (53%). Thus, adding Mx/DBT to MRI led to an only minute increase of invasive cancer detection (from 14.7 to 15.2 per 1000 screens) overall, and this was only observed in high risk women at all (where it increased invasive cancer detection from 16.3 to 16.9 per 1000 screens), but not in average risk women (where invasive cancer detection was 9.05 per 1000 screens with or without Mx/DBT).*Conclusions The added value of mammography to overall cancer detection, and in particular to invasive cancer detection, is limited in women undergoing MRI for screening in general, and appears to be particularly low in women at average risk. Beyond issues of cost-effectiveness, this should prompt a careful and comprehensive reappraisal of the risk/benefit ratio associated with the systematic use of Mx/DBT in women who have access to breast MRI*Clinical Relevance/Application Given the low cancer detection rates attributable to Mx/DBT in women undergoing MRI screening, the cumulative dose of ionizing radiation needed to detect one additional cancer, or needed to save one additional woman's life, may be prohibitively high

RESULTS

A total 9 studies were identified; 7 on high-risk (37,964 screening rounds), and 2 studies on average risk (3,185 screening rounds). The mean overall cancer detection rate (CDR) was 20.4 per 1000 screens. Of the total 672 cancers observed in the cohorts, 47 (6.9%) were only detected by Mx/DBT. Thus, additional Mx/DBT increased CDR only marginally compared to the use of MRI alone, from 19.1 per 1000 (with MRI alone) to 20.4 per 1000 (MRI plus Mx/DBT). Stratified by personal risk, the contribution of Mx/DBT to CDR was similarly low in women at high risk (from 21.3 to 22.9 per 1000 screens) as in average risk (from 11.4 to 11.7 per 1000). Among cancers detected by Mx/DBT alone, i.e. in addition to MRI, DCIS was over-represented (53%). Thus, adding Mx/DBT to MRI led to an only minute increase of invasive cancer detection (from 14.7 to 15.2 per 1000 screens) overall, and this was only observed in high risk women at all (where it increased invasive cancer detection from 16.3 to 16.9 per 1000 screens), but not in average risk women (where invasive cancer detection was 9.05 per 1000 screens with or without Mx/DBT).

CLINICAL RELEVANCE/APPLICATION

Given the low cancer detection rates attributable to Mx/DBT in women undergoing MRI screening, the cumulative dose of ionizing

radiation needed to detect one additional cancer, or needed to save one additional woman's life, may be prohibitively high

SDP-BR-24   Immunogenic Response And Abnormal Axillary Node Morphology In Triple Negative Breast Cancer Patients

Participants
Rosalind P. Candelaria, MD, Houston, Texas (*Presenter*) Nothing to Disclose

PURPOSE

We have observed a segment of triple-negative breast cancer (TNBC) patients with grossly abnormal axillary lymph node (AXLN) morphology and subsequent benign histopathology. We hypothesize that these sonographically-abnormal, benign AXLNs result from an immunogenic tumor response. The goal of this study is to investigate the relationship between AXLN appearance on ultrasound and the following immune response biomarkers: 1) sTIL levels and 2) PD-L1 expression.*Methods and Materials This imaging substudy was part of an active, single-institution, IRB-approved clinical trial of TNBC patients. The analysis included 289 patients who were enrolled between 11/2015 and 04/2019. All patients had pretreatment ultrasound evaluation of the AXLNs as part of their staging evaluation. The criteria for defining a sonographically-abnormal AXLN was having at least one of the following: absence of normal fatty hilum, cortex >3 mm, round shape, focal cortical lobulation. All patients with sonographically-abnormal AXLNs underwent biopsy. Pathology results were obtained from ultrasound-guided FNA ± core needle biopsy of the index abnormal AXLNs. sTIL levels were defined as low <20% and high =20%. Fisher's exact tests were used to compare between groups. P<0.05 was considered statistically significant.*Results There were 95/289 (33%) patients with sonographically-normal, benign AXLNs; 112/289 (39%) patients with sonographically-abnormal, biopsy-proven malignant AXLNs; and 82/289 (28%) patients with sonographically-abnormal, biopsy-proven benign AXLNs. There was a significant difference in the sTIL levels in patients with sonographically-normal AXLNs and sonographically-abnormal AXLNs (p=0.00014). Uniquely identified in patients with sonographically-abnormal, benign AXLNs was a combination of having both a much higher likelihood of tumors with increased sTIL levels (p<0.0001) and a higher likelihood of PD-L1 expression in the tumor microenvironment immune cells (p=0.02) when compared to patients with sonographically-normal, benign AXLNs.*Conclusions The sTIL levels and the PD-L1 expression in the immune cells are associated with AXLN morphology in TNBC patients. Benign AXLNs in TNBC patients with high-sTIL tumors and with PD-L1 expression in the immune cells can manifest with abnormal appearance because of an immune response rather than metastatic infiltration.*Clinical Relevance/Application To our knowledge, this is the first study to demonstrate an association between immunogenic response and abnormal ultrasound appearance of benign AXLNs. Radiologic-pathologic concordance can be accepted with a benign biopsy of a sonographically-abnormal AXLN in TNBC patients with high-sTIL tumors and with PD-L1 expression in the immune cells.

RESULTS

There were 95/289 (33%) patients with sonographically-normal, benign AXLNs; 112/289 (39%) patients with sonographically-abnormal, biopsy-proven malignant AXLNs; and 82/289 (28%) patients with sonographically-abnormal, biopsy-proven benign AXLNs. There was a significant difference in the sTIL levels in patients with sonographically-normal AXLNs and sonographically-abnormal AXLNs (p=0.00014). Uniquely identified in patients with sonographically-abnormal, benign AXLNs was a combination of having both a much higher likelihood of tumors with increased sTIL levels (p<0.0001) and a higher likelihood of PD-L1 expression in the tumor microenvironment immune cells (p=0.02) when compared to patients with sonographically-normal, benign AXLNs.

CLINICAL RELEVANCE/APPLICATION

To our knowledge, this is the first study to demonstrate an association between immunogenic response and abnormal ultrasound appearance of benign AXLNs. Radiologic-pathologic concordance can be accepted with a benign biopsy of a sonographically-abnormal AXLN in TNBC patients with high-sTIL tumors and with PD-L1 expression in the immune cells.

SDP-BR-25   Multimodal Artificial Intelligence For Breast Cancer Detection In A Population Of Women With Predominantly Dense Breasts

Participants
Tianyu Zhang, AMSTERDAM, Netherlands (*Presenter*) Nothing to Disclose

PURPOSE

To assess the stand-alone and combined performance of artificial intelligence (AI) detection systems for digital mammography (DM) and automated 3D breast ultrasound (ABUS) in detecting breast cancer in women with dense breasts.*Methods and Materials 430 paired cases of DM and ABUS examinations from an Asian population with dense breasts were retrospectively collected. All cases were analyzed by two AI systems, one for DM exams and one for ABUS exams. Outputs were combined with different weights (ranging from 0.01 to 0.99, the sum of 1). A selected subset (n=152) was read by four radiologists. The performance of AI systems was based on analysis of the area under the receiver operating characteristic curve (AUC). The maximum Youden's index and its associated sensitivity and specificity were also reported for each AI systems. Detection performance of human readers in the sub-cohort of the reader study was measured in terms of sensitivity and specificity.*Results In the full cohort, the performance of the AI systems in a multimodal setting was significantly better when the weights of AI-DM and AI-ABUS were 0.25 and 0.75, respectively, than each system individually in a single-modal setting (AUC-AI-Multimodal = 0.865; AUC-AI-DM=0.832, P=0.026; AUC-AI-ABUS=0.841, P=0.041). The maximum Youden's index for AI-DM was 0.650 (sensitivity and specificity of 76.1% and 88.9%), for AI-ABUS was 0.680 (sensitivity and specificity of 80.8% and 87.2%), and for AI-Multimodal was 0.707 (sensitivity and specificity of 79.4% and 91.2%). The AUC of AI systems was similar in the full cohort and the sub-cohort that also underwent human reading. The panel of 4 readers achieved a sensitivity of 93.2% and specificity of 32.7%. When the receiver operating characteristic curve of AI systems overlayed with the operating points of radiologists, it was observed that AI-multimodal achieves superior or equal sensitivity than single human readers at the same specificity operating points.*Conclusions In women with dense breasts, the automated AI readings on DM and ABUS exams perform better than radiologists. Multimodal (ABUS+DM) AI systems for detecting breast cancer in women with dense breasts are a potential solution for breast screening in radiologist-scarce regions.*Clinical Relevance/Application This research helps detect breast cancer in women with dense breasts. Multimodal AI systems for detecting breast cancer in women with dense breasts may be a potential solution for breast screening in radiologist-scarce regions.

RESULTS

In the full cohort, the performance of the AI systems in a multimodal setting was significantly better when the weights of AI-DM and AI-ABUS were 0.25 and 0.75, respectively, than each system individually in a single-modal setting (AUC-AI-Multimodal = 0.865; AUC-AI-DM=0.832, P=0.026; AUC-AI-ABUS=0.841, P=0.041). The maximum Youden's index for AI-DM was 0.650 (sensitivity and specificity of 76.1% and 88.9%), for AI-ABUS was 0.680 (sensitivity and specificity of 80.8% and 87.2%), and for AI-Multimodal

was 0.707 (sensitivity and specificity of 79.4% and 91.2%). The AUC of AI systems was similar in the full cohort and the sub-cohort that also underwent human reading. The panel of 4 readers achieved a sensitivity of 93.2% and specificity of 32.7%. When the receiver operating characteristic curve of AI systems overlayed with the operating points of radiologists, it was observed that AI-multimodal achieves superior or equal sensitivity than single human readers at the same specificity operating points.

CLINICAL RELEVANCE/APPLICATION

This research helps detect breast cancer in women with dense breasts. Multimodal AI systems for detecting breast cancer in women with dense breasts may be a potential solution for breast screening in radiologist-scarce regions.

SDP-BR-26   Prediction Of Pathologic Complete Response In Triple Negative Breast Cancer Using Baseline Tumor MRI Characteristics And Patterns Of Response During Neoadjuvant Chemotherapy

Participants
Mary Guirguis, MD, Houston, Texas (*Presenter*) Nothing to Disclose

PURPOSE

To investigate if pre-treatment breast MRI morphological characteristics and response patterns during neoadjuvant chemotherapy (NAT) predict pathologic complete response (pCR) in triple negative breast cancer (TNBC) patients.*Methods and Materials As part of a prospective IRB-approved clinical trial (ARTEMIS, NCT02276443), 199 patients with biopsy-proven stage I-III TNBC received NAT and were classified as pCR or non-pCR based on histopathology at surgery. Patients underwent 3T breast MRI at baseline (BL), and after 2 cycles (C2) and 4 cycles (C4) of Adriamycin-based chemotherapy (AC). Subsequently, patients received either taxane-based NAT or targeted therapy guided by mid-treatment imaging response. MRI studies were reviewed by two fellowship-trained breast radiologists who were blinded to the pathology results. ACR MRI BIRADS lexicon (5th Ed) was used to describe BL tumor morphology. Imaging response pattern at C2 and C4 MRI was classified as follows: type 0 (complete), type 1 (concentric shrinkage), type 2 (crumble), type 3 (diffuse enhancement), type 4 (stable), or type 5 (progression). Morphological features and response patterns were summarized and compared to the pCR status using Fisher's exact test. P values less than 0.05 were considered statistically significant.*Results Median patient age was 53 years, range 24-79. Of 199 patients, 95 (48%) had pCR and 104 (52%) had non-pCR. At BL MRI, an irregularly-shaped mass and homogenous or clumped non-mass enhancement were associated with pCR (p=0.026 and p=0.013, respectively). Multifocality, peritumoral edema, and intratumoral necrosis were independent of pCR. Following NAT, the most common MRI response pattern was type 1, seen with equal frequency in pCR and non-pCR at C2 (58% and 42%, respectively) and C4 (47% and 53%, respectively). The following response pattern associations were found: type 0 was associated with pCR at both C2 and C4 timepoints (p<0.001), while types 4 and 5 were associated with non-pCR at C2, (p<0.001). The four patterns: types 2, 3, 4, 5, were associated with non-pCR at C4 (p<0.001).*Conclusions Baseline MRI tumor morphological characteristics and MRI imaging response patterns during NAT may be valuable markers for pCR prediction in TNBC.*Clinical Relevance/Application Qualitative Breast MRI assessment may serve as an accessible clinical tool before and during NAT to identify TNBC patients who are unlikely to achieve pCR and may benefit from targeted therapies.

RESULTS

Median patient age was 53 years, range 24-79. Of 199 patients, 95 (48%) had pCR and 104 (52%) had non-pCR. At BL MRI, an irregularly-shaped mass and homogenous or clumped non-mass enhancement were associated with pCR (p=0.026 and p=0.013, respectively). Multifocality, peritumoral edema, and intratumoral necrosis were independent of pCR. Following NAT, the most common MRI response pattern was type 1, seen with equal frequency in pCR and non-pCR at C2 (58% and 42%, respectively) and C4 (47% and 53%, respectively). The following response pattern associations were found: type 0 was associated with pCR at both C2 and C4 timepoints (p<0.001), while types 4 and 5 were associated with non-pCR at C2, (p<0.001). The four patterns: types 2, 3, 4, 5, were associated with non-pCR at C4 (p<0.001).

CLINICAL RELEVANCE/APPLICATION

Qualitative Breast MRI assessment may serve as an accessible clinical tool before and during NAT to identify TNBC patients who are unlikely to achieve pCR and may benefit from targeted therapies.

SDP-BR-27   Women's Experience With Screening Mammography During The COVID-19 Pandemic: A Multi-institutional Prospective Study

Participants
Laura Parra, MD, Phoenix, Arizona (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate patients' anxiety and experience with screening mammography during the COVID-19 pandemic.*Methods and Materials An anonymous 19-question survey was administered to women receiving screening mammography patients at six sites in two countries, one in Singapore and five in the United States. Surveys were offered between 10/7/2020 and 3/11/2021 in either paper or electronic (QR code access) format. Women rated their level of pre- and post-visit anxiety (Likert scale, 1-5) and ranked the level of importance of various COVID-19 related precautions observed during their appointment. Demographic data, including risk factors for breast cancer and severe COVID-19 illness, were also collected. Multivariable logistic regression was used to evaluate and test associations of pre-visit anxiety (at least slightly anxious) with risk factors, race, and other factors.*Results The survey was completed by 1086 women with median age of 56 years (range: 29-84); 338 (31%) were of non-white race or ethnicity. Most had >1 breast cancer risk factors (N=628, 58%); fewer had >1 COVID-19 risk factors (N=282; 26%). Of the 1065 women who rated their anxiety level, 445 (42%) reported pre-visit anxiety. Anxiety decreased during their visits, with 272 (26%) reporting post-visit anxiety (p<0.001). The COVID-19 precautions ranked very important, in decreasing order, were: masking (88%), institution reputation (84%), physical distancing (79%), signs that the rooms/equipment was clean (79%), seeing staff clean hands (73%), pre-visit symptom screening (63%), temperature screening (58%), pre-visit information regarding precautions in place (57%), staff wearing eye protection (41%). Pre-visit anxiety was independently associated with the number of risk factors for severe COVID-19 illness (odds ratio [OR] for >2 vs. 0 risk factors: 2.0, 95% CI: 1.1-3.8) and breast cancer (OR for >2 vs. 0 risk factors: 1.7, 95% CI: 1.2-2.5) after adjusting for age, site, and race/ethnicity.*Conclusions Women presenting for screening mammography during the COVID-19 pandemic were frequently anxious, with higher levels of anxiety observed in patients with multiple risk factors for either severe COVID-19 illness or breast cancer. Masking and physical distancing were the most important actions that clinics may take to reduce anxiety during screening mammography visits.*Clinical Relevance/Application Understanding women's experiences can help to prioritize interventions to reduce patient anxiety and support return to care during the ongoing COVID-19 and future pandemics.

RESULTS

The survey was completed by 1086 women with median age of 56 years (range: 29-84); 338 (31%) were of non-white race or ethnicity. Most had >1 breast cancer risk factors (N=628, 58%); fewer had >1 COVID-19 risk factors (N=282; 26%). Of the 1065 women who rated their anxiety level, 445 (42%) reported pre-visit anxiety. Anxiety decreased during their visits, with 272 (26%) reporting post-visit anxiety (p<0.001). The COVID-19 precautions ranked very important, in decreasing order, were: masking (88%), institution reputation (84%), physical distancing (79%), signs that the rooms/equipment was clean (79%), seeing staff clean hands (73%), pre-visit symptom screening (63%), temperature screening (58%), pre-visit information regarding precautions in place (57%), staff wearing eye protection (41%). Pre-visit anxiety was independently associated with the number of risk factors for severe COVID-19 illness (odds ratio [OR] for >2 vs. 0 risk factors: 2.0, 95% CI: 1.1-3.8) and breast cancer (OR for >2 vs. 0 risk factors: 1.7, 95% CI: 1.2-2.5) after adjusting for age, site, and race/ethnicity.

CLINICAL RELEVANCE/APPLICATION

Understanding women's experiences can help to prioritize interventions to reduce patient anxiety and support return to care during the ongoing COVID-19 and future pandemics.

SDP-BR-28 Hematoma Complication Rate With Anticoagulation Therapy During Image-guided Core Needle Breast Biopsy

Participants
Vilert A. Loving, MD, Gilbert, Arizona (*Presenter*) Nothing to Disclose

PURPOSE

Core needle breast biopsies carry bleeding complication risk. Anticoagulation medications increase bleeding risk. This study assessed if anticoagulation medications impact hematoma incidence in patients undergoing image-guided core needle breast biopsies.*Methods and Materials This was a retrospective study of image-guided core needle breast biopsies performed at 12 breast centers within a large integrated health system between 4/2019-4/2021. Post biopsy hematomas were recorded by the radiologist at the time of biopsy according to a standardized definition as either (1) newly palpable lump at the biopsy site or (2) new mass = 2 cm at the biopsy site on post-procedure mammogram. Patient demographic information, anticoagulation type, biopsy type, and clinical outcomes were collected.*Results From 4/2019-4/2021, 2378 image-guided core needle breast biopsies were performed in 2337 patients. 333 biopsies (14.0%) were in patients on anticoagulation, including 42 (12.6%) rivaroxaban, apixaban, or dabigatran (Factor Xa and thrombin inhibitors), 24 (7.2%) warfarin, 20 (6.0%) dual-antiplatelet therapy (DAPT), 17 (5.1%) daily 325 mg aspirin, and 230 (69.1%) daily 81 mg aspirin.Hematomas occurred in 28/333 (8.4%) of biopsies with anticoagulation versus 145/2045 (7.1%) of biopsies without anticoagulation (p=0.39). Post biopsy hematomas developed in 4 (9.5%) using Factor Xa/thrombin inhibitor, 2 (8.3%) warfarin, 4 (20.0%) DAPT, 2 (11.8%) 325 mg aspirin, and 16 (7.0%) 81 mg aspirin. DAPT was significantly more likely to result in hematomas versus no anticoagulation therapy (p=0.03). No other anticoagulants significantly increased hematoma risk.Post-biopsy adverse clinical events did not significantly differ in anticoagulation patients versus no anticoagulation (p=0.14). One patient on warfarin developed a pseudoaneurysm treated with thrombin injection, and one patient not on anticoagulation was referred for emergent bleeding management.*Conclusions DAPT significantly increases hematoma risk after breast biopsy. No other anticoagulation medications were associated with increased hematoma risk.*Clinical Relevance/Application Patients undergoing image-guided breast biopsies may continue taking most anticoagulation medications without significant bleeding risk.

RESULTS

From 4/2019-4/2021, 2378 image-guided core needle breast biopsies were performed in 2337 patients. 333 biopsies (14.0%) were in patients on anticoagulation, including 42 (12.6%) rivaroxaban, apixaban, or dabigatran (Factor Xa and thrombin inhibitors), 24 (7.2%) warfarin, 20 (6.0%) dual-antiplatelet therapy (DAPT), 17 (5.1%) daily 325 mg aspirin, and 230 (69.1%) daily 81 mg aspirin.Hematomas occurred in 28/333 (8.4%) of biopsies with anticoagulation versus 145/2045 (7.1%) of biopsies without anticoagulation (p=0.39). Post biopsy hematomas developed in 4 (9.5%) using Factor Xa/thrombin inhibitor, 2 (8.3%) warfarin, 4 (20.0%) DAPT, 2 (11.8%) 325 mg aspirin, and 16 (7.0%) 81 mg aspirin. DAPT was significantly more likely to result in hematomas versus no anticoagulation therapy (p=0.03). No other anticoagulants significantly increased hematoma risk.Post-biopsy adverse clinical events did not significantly differ in anticoagulation patients versus no anticoagulation (p=0.14). One patient on warfarin developed a pseudoaneurysm treated with thrombin injection, and one patient not on anticoagulation was referred for emergent bleeding management.

CLINICAL RELEVANCE/APPLICATION

Patients undergoing image-guided breast biopsies may continue taking most anticoagulation medications without significant bleeding risk.

SDP-BR-29 Artificial Intelligence As A Support To The Radiologists' Screen Reading Of Mammograms-A Retrospective Study

Participants
Solveig S. Hofvind, Oslo, Norway (*Presenter*) Nothing to Disclose

PURPOSE

To explore the performance of an artificial intelligence (AI)-system on cancer detection in a population based screening program using independent double reading with consensus, and describe histopathological characteristics of the cancers detected.*Methods and Materials We included data from 65,983 screening examinations including 421 screen-detected and 114 interval cancers, resulting in a program sensitivity of 79% (421/535). The screening examinations were performed as a part of the regular screening setting in two counties in BreastScreen Norway, 2014-2018. We retrospectively processed the mammograms using an AI-system (Transpara version 1.7.0 beta, ScreenPoint Medical) which gives each examination a score from 1 to 10. We present the number of breast cancers that were given a threshold value of 9.01 (score=10) and 9.63 by the AI-system. The latter corresponded to a recall rate of 3.5%, which represent the average for the population studied. Median tumor diameter and the proportion of lymph node positive tumors (LN+) were described for cancers with a score of 10 and a score below 10.*Results The AI-system scored 10 for 81% (341/421) of the screen-detected and 41% (47/114) of the interval cancers. Using a threshold of 9.63, 70% (294/421) of the screen-detected and 20% (23/114) of the interval cancers were marked. Screen-detected cancers with an AI-score 10 had a median tumor diameter of 13mm (IQR: 9-20) and 18% were LN+, while those with a score below 10 had a median diameter of 10mm (IQR: 7-18) and 12% were LN+. Interval cancers with an AI-score of 10 had a median tumor diameter of 18m (IQR: 13-25) while those with a score below 10 were 15mm (IQR: 10-20).*Conclusions AI marks a substantial number of the screen-detected and

interval cancer and could potentially aid radiologists in their screen-reading and increase the sensitivity of the screening program. Prior to implementation of AI-systems in mammographic screening, more studies, retrospective as well as prospective, including analyses of the cost-benefit, are needed.*Clinical Relevance/Application Using AI as a support or replacement for radiologists in screen-reading mammograms requires analyses on retrospective data to ensure the sensitivity and specificity and to calibrate the systems.

RESULTS

The AI-system scored 10 for 81% (341/421) of the screen-detected and 41% (47/114) of the interval cancers. Using a threshold of 9.63, 70% (294/421) of the screen-detected and 20% (23/114) of the interval cancers were marked. Screen-detected cancers with an AI-score 10 had a median tumor diameter of 13mm (IQR: 9-20) and 18% were LN+, while those with a score below 10 had a median diameter of 10mm (IQR: 7-18) and 12% were LN+. Interval cancers with an AI-score of 10 had a median tumor diameter of 18m (IQR: 13-25) while those with a score below 10 were 15mm (IQR: 10-20).

CLINICAL RELEVANCE/APPLICATION

Using AI as a support or replacement for radiologists in screen-reading mammograms requires analyses on retrospective data to ensure the sensitivity and specificity and to calibrate the systems.

SDP-BR-3   Clinical Outcomes And Effectiveness Of A High Risk Breast MRI Screening Program

Participants
Wahida Rahman, MD, Ann Arbor, Michigan (*Presenter*) Nothing to Disclose

PURPOSE

Evaluate effectiveness, performance, and outcomes of a clinical breast MRI screening program in high risk women without prior history of breast cancer. Inform high risk women expected outcomes of screening breast MRI when risk-reducing prophylactic mastectomy is not elected.*Methods and Materials IRB approved, HIPAA-compliant retrospective study of 3821 MRI studies at an NCCN cancer center from 1/1/2015 - 12/31/2019. Included patients were asymptomatic with elevated lifetime risk of breast cancer, no prior history of breast cancer, and had follow up with a histopathological diagnosis or 12-month imaging or clinical follow up. Of 3821 studies, 1695 MRI examinations in 835 women were included. Patient age range 18-81 years, median age 50 years. Full contrast-enhanced breast MR protocol obtained using a 3 Tesla magnet and dedicated 16-channel breast coil, was interpreted by one of 13 MQSA-certified, fellowship-trained breast imagers with 1-13 years experience. Outcomes and pathologic characteristics of prevalent and incident screen detected cancers were reviewed. Sensitivity, specificity, PPV, NPV, FNR, and CDR were calculated.*Results Of 1695 MRIs, there were 37 (2.2%, CDR 22/1000) screen detected cancers- 23 (62.1%) invasive, 14 (37.8%) DCIS. Overall and incident screened median size was 7.0 and 8.0 mm for invasive, respectively, 9.0 mm for both for DCIS. 94.6% (35/37) of cancers were stage 0 or 1. 2 cases were stage 2A and 3A. All 16 incident cancers were stage 0 or 1. Overall node negativity rate was 89.2% (33/37). All 14 DCIS cases were node negative. 90.0% (9/10) of incident invasive carcinomas were node negative. The positive case had 1 lymph node with isolated tumor cells. Considering BI-RADS 3 studies as a positive result, sensitivity, specificity, PPV, NPV, FNR, and CDR were 95%, 83%, 12%, 100%, 0.12%, and 22/1000, respectively. When BI-RADS 3 studies were considered a negative result, these metrics were 74%, 92%, 17%, 99%, 0.59% and 17/1000.*Conclusions Screening breast MRI in the clinical setting in a high risk population without prior breast cancer detected cancers at low stage, with high CDR, and very low FNR. All incident cancers were stage 0 or 1. Effectiveness was similar to prior efficacy studies with favorable outcomes, further informing women considering management decisions and alternatives to risk-reducing mastectomy.*Clinical Relevance/Application High risk screening breast MRI in the clinical setting led to high CDR and favorable outcomes, providing information for women considering alternatives to risk-reducing mastectomy.

RESULTS

Of 1695 MRIs, there were 37 (2.2%, CDR 22/1000) screen detected cancers- 23 (62.1%) invasive, 14 (37.8%) DCIS. Overall and incident screened median size was 7.0 and 8.0 mm for invasive, respectively, 9.0 mm for both for DCIS. 94.6% (35/37) of cancers were stage 0 or 1. 2 cases were stage 2A and 3A. All 16 incident cancers were stage 0 or 1. Overall node negativity rate was 89.2% (33/37). All 14 DCIS cases were node negative. 90.0% (9/10) of incident invasive carcinomas were node negative. The positive case had 1 lymph node with isolated tumor cells. Considering BI-RADS 3 studies as a positive result, sensitivity, specificity, PPV, NPV, FNR, and CDR were 95%, 83%, 12%, 100%, 0.12%, and 22/1000, respectively. When BI-RADS 3 studies were considered a negative result, these metrics were 74%, 92%, 17%, 99%, 0.59% and 17/1000.

CLINICAL RELEVANCE/APPLICATION

High risk screening breast MRI in the clinical setting led to high CDR and favorable outcomes, providing information for women considering alternatives to risk-reducing mastectomy.

SDP-BR-30   High Risk Lesions Of The Breast: Development Of Presurgical Nomogram For Prediction Of Upgrade To Malignancy

Participants
Jennifer Schopp, MD, Dallas, Texas (*Presenter*) Nothing to Disclose

PURPOSE

To develop a predictive nomogram to estimate surgical cancer upgrade of high-risk breast lesions (HRL) identified on imaging-guided needle biopsy.*Methods and Materials In an IRB approved, HIPAA compliant study, we retrospectively reviewed all atypical ductal hyperplasia (ADH), atypical lobular hyperplasia (ALH), lobular carcinoma in situ (LCIS), and atypical papilloma (AP) diagnosed by image guided biopsy in our institution between 06/2014 and 04/2020, collecting HRL type, number of cores, needle gauge, mode of detection, patient age, breast density, surgical excision and cancer upgrade. Data was separated into training (n=235) and testing sets (n=102). A logistic regression model was built using the training set. Variables were selected by stepwise selection algorithm. The trained model was applied to the testing dataset. ROC and AUC for the model under training and testing sets were reported with 95% CIs.*Results Of 337 HRL that underwent surgery, upgrade rate of ADH lesions was 24.7 % (190/337), LCIS 13.6% (44/337), ALH 5.1% (78/337), and AP 64.0% (25/337), (p<0.001). Mean age was 55.4yrs (+-SD 10.3yrs), mean lesion size 1.7 cm(+_SD 1.9cm). Surgical excision showed DCIS in 16% of patients (53/337) and invasive carcinoma for 6 % (20/337). Screening detection (p<0.001), stereo biopsy (p<0.008) and small needle gauge (greater than 11gauge, p less 0.002) were associated with higher upgrade. Multivariate logistic regression showed AUC 0.74 for training (with 95% CI of 0.66 and 0.83) and 0.75 for testing set (with 95% CI of 0.63 and 0.87), with an optimal sensitivity of 85%, specificity of 56%. Of testing set with 102 patients, 13 were removed due to lack of size measurement, leaving 25 patients with malignancy (DCIS or invasive) within test set. Using 85%

sensitivity, the model has NPV= 89 and PPV =36. At 90% sensitivity, model has NPV=89 and PPV=32 .*Conclusions High risk lesion nomogram is able to predict upgrade based on lesion variables. Testing and training data sets demonstrated similar AUCs, with only small variation. In collaboration with radiologic pathologic correlation, the model can be valuable in management decisions. With 85% sensitivity, surgery would be avoided in 24 patients, with 3 invasive cancers missed. Using 90% sensitivity, surgery would be avoided in 16 patients and 2 invasive cancers missed. Using 85 and 90% sensitivity in the model, no DCIS cases were missed.*Clinical Relevance/Application Prediction of upgrade rate to malignancy upon surgical excision for high risk lesions utilizing the nomogram technique can provide valuable pre-surgical management evaluation to inform patients and clinicians of risk of upgrade to malignancy. This can be particularly for pre-surgical planning and timing for patients with multiple co-morbidities.

RESULTS

Of 337 HRL that underwent surgery, upgrade rate of ADH lesions was 24.7 % (190/337), LCIS 13.6% (44/337), ALH 5.1% (78/337), and AP 64.0% (25/337), (p<0.001). Mean age was 55.4yrs (+-SD 10.3yrs), mean lesion size 1.7 cm(+_SD 1.9cm). Surgical excision showed DCIS in 16% of patients (53/337) and invasive carcinoma for 6 % (20/337). Screening detection (p<0.001), stereo biopsy (p<0.008) and small needle gauge (greater than 11gauge, p less 0.002) were associated with higher upgrade. Multivariate logistic regression showed AUC 0.74 for training (with 95% CI of 0.66 and 0.83) and 0.75 for testing set (with 95% CI of 0.63 and 0.87), with an optimal sensitivity of 85%, specificity of 56%. Of testing set with 102 patients, 13 were removed due to lack of size measurement, leaving 25 patients with malignancy (DCIS or invasive) within test set. Using 85% sensitivity, the model has NPV= 89 and PPV =36. At 90% sensitivity, model has NPV=89 and PPV=32 .

CLINICAL RELEVANCE/APPLICATION

Prediction of upgrade rate to malignancy upon surgical excision for high risk lesions utilizing the nomogram technique can provide valuable pre-surgical management evaluation to inform patients and clinicians of risk of upgrade to malignancy. This can be particularly for pre-surgical planning and timing for patients with multiple co-morbidities.

SDP-BR-31   Peritumoral Fat Content Using Iterative Decomposition Of Water And Fat With Echo Asymmetry And Least-squares Estimation (ideal) Correlates With Lymph Node Metastasis And Relapse-free Survival In Breast Carcinoma: A Preliminary Comparative Study.

Participants
Natsumi Hirano, MD, Kitakyushu, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Breast cancer cells express receptors for adipokines secreted by adipocytes, which can affect tumor growth. In vitro and in vivo data indicate that adipocytes are modified by cancer cells to acquire characteristics different from naive adipocytes (cancer-associated adipocytes: CAAs). Histologically, CAAs located around breast cancer display smaller sizes and are less lipid, and peritumoral edema caused by the release of cytokines from CAAs can conduce to decrease the peritumoral fat proportion. The purpose of this study is to correlate peritumoral fat content using IDEAL with lymph node metastasis and relapse-free survival in breast carcinoma and to compare with T2-weighted (T2WI) and diffusion weighted (DWI) images.*Methods and Materials This study consisted of 83 patients who were diagnosed with invasive carcinoma of breast and underwent MRI including IDEAL before surgery. The scan time of IDEAL fat fraction (FF) map imaging was 33s. Four regions of interests (ROIs), which are a distance of 5 mm from the tumor edge, and one ROI in the mammary fat of the healthy side were set on the FF map. Then average peritumoral FF values (FFt), average FF values in the healthy side (FFh), and peritumoral fat ratio (pTFR: defined as FFt/FFh) were calculated. Tumor apparent diffusion coefficient (ADC) values were measured on ADC map obtained by DWI. Peritumoral edema was classified into 3 grades based on the degree of signal intensity around the tumor in T2WI (T2 edema) according to the previously described grading method (Cheon H, et al. Radiology. 2018). The presence of lymph node metastasis was histologically evaluated by 2 pathologists.*Results Result of stepwise logistic regression analysis for 4 variables (FF, pTFR, T2 edema and ADC) indicated that FF and T2 edema were significant factors of lymph node metastasis (p<0.01). Recurrence-free survival was significantly associated with FF (p<0.01), and 60 of 62 (96.8%) patients with FF more than 90% were alive without recurrence.*Conclusions Peritumoral fat content using IDEAL-IQ is associated with lymph node metastasis and relapse-free survival, and may therefore be a useful prognostic biomarker for breast carcinoma.*Clinical Relevance/Application In vivo IDEAL imaging is simple to perform without extrinsic contrast agent and the quantification of the peritumoral FF using IDEAL may be useful for therapeutic strategy for breast carcinoma.

RESULTS

Result of stepwise logistic regression analysis for 4 variables (FF, pFTR, T2 edema and ADC) indicated that FF and T2 edema were significant factors of lymph node metastasis (p<0.01). Recurrence-free survival was significantly associated with FF (p<0.01), and 60 of 62 (96.8%) patients with FF more than 90% were alive without recurrence.

CLINICAL RELEVANCE/APPLICATION

In vivo IDEAL imaging is simple to perform without extrinsic contrast agent and the quantification of the peritumoral FF using IDEAL may be useful for therapeutic strategy for breast carcinoma.

SDP-BR-32   Predictors Of Tumor Progression During Neoadjuvant Chemotherapy In Triple-negative Breast Cancer

Participants
Heera Yoen, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Little is known on the predictors of progressive disease (PD) during neoadjuvant chemotherapy (NAC) in triple-negative breast cancer (TNBC). We investigated the clinicopathological and MRI variables associated with PD and distant metastasis-free survival (DMFS) after NAC in patients with TNBC.*Methods and Materials In this single center retrospective study, 252 women (mean age, 48±10 [standard deviation]) with TNBC who underwent NAC between January 2010 and December 2019 were included. Pre-NAC clinicopathological data (age, clinical stage, histology/grade/Ki-67 from needle biopsy samples), NAC regimen, surgery method, surgical pathology (lymphovascular invasion [LVI], pathologic stage), and adjuvant treatment data were collected. BI-RADS lexicon-based pre-NAC MRI findings plus edema (no/peritumoral alone/prepectoral/subcutaneous) and necrosis (no/<25%/25-50%/50-75%/>75% of tumor volume) were analyzed by two breast radiologists in consensus. PD was defined as increase in tumor size (>20%) or the development of new lesions. Logistic regression and Cox proportional hazard regression were performed to

identify factors associated with PD and DMFS, respectively: variables with P <0.1 on univariable analysis were entered into multivariable analysis.*Results Of 252 women, 211 (84%) had complete or partial response, 15 (6%) had stable disease, and 26 (10%) had PD. Of the 26 women with PD, 20 had progression in primary breast tumors, 5 had progression in both breast and nodal lesions, and 1 had new lung metastasis. Of pre-NAC clinicopathological and MRI data, prepectoral (odds ratio [OR] 8.8, P=0.045) or subcutaneous (OR, 17.2, P = .013) edema was the only independent predictor of PD. Distant metastasis occurred in 66 (26%) women during a median follow-up period of 44 months. LVI (hazard ratio [HR], 2.5, P=0.003) and residual tumor in both breast and nodes (ypTis/inv and ypN+) (HR, 6.4, P=0.006) were independent negative predictors of DMFS. Edema and PD were not independently associated with DMFS (P <0.05).*Conclusions Prepectoral or subcutaneous edema was an independent predictor of PD. However, neither edema nor PD were independently associated with DMFS.*Clinical Relevance/Application Prepectoral or subcutaneous edema predicted PD during NAC, but its presence does not seem to strongly suggest the need of a first-line surgical approach or a novel or more aggressive chemotherapy.

RESULTS

Of 252 women, 211 (84%) had complete or partial response, 15 (6%) had stable disease, and 26 (10%) had PD. Of the 26 women with PD, 20 had progression in primary breast tumors, 5 had progression in both breast and nodal lesions, and 1 had new lung metastasis. Of pre-NAC clinicopathological and MRI data, prepectoral (odds ratio [OR] 8.8, P=0.045) or subcutaneous (OR, 17.2, P = .013) edema was the only independent predictor of PD. Distant metastasis occurred in 66 (26%) women during a median follow-up period of 44 months. LVI (hazard ratio [HR], 2.5, P=0.003) and residual tumor in both breast and nodes (ypTis/inv and ypN+) (HR, 6.4, P=0.006) were independent negative predictors of DMFS. Edema and PD were not independently associated with DMFS (P <0.05).

CLINICAL RELEVANCE/APPLICATION

Prepectoral or subcutaneous edema predicted PD during NAC, but its presence does not seem to strongly suggest the need of a first-line surgical approach or a novel or more aggressive chemotherapy.

SDP-BR-33   Preliminary Evaluation Of Fat Fraction In Differential Diagnosis Of MR BI-RADS 4 Breast Tumors

Participants
Qi Wu, Dalian, China (*Presenter*) Nothing to Disclose

PURPOSE

To explore the value of fat fraction (FF) derived from CS2-mDIXON-Quant sequence differential diagnosis of BI-RADS 4 malignant and benign breast tumors.*Methods and Materials This retrospective study enrolled 20 women patients (23 lesions) with suspected BI-RADS 4 breast tumors and performed CS2-mDIXON-Quant and Dynamic contrast enhancement (DCE) MR imaging (Table1). Based on the histopathology results, patients were divided into group 1 with malignant breast tumors (n=13) and group 2 with benign breast tumors (n=10). The measured image parameters (lesion volume, maximum diameter, the mean FF value of lesion and contralateral normal fibroglandular tissue) were compared between the two groups, and the diagnostic performance based on these parameters was quantified with ROC curve. Sensitivity and specificity of CS2-mDixon-Quant were calculated from ROC.*Results Twenty women patients (mean age 42.5±6.05 years, range 32-62 years) were analyzed. The intraclass correlation coefficients indicated a good inter-observer agreement of the measured lesion and normal tissue FF value(ICC=0.971,0.987,respectively) (fig1, 2). There was no significant difference in lesion volume,maximum lesion diameter and menopause between the two groups(p=0.292, 0.385, 0.059, respectively). The mean FF value of malignant group was significantly higher than that of benign group. There was significant difference in mean FF value of lesion and contralateral normal fibroglandular tissue between the Group1 or Group2 (p=0.022, 0.018,respectively)(table 2). There was also significant difference of mean FF of lesion and contralateral normal fibroglandular tissue between the two groups(p?0.01)(table 2). A cut-off of 18.99% was obtained to differentiate malignant from benign breast tumors with sensitivity, specificity and AUC of 61.5%, 90%, and 0.797, respectively (Figure 3).*Conclusions FF derived from CS2-mDIXON-Quant imaging yielded better diagnosis performance in discriminating MR BI-RADS 4 benign and malignant breast tumors with a sensitivity of 61.5% and a specificity of 90%, provided supplement information on tumor-fat contents in different breast tumors.*Clinical Relevance/Application Compression sensing combining with mDIXON Quant technique was used to measure the fat fraction of breast lesions. Studies shown Lipids orchestrate signal transduction cascades can be broken down into bioactive lipid mediators, which regulate a variety of carcinogenic processes, including cell growth,cell migration and metastasis formation. The increased fat content with proliferation rate of breast malignant tumors was shown in our study. FF derived from CS2-mDIXON-Quant imaging can provide supplement information on tumor-fat contents in different breast tumors.

RESULTS

Twenty women patients (mean age 42.5±6.05 years, range 32-62 years) were analyzed. The intraclass correlation coefficients indicated a good inter-observer agreement of the measured lesion and normal tissue FF value(ICC=0.971,0.987,respectively) (fig1, 2). There was no significant difference in lesion volume,maximum lesion diameter and menopause between the two groups(p=0.292, 0.385, 0.059, respectively). The mean FF value of malignant group was significantly higher than that of benign group. There was significant difference in mean FF value of lesion and contralateral normal fibroglandular tissue between the Group1 or Group2 (p=0.022, 0.018,respectively)(table 2). There was also significant difference of mean FF of lesion and contralateral normal fibroglandular tissue between the two groups(p?0.01)(table 2). A cut-off of 18.99% was obtained to differentiate malignant from benign breast tumors with sensitivity, specificity and AUC of 61.5%, 90%, and 0.797, respectively (Figure 3).

CLINICAL RELEVANCE/APPLICATION

Compression sensing combining with mDIXON Quant technique was used to measure the fat fraction of breast lesions. Studies shown Lipids orchestrate signal transduction cascades can be broken down into bioactive lipid mediators, which regulate a variety of carcinogenic processes, including cell growth,cell migration and metastasis formation. The increased fat content with proliferation rate of breast malignant tumors was shown in our study. FF derived from CS2-mDIXON-Quant imaging can provide supplement information on tumor-fat contents in different breast tumors.

SDP-BR-34   Potential Of Tumor Adjacent Feeding Vessels To Predict Pathological Tumor Response In Breast Cancer Patients Receiving Neoadjuvant Chemotherapy

Participants
Julia Carmona-Bozo, MD, Cambridge, United Kingdom (*Presenter*) Nothing to Disclose

PURPOSE

To assess the ability of the number of tumor-adjacent feeding vessels (AFV) to predict pathological response to neoadjuvant

chemotherapy (NAC) in breast cancer*Methods and Materials Women >18 years undergoing NAC prior to surgery for breast cancer underwent DCE-MRI examinations on a 3T MRI scanner at baseline, post cycle 1, mid-treatment, and at the end of NAC. Tumor vascularity was assessed by counting the number of adjacent feeding vessels (AFV) in contact with or penetrating the cancer on maximum intensity projections generated from subtractions of unenhanced and peak-enhancing images of the DCE-MRI series. Tumor size was estimated according to RECIST 1.1. Pathological complete response (pCR) was defined as no residual invasive cancer in the breast but allowing for the presence of residual in situ carcinoma. Negative binomial mixed-effects models with random intercepts and slopes for subjects were used to assess changes in the number of AFV among response groups (pCR vs non-pCR) during NAC.*Results Images from 82 patients (53 ± 10 years) with 86 cancers were analyzed. The majority were invasive ductal cancers (71/86, 83%), positive for hormone receptors (57/86, 66%), with 31% also HER2 positive. All tumours were either grade 2 or 3. pCR was observed in 27/86 (31%) lesions. There was a significant decrease in the number of AFV per NAC cycle (-8.8 ± 3.1%, p<0.001), which was independent of tumour histology, grade, molecular subtype or the presence of in situ carcinoma (all p>0.05), while a positive association was observed with tumour size (p<0.001). The mean number of AFV during NAC showed a statistically significant difference between response groups (pCR vs non-pCR: 16 ± 2 vs 21 ± 1 vessels, p=0.02), with cancers displaying pCR showing a larger reduction in AFV on average in comparison with partial responders (pCR vs non-pCR: -22.3 ± 1.8 vs -19.7 ± 3.6 % change/cycle).*Conclusions Tumour AFVs can differentiate pathological complete response from partial response in breast cancer patients.*Clinical Relevance/Application Afferent feeding vessels indicating peritumoral vascularity derived from DCE-MRI may enable response prediction to neoadjuvant therapy in breast cancer.

RESULTS

Images from 82 patients (53 ± 10 years) with 86 cancers were analyzed. The majority were invasive ductal cancers (71/86, 83%), positive for hormone receptors (57/86, 66%), with 31% also HER2 positive. All tumours were either grade 2 or 3. pCR was observed in 27/86 (31%) lesions. There was a significant decrease in the number of AFV per NAC cycle (-8.8 ± 3.1%, p<0.001), which was independent of tumour histology, grade, molecular subtype or the presence of in situ carcinoma (all p>0.05), while a positive association was observed with tumour size (p<0.001). The mean number of AFV during NAC showed a statistically significant difference between response groups (pCR vs non-pCR: 16 ± 2 vs 21 ± 1 vessels, p=0.02), with cancers displaying pCR showing a larger reduction in AFV on average in comparison with partial responders (pCR vs non-pCR: -22.3 ± 1.8 vs -19.7 ± 3.6 % change/cycle).

CLINICAL RELEVANCE/APPLICATION

Afferent feeding vessels indicating peritumoral vascularity derived from DCE-MRI may enable response prediction to neoadjuvant therapy in breast cancer.

SDP-BR-35 The Relationship Between Radiological Descriptors Of Local And Whole-breast Vascularity And PET/MR Imaging Metrics Of Hypoxia And Vascular Function In Breast Cancer

Participants
Julia Carmona-Bozo, MD, Cambridge, United Kingdom (*Presenter*) Nothing to Disclose

PURPOSE

To explore associations between imaging parameters of peritumoral and ipsilateral whole-breast vascularity, and quantitative metrics of tumor hypoxia and vascularity derived from combined PET/MRI with 18F-fluoro-misonidazole (18F-FMISO)*Methods and Materials Women aged >18 years with biopsy-confirmed breast cancer underwent a 60-min PET/MR scan after injection of 300 MBq of 18F-FMISO and a 2-hour uptake period. Pharmacokinetic parameters were derived from DCE-MRI using the extended Tofts' model (Ktrans, kep, ve, vp), while tumor hypoxia was assessed using the 18F-FMISO influx rate constant Ki determined by Patlak-plot analysis. Peritumoral vascularity was analyzed by counting the vessels in contact with or penetrating the lesion (adjacent feeding vessels, AFV) while whole-breast vascularity was assessed by counting significant vessels in the ipsilateral breast (=3 cm in length and =2 mm in maximal diameter). Pathological correlates included tumor type, grade, and molecular subtype. Linear or log-linear regression analysis was used for assessing associations between imaging and pathological variables*Results Overall, 32 lesions were assessed with the majority being ductal cancers (21/32; 66%), grade 2 or 3 (16/32; 50%), and positive for hormone receptors (31/32; 97%). The number of AFV associated positively with mean tumor Ktrans (R2=0.20, p=0.04) and ve (R2=0.41, p=0.001) after adjusting for the effect of tumor volume in regression analyses. Conversely, a negative association was found between AFV and 18F-FMISO Ki (R2=0.15, p=0.04). The number of significant vessels in the ipsilateral breast showed positive associations with Ktrans (R2=0.41, p<0.001), ve (R2=0.32, p=0.02) and vp (R2=0.45, p=<0.001), while a negative relationship was observed with 18F-FMISO Ki (R2= 0.19, p=0.02). No association was observed between the number of AFV or significant breast vessels and tumor histology, grade or molecular subtype (all p>0.05).*Conclusions Peritumoral and ipsilateral whole-breast vascularity negatively correlated with tumor hypoxia measured by 18F-FMISO-PET, whereas positive associations were observed with DCE-MRI parameters of vascularity in breast cancer*Clinical Relevance/Application Inadequate tumor vascularity and hypoxia are influenced by poor peritumoral and whole- breast vascularity hence, these radiological descriptors have potential in characterizing the tumor macroenvironment

RESULTS

Overall, 32 lesions were assessed with the majority being ductal cancers (21/32; 66%), grade 2 or 3 (16/32; 50%), and positive for hormone receptors (31/32; 97%). The number of AFV associated positively with mean tumor Ktrans (R2=0.20, p=0.04) and ve (R2=0.41, p=0.001) after adjusting for the effect of tumor volume in regression analyses. Conversely, a negative association was found between AFV and 18F-FMISO Ki (R2=0.15, p=0.04). The number of significant vessels in the ipsilateral breast showed positive associations with Ktrans (R2=0.41, p<0.001), ve (R2=0.32, p=0.02) and vp (R2=0.45, p=<0.001), while a negative relationship was observed with 18F-FMISO Ki (R2= 0.19, p=0.02). No association was observed between the number of AFV or significant breast vessels and tumor histology, grade or molecular subtype (all p>0.05).

CLINICAL RELEVANCE/APPLICATION

Inadequate tumor vascularity and hypoxia are influenced by poor peritumoral and whole- breast vascularity hence, these radiological descriptors have potential in characterizing the tumor macroenvironment

SDP-BR-36 A Composite Model For Pathologic Complete Response (pCR) Prediction In Triple Negative Breast Cancer (TNBC)

Participants
Gaiane M. Rauch, MD, PhD, Houston, Texas (*Presenter*) Nothing to Disclose

PURPOSE

TNBC constitutes an aggressive and heterogeneous group of tumors with variable response to neoadjuvant therapy (NAT) that currently lacks clinically available profiling strategies for prediction. We aimed to develop a composite predictive model based on imaging, pathological and clinical data to address this unmet need.*Methods and Materials 125 Stage I-III TNBC patients enrolled in an IRB approved prospective clinical trial (NCT02276433) who had DCE-MRI (temporal-resolution: 9-12 sec) at baseline (BL) and post 2 cycles (C2) of NAT, and had surgery were included in this analysis. Tumor volume was calculated using 3D measurements at BL and C2, during the early (9-12 sec) and late (360 sec) phases of the DCE-MRI. Percent tumor volume reduction (TVR) between BL and C2 was calculated. Demographic, clinical, and pathologic data (age, T and N stage, histology, androgen receptor expression, Ki-67, stromal tumor infiltrating lymphocytes level (sTIL), and PD-L1 expression), and treatment response at surgery (pCR vs non-pCR) were documented. Recursive partitioning was used to identify TVR cutoff value. Multivariate logistic regression and ROC analysis were used to assess associations and build and evaluate predictive models.*Results 61 (49%) TNBC pts showed pCR at surgery, and 64 (51%) non-pCR. Recursive partitioning analysis identified =65% TVR at early and = 55% TVR at late phase DCE-MRI as the optimal cutoff values for pCR prediction at C2. TVR, N stage and sTIL were significantly associated with pCR in the multivariate analyses (p<0.002, p<0.01, p<0.001, respectively). Composite model containing TVR (=65% vs <65% for early phase and =55% vs <55% for late phase DCE-MRI), N stage (N0 vs N+) and sTIL (=20% vs <20%) was predictive of pCR with AUC 0.85 (90% CI:0.78-0.92) for early phase DCE-MRI and 0.84 (95% CI:0.77-0.91) for late phase DCE-MRI. Composite model performance was significantly better than TVR only or clinical (sTIL, and N stage) model only (p<0.001).*Conclusions A composite model integrating imaging (DCE-MRI TVR), clinical (N stage) and pathological (sTIL) data showed high accuracy for prediction of pCR in TNBC patients. Validation of these results in a larger prospective study is ongoing.*Clinical Relevance/Application A composite predictive model using readily available imaging, clinical and pathological data may serve as a clinical tool for appropriate treatment strategy selection for TNBC patients.

RESULTS

61 (49%) TNBC pts showed pCR at surgery, and 64 (51%) non-pCR. Recursive partitioning analysis identified =65% TVR at early and = 55% TVR at late phase DCE-MRI as the optimal cutoff values for pCR prediction at C2. TVR, N stage and sTIL were significantly associated with pCR in the multivariate analyses (p<0.002, p<0.01, p<0.001, respectively). Composite model containing TVR (=65% vs <65% for early phase and =55% vs <55% for late phase DCE-MRI), N stage (N0 vs N+) and sTIL (=20% vs <20%) was predictive of pCR with AUC 0.85 (90% CI:0.78-0.92) for early phase DCE-MRI and 0.84 (95% CI:0.77-0.91) for late phase DCE-MRI. Composite model performance was significantly better than TVR only or clinical (sTIL, and N stage) model only (p<0.001).

CLINICAL RELEVANCE/APPLICATION

A composite predictive model using readily available imaging, clinical and pathological data may serve as a clinical tool for appropriate treatment strategy selection for TNBC patients.

SDP-BR-37   Early Prediction Of Chemoresistance Versus Excellent Response In Triple Negative Breast Cancer Patients (TNBC) With DCE-MRI

Participants
Gaiane M. Rauch, MD, PhD, Houston, Texas (*Presenter*) Nothing to Disclose

PURPOSE

TNBC is a heterogeneous disease with distinct molecular subtypes that convey diverse clinical behavior and response to NAT. The aim of this study was to determine if DCE-MRI after two cycles of NAT can identify patients with high likelihood to achieve pathologic complete response (pCR) to standard NAT - excellent responders, triaging them to standard of care (SOC), or when appropriate to de-escalation trials, and select chemoresistant patients who are unlikely to achieve pCR - nonresponders, for targeted therapeutic trials.*Methods and Materials This prospective IRB approved study (NCT02276443) included 100 patients with stage I-III TNBC who underwent DCE-MRI (temporal-resolution: 9-12 sec) at baseline (BL), and after 2 cycles (C2) of Adriamycin-based NAT. Tumor volume was calculated using 3D measurements of the index lesion at BL and C2, during the early phase of the DCE-MRI (9-12 sec) and late phase (360 sec). Percent tumor volume reduction (TVR) between BL and C2 was calculated. Pathologic response was assessed at the surgery after completing standard of care (SOC) anthracycline/taxane-based NAT. The relationship between pCR and TVR by MRI was evaluated using ROC analysis.*Results 50% (50/100) of TNBC achieved pCR. TVR =75% after C2 during early phase DCE-MRI predicted pCR with PPV 80% (31/39 patients), and TVR = 50% predicted non-pCR with NPV 90% (29/32 patients, AUC 0.82, 95% CI:0.74-0.91). During late phase DCE-MRI after C2 =75% TVR predicted pCR with PPV 78% (28/36 patients), and = 50% TVR had NPV 81% (30/37 patients) for prediction of non-pCR after NAT (AUC 0.80, 95% CI:0.71-0.89). Therefore, almost 60% of TNBC were correctly classified as pCR or non-pCR by both early and late phase DCE-MRI, while only 8% and 3% were misclassified as pCR and non pCR respectively by early phase DCE-MRI; 8% and 7% respectively by late phase DCE-MRI.*Conclusions DCE-MRI after 2 cycles of AC-based NAT was able to correctly classify 60% of TNBC patients either as excellent responders or nonresponders with high accuracy at early and late phases of imaging (AUC 0.82; 0.80). These results are being further validated in an ongoing large prospective trial for clinical implementation.*Clinical Relevance/Application DCE MRI after 2 cycles of NAT can identify TNBC patients with high or low likelihood of pCR, triaging them to SOC NAT with option for de-escalation trials or to targeted therapies respectively.

RESULTS

50% (50/100) of TNBC achieved pCR. TVR =75% after C2 during early phase DCE-MRI predicted pCR with PPV 80% (31/39 patients), and TVR = 50% predicted non-pCR with NPV 90% (29/32 patients, AUC 0.82, 95% CI:0.74-0.91). During late phase DCE-MRI after C2 =75% TVR predicted pCR with PPV 78% (28/36 patients), and = 50% TVR had NPV 81% (30/37 patients) for prediction of non-pCR after NAT (AUC 0.80, 95% CI:0.71-0.89). Therefore, almost 60% of TNBC were correctly classified as pCR or non-pCR by both early and late phase DCE-MRI, while only 8% and 3% were misclassified as pCR and non pCR respectively by early phase DCE-MRI; 8% and 7% respectively by late phase DCE-MRI.

CLINICAL RELEVANCE/APPLICATION

DCE MRI after 2 cycles of NAT can identify TNBC patients with high or low likelihood of pCR, triaging them to SOC NAT with option for de-escalation trials or to targeted therapies respectively.

SDP-BR-38   Breast Parenchyma Topology As A Predictive Biomarker For Neoadjuvant Chemotherapy Treatment In Breast Cancer

Participants

Prateek Prasanna, PhD, Stony Brook, New York (*Presenter*) Nothing to Disclose

PURPOSE

Radiomics and deep learning approaches have been recently used to learn prognostic signatures from breast tumors and surrounding peritumoral regions. Although promising, such features cannot explicitly model the complex and subtle parenchymal tissue structures. Therefore, the learning outcome lacks sufficient interpretability. We present a novel topological biomarker for breast DCE-MRI and evaluate its efficacy in predicting pathological complete response (pCR) to neoadjuvant chemotherapy (NAC). Our method bridges the two extremes, i.e, hand-crafted imaging features vs. completely data-driven convolutional neural networks (CNNs). The key idea is to direct the model's attention to a much smaller set of 'biologically relevant' voxels. This way, the CNNs can be efficiently trained with limited MRI data.*Methods and Materials We validate our method in a 5-fold cross-validation setting on the task of pCR prediction with ISPY-1 post-contrast DCE-MRI. A total of 162 patients are considered - 47 achieving pCR (mean age 48.8 years), 115 non-pCR (mean age 48.5 years). We compute salient topological structures from the input image based on the theory of persistent homology. Topological structures of dimensions 1 and 2, i.e., loops and bubbles, can both correspond to important tissue structures. 1D topological structures capture curvelinear constructs such as ducts and vessels. 2D structures represent voids enclosed by the tissue and their attached glands. These structures directly delineate the critical tissue structure with high biological relevance. By focusing on these tissue structures and their affinity, we have relevant contextual information for response prediction. We explicitly mask the input image so that only voxels of the extracted topological structures and their vicinity regions are visible. We then train a 3D CNN on this masked image. We compare our method against a Random Forests (RF) based textural radiomics model.*Results We observe that direct application of a 3D CNN does not perform well (area under the curve AUC=0.63), presumably due to the lack of phenotypically relevant data. Our proposed approach (AUC=0.85) also outperforms the radiomics model (AUC=0.56). Unlike the non-PCR breasts, the pCR breasts were found to have more scattered fibroglandular density with minimal background parenchymal enhancement.*Conclusions We developed and validated a topological prognostic biomarker based on the persistent homology to explicitly direct the attention of CNNs.*Clinical Relevance/Application The extracted topological structures capture the breast tissue structures. Learning directly on these structures and their vicinity provides the opportunity for interpreting the learning outcomes and drawing novel biological insights.

RESULTS

We observe that direct application of a 3D CNN does not perform well (area under the curve AUC=0.63), presumably due to the lack of phenotypically relevant data. Our proposed approach (AUC=0.85) also outperforms the radiomics model (AUC=0.56). Unlike the non-PCR breasts, the pCR breasts were found to have more scattered fibroglandular density with minimal background parenchymal enhancement.

CLINICAL RELEVANCE/APPLICATION

The extracted topological structures capture the breast tissue structures. Learning directly on these structures and their vicinity provides the opportunity for interpreting the learning outcomes and drawing novel biological insights.

SDP-BR-39 **Synchronous Contralateral Breast Cancer Detected By Contrast-enhanced Mammography**

PURPOSE

Contrast-enhanced mammography (CEM) utilizes a dual-energy technique after the administration of intravenous contrast iodine, and similar to magnetic resonance imaging (MRI) relies on tumor angiogenesis. Preoperative CEM is increasingly used in the replacement of MRI for staging women with breast cancer. This study aims to evaluate the yield of CEM in detecting incidental synchronous contralateral disease, in patients with newly diagnosed breast cancer, in comparison to what was previously reported with MRI.*Methods and Materials A retrospective study was approved by our institutional ethical board. The consecutive records of 2732 patients who underwent contrast-enhanced mammography (CEM) exam between 0ctober 2017 and December 2020 were reviewed. A total of 1110 patients who underwent CEM as part of their initial assessment of unilateral cancer were eligible for the study. The imaging reports, histopathology results, and follow-up records were reviewed. The diagnosis of CEM-detected cancer was confirmed by means of biopsy. The absence of breast cancer was determined by means of biopsy, or the absence of positive findings on repeat imaging at 1 year of follow-up, if available.*Results Out of 1110 patients, 116 (10.4%) patients required contralateral biopsy due to suspicious lesions detected by CEM; 59 (50.86%) of those were malignant. In 39 out of 1100 (3.5%) cases, the contralateral cancer was detected solely based on enhancement; of those 34 (87.2%) invasive (mean diameter of 11 mm) and 5 (12.8%) ductal carcinoma in situ (DCIS). A total of 757 patients completed at least a one-year follow-up after the CEM, 2 presented with contralateral invasive malignancy (average size 8mm), yielding sensitivity of 94.87%, specificity of 95.49%, positive predictive value (PPV) of 52.11% and negative predictive value (PNV) of 99.72%.*Conclusions CEM detected additional clinically and mammographically occult synchronous contralateral cancer in 3.5% of the patients, similar to what was previously reported with MRI.*Clinical Relevance/Application CEM detects contralateral lesions in a substantial proportion of women at high specificity.

RESULTS

Out of 1110 patients, 116 (10.4%) patients required contralateral biopsy due to suspicious lesions detected by CEM; 59 (50.86%) of those were malignant. In 39 out of 1100 (3.5%) cases, the contralateral cancer was detected solely based on enhancement; of those 34 (87.2%) invasive (mean diameter of 11 mm) and 5 (12.8%) ductal carcinoma in situ (DCIS). A total of 757 patients completed at least a one-year follow-up after the CEM, 2 presented with contralateral invasive malignancy (average size 8mm), yielding sensitivity of 94.87%, specificity of 95.49%, positive predictive value (PPV) of 52.11% and negative predictive value (PNV) of 99.72%.

CLINICAL RELEVANCE/APPLICATION

CEM detects contralateral lesions in a substantial proportion of women at high specificity.

SDP-BR-40 **Development And Validation Of A Deep Learning Method For Breast Cancer Diagnosis Using Ultrasound**

Participants
Huiling Xiang, Guangzhou, China (*Presenter*) Nothing to Disclose

PURPOSE

To develop/validate a deep learning (DL) model for breast cancer diagnosis*Methods and Materials From 2011 to 2020, B-mode and color Doppler images of pathology-proven lesions were included to develop and validate a DL model for breast cancer diagnosis in this retrospective, multicohort, diagnostic study. We assessed the diagnostic value of three DL models (DL-C, DL-B, DL-internal), which were developed using color Doppler images, B-mode images, and a combination of both, respectively. The performance of the DL model was compared with that of radiologists. Area under the curve (AUC), accuracy, sensitivity, specificity, positive predictive value, negative predictive value, precision, F1 score and kappa score were evaluated.*Results This DL model included 31,856 B-mode and color Doppler images of 6.492 lesions and was tested using 8,086 images of 1,604 lesions in the internal set. External validation included 2,651 images of 118 lesions, 2,453 images of 650 lesions in H2, and 1,035 images of 418 lesions in H3. Lesion-level performance was superior to image-level performance, with AUCs of 0.934 (95% confidence interval [CI]: 0.921 to 0.946) with the internal set, 0.913 (95% CI: 0.894 to 0.933) with H1, 0.922 (95% CI: 0.901 to 0.942) with H2, and 0.955 (95% CI: 0.936 to 0.975) with H3. The DL model was at least non-inferior to senior radiologists, but outperformed junior radiologists significantly. DL-internal demonstrated better diagnostic accuracy compared with DL-B and DL-C (AUC = 0.937 [95% CI: 0.925 to 0.949]) in the test set with combined images.*Conclusions Our DL model achieved expert-level diagnostic accuracy with B-mode and color Doppler images combined in an internal and three independent external validation sets. *Clinical Relevance/Application With satisfying performance, our DL model could potentially serve as an efficient, non-invasive, and cost-effective tool to assist radiologists in diagnosing breast tumor.

RESULTS

This DL model included 31,856 B-mode and color Doppler images of 6.492 lesions and was tested using 8,086 images of 1,604 lesions in the internal set. External validation included 2,651 images of 118 lesions, 2,453 images of 650 lesions in H2, and 1,035 images of 418 lesions in H3. Lesion-level performance was superior to image-level performance, with AUCs of 0.934 (95% confidence interval [CI]: 0.921 to 0.946) with the internal set, 0.913 (95% CI: 0.894 to 0.933) with H1, 0.922 (95% CI: 0.901 to 0.942) with H2, and 0.955 (95% CI: 0.936 to 0.975) with H3. The DL model was at least non-inferior to senior radiologists, but outperformed junior radiologists significantly. DL-internal demonstrated better diagnostic accuracy compared with DL-B and DL-C (AUC = 0.937 [95% CI: 0.925 to 0.949]) in the test set with combined images.

CLINICAL RELEVANCE/APPLICATION

With satisfying performance, our DL model could potentially serve as an efficient, non-invasive, and cost-effective tool to assist radiologists in diagnosing breast tumor.

SDP-BR-41 Explainable Deep Learning Algorithm Of Standard Mammography Phantom Images For Medical Image Quality Management

Participants
Hyug-Gi Kim, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

An image quality assessment of mammography phantom is essential to reduce patient radiation exposure and ensure proper and consistent patient image quality. The purpose of this study was to develop an explainable deep learning algorithm (explainable AI, XAI) to evaluate the quality of an ACR mammography phantom image.*Methods and Materials For the study, we use the standard mammography phantom image database in KIAMI (Korean Institute for Accreditation of Medical Imaging) of South Korea. A total of 3,000 mammography phantom images were divided into training (70%), validation (15%) and test (15%) sets to develop a deep learning algorithm. Phantom images were independently labeled as three steps- 1) classified as fiber, speck and mass, 2) scoring for each subject (0, 0.5, 1) and 3) pass or fail of the phantom images which is based on the ACR mammography QC manual. We implemented optimized U-net based convolutional neural network and learning algorithm was conducted by three pre-processing: First is inverted input image as 'black' background, second is target cropping (patched image) using object detection deep learning model and third is image resize to reduce cost function of computing (fig1 A-D). Each object was segmented and extracted using U-net model. We used curriculum learning method which means that knowledge transfer learning was performed on the computed radiography (CR) after learning digital radiography (DR). Area under the receiver operating characteristics curve (AUC), accuracy, sensitivity, and specificity of the algorithm and 5 radiologists were assessed.*Results The performance showed 0.88 AUC (p value<0.003), 87.45 accuracy, 100 sensitivity and 75 specificity and showed statistically significantly higher AUC, sensitivity than radiologists in test sets. The model with phantom evaluator can provide lesion location as well as more reasonable/explainable lesion detection (Fig 1 E-G).*Conclusions Deep learning algorithm for mammography phantom image can be used to improve the accuracy for quality control study for medical phantom image with superior AUC and comparable sensitivity and specificity to those of radiologists.*Clinical Relevance/Application Deep learning algorithm with phantom image evaluator can demonstrate to be used to assess quality control for mammography, CT and MRI as a practical method for early and precision diagnosis.

RESULTS

The performance showed 0.88 AUC (p value<0.003), 87.45 accuracy, 100 sensitivity and 75 specificity and showed statistically significantly higher AUC, sensitivity than radiologists in test sets. The model with phantom evaluator can provide lesion location as well as more reasonable/explainable lesion detection (Fig 1 E-G).

CLINICAL RELEVANCE/APPLICATION

Deep learning algorithm with phantom image evaluator can demonstrate to be used to assess quality control for mammography, CT and MRI as a practical method for early and precision diagnosis.

SDP-BR-42 Contrast Enhanced Mammography-A Functional Imaging Modality Decoding Obscured Shadows Of Digital Mammography In HER 2 Positive Breast Cancer.

Participants
Palak Popat, MBBS, MD, Mumbai, India (*Presenter*) Nothing to Disclose

PURPOSE

Contrast-enhanced mammography (CEM), a novel emerging technique, combining digital mammography (DM) with functional imaging is based on principle of neoangiogenesis. Aim-To assess incremental value of Dual-Energy Contrast-Enhanced Mammography over Digital Mammography in HER 2 positive breast cancer patients.*Methods and Materials Low energy, subtracted images of CEM are acquired between 2 to 8 minutes in the standard Craniocaudal and Mediolateral projections, post intravenous administration of iodinated contrast agent on a full field DM unit. A retrospective analysis was performed on HER 2 positive patients undergoing CEM

during the pandemic between November'20 and April'21 in a tertiary cancer referral center. Comparative analysis between DM and CEM to assess for concordance with histopathology, additional lesion, asymmetries, and post neoadjuvant chemotherapy viability.*Results 184 patients underwent CEM in our hospital, of which 46 were positive for HER-2/neu receptor status. Among these 46 patients, 63 lesions were detected, of which 56 lesions were malignant, while 7 were benign. The sensitivity and specificity of DM in detecting malignancy is 89.2% and 66.7 % respectively with a diagnostic accuracy of 87.1%. The sensitivity and specificity of CEM are 98.2 and 66.7 % respectively with a diagnostic accuracy of 95.2 %. CEM was discordant in 34 patients (74%) with superior benefit in 32 patients (69.5%), and not beneficial in 2 patients (4%). CEM was concordant with DM with no additional benefit in 12 (26%) patients. CEM was beneficial over DM in 32(69.5%) patients. The distribution of the benefit is in terms of extent of disease in 16(50%) patients, additional lesion detection in 15 (46%) patients, ruling out asymmetries as possible lesions in 6 (18%) patients, characterizing in 6(18%) patients. Out of 3 patients post neoadjuvant chemotherapy, CEM was 100% beneficial in evaluating viability status post neoadjuvant chemotherapy. CEM was not beneficial over DM in 2(4%) patients where the extent was more on DM than CEM due to microcalcifications.*Conclusions Our findings conclude that the CEM is certainly more superior to DM in evaluating the extent of disease, additional satellite lesion detection, post neoadjuvant chemotherapy viability assessment, and ruling out ambiguous findings(asymmetries) in HER 2 positive breast cancer.*Clinical Relevance/Application Judicious use of CEM in selected cases helps in better estimation of the extent of disease and satellite lesion detection, enhancing appropriate management of breast cancer. CEM disease extent with a concurrent assessment of the extent of microcalcifications on DM in HER 2 positive breast cancer enhances management with greater accuracy, compared to DM alone.

RESULTS

184 patients underwent CEM in our hospital, of which 46 were positive for HER-2/neu receptor status. Among these 46 patients, 63 lesions were detected, of which 56 lesions were malignant, while 7 were benign. The sensitivity and specificity of DM in detecting malignancy is 89.2% and 66.7 % respectively with a diagnostic accuracy of 87.1%. The sensitivity and specificity of CEM are 98.2 and 66.7 % respectively with a diagnostic accuracy of 95.2 %. CEM was discordant in 34 patients (74%) with superior benefit in 32 patients (69.5%), and not beneficial in 2 patients (4%). CEM was concordant with DM with no additional benefit in 12 (26%) patients. CEM was beneficial over DM in 32(69.5%) patients. The distribution of the benefit is in terms of extent of disease in 16(50%) patients, additional lesion detection in 15 (46%) patients, ruling out asymmetries as possible lesions in 6 (18%) patients, characterizing in 6(18%) patients. Out of 3 patients post neoadjuvant chemotherapy, CEM was 100% beneficial in evaluating viability status post neoadjuvant chemotherapy. CEM was not beneficial over DM in 2(4%) patients where the extent was more on DM than CEM due to microcalcifications.

CLINICAL RELEVANCE/APPLICATION

Judicious use of CEM in selected cases helps in better estimation of the extent of disease and satellite lesion detection, enhancing appropriate management of breast cancer. CEM disease extent with a concurrent assessment of the extent of microcalcifications on DM in HER 2 positive breast cancer enhances management with greater accuracy, compared to DM alone.

SDP-BR-43   Commercially Available AI System For Breast Cancer Detection Shows Promise For Risk Prediction, Including Among Women With Dense Breasts

Participants
Celine Vachon, Rochester, Minnesota (*Presenter*) Research funded, GRAIL

PURPOSE

AI algorithms have been developed to improve detection of breast cancer at the time of mammography. Whether these algorithms can assist in risk prediction has not been well-studied.*Methods and Materials We identified 3,387 women with invasive breast cancer (n=462 interval, 2309 screen-detected) and 7,140 controls, matched on age and date of mammogram, from two US mammography cohorts between 2007 and 2017. We obtained 2D full-field digital mammograms an average 3.6 years (6 months to 10 years) prior to cancer diagnosis and assessed a malignancy risk score using a commercially available AI system (Transpara v1.7.0, ScreenPoint Medical) and volumetric density using Volpara (version 1.5.4). We used conditional logistic regression (odds ratios (OR) and 95% confidence (CI) intervals), adjusted for age and BMI, and C-statistics (AUC), to describe the association of the continuous AI risk score (per 1 unit increase) with invasive breast cancer. We performed analyses stratified by dense breasts (BI-RADS density a-b vs. c-d), time to cancer (=3.6 years vs. >3.6 years), and interval vs. screen-detected breast cancer.*Results Adjusted for age and BMI, a one unit increase in AI risk score was associated with 23% greater odds of invasive breast cancer [OR=1.23 (1.21-1.25); AUC=0.65 (0.64-0.67)]. Associations were similar among women with dense [OR=1.24 (1.20-1.27)] and non-dense breasts [OR=1.20 (1.18-1.23)](p=0.30) [AUCs 0.65-0.66] and for interval and screen detected cancers [ORs both 1.24, (p=0.98) and AUCs both 0.66]. There were stronger associations for AI risk score assessed on mammograms within 3.6 years prior to breast cancer diagnosis [OR=1.30 (1.26-1.33)][AUC=0.68 (0.67-0.70)] vs. greater than 3.6 years [OR=1.18 (1.15-1.20)(P<0.001)][AUC=0.63 (0.61-0.64)]. Inclusion of volumetric density measures in models with the AI risk score improved discrimination, but the increase was only statistically significant for prediction of interval cancers; the AUC increased from 0.66 to 0.72 (change in AUC=0.06 (0.03-0.09)) with inclusion of percent volumetric density.*Conclusions AI imaging-based measures combined with volumetric density improved discrimination of invasive breast cancer. Including these measures in risk models could better inform tailored screening and supplemental imaging strategies.*Clinical Relevance/Application AI algorithms developed for detection can inform risk prediction, including among women with dense breasts and women at risk of interval cancers.

RESULTS

Adjusted for age and BMI, a one unit increase in AI risk score was associated with 23% greater odds of invasive breast cancer [OR=1.23 (1.21-1.25); AUC=0.65 (0.64-0.67)]. Associations were similar among women with dense [OR=1.24 (1.20-1.27)] and non-dense breasts [OR=1.20 (1.18-1.23)](p=0.30) [AUCs 0.65-0.66] and for interval and screen detected cancers [ORs both 1.24, (p=0.98) and AUCs both 0.66]. There were stronger associations for AI risk score assessed on mammograms within 3.6 years prior to breast cancer diagnosis [OR=1.30 (1.26-1.33)][AUC=0.68 (0.67-0.70)] vs. greater than 3.6 years [OR=1.18 (1.15-1.20) (P<0.001)][AUC=0.63 (0.61-0.64)]. Inclusion of volumetric density measures in models with the AI risk score improved discrimination, but the increase was only statistically significant for prediction of interval cancers; the AUC increased from 0.66 to 0.72 (change in AUC=0.06 (0.03-0.09)) with inclusion of percent volumetric density.

CLINICAL RELEVANCE/APPLICATION

AI algorithms developed for detection can inform risk prediction, including among women with dense breasts and women at risk of interval cancers.

SDP-BR-44   Ductal Carcinoma In Situ Presenting As Screen-detected Calcifications: Patient, Imaging, And Pathological Features Associated With Surgical Upstaging

Participants
Manisha Bahl, MD,MPH, Boston, Massachusetts (*Presenter*) Consultant, Lunit Inc;Advisory Board, Accolade Inc

PURPOSE

Several clinical trials are underway across the world to evaluate the safety and efficacy of active surveillance (AS) for women with ductal carcinoma in situ (DCIS) presenting as screen-detected calcifications. The variable with the greatest risk of mortality for AS versus standard treatment is understaging invasive disease at time of diagnosis. The purpose of this study is to identify patient, imaging, and pathological features associated with surgical upstaging of DCIS to any invasive disease or non-microinvasive disease, in order to inform eligibility criteria for AS trials.*Methods and Materials In this HIPAA-compliant and IRB-approved retrospective study, medical records were reviewed of consecutive women presenting from 2007-2016 with screen-detected calcifications who were diagnosed with pure DCIS at image-guided core needle biopsy and then underwent surgery. Two multiply imputed multivariable logistic regression models were fit to assess features associated with risk of upstaging to (1) any invasive disease (microinvasive disease [less than or equal to 1 mm of invasive disease] or non-microinvasive disease) or (2) non-microinvasive disease only. Prespecified features with p<0.2 in univariable analyses were included in the multivariable models. For each model, adjusted odds ratios, 95% confidence intervals (CI), and corresponding Wald p-values were calculated. Optimism-corrected area under the receiver operating characteristic curves (AUC) were also estimated.*Results 1,029 women (average age 58, range 28-89 years) with DCIS presenting as screen-detected calcifications underwent surgery. The surgical upstaging rate of DCIS to invasive disease was 16% (n=161). Of 161 upgrades, 35% (n=57) were upstaged to microinvasive disease and 65% (n=104) to non-microinvasive disease. The features associated with upstaging to any invasive disease (microinvasive or non-microinvasive) were menopause above the age of 50, breast MR imaging, and intermediate or high nuclear grade of DCIS at biopsy (all p<0.05). The only feature associated with upstaging to non-microinvasive disease was breast MR imaging (p=0.004). The optimism-corrected AUCs for both models were 0.63 (95% CI of 0.56-0.67 and 95% CI of 0.56-0.69, respectively).*Conclusions In women with DCIS presenting as screen-detected calcifications, features associated with higher surgical upstaging risk to invasive disease include menopause above the age of 50, breast MR imaging, and intermediate or high nuclear grade of DCIS at biopsy.*Clinical Relevance/Application Identification of patient, imaging, and pathological features associated with higher surgical upstaging risk of DCIS could be used to exclude certain women with high-risk DCIS from AS trials.

RESULTS

1,029 women (average age 58, range 28-89 years) with DCIS presenting as screen-detected calcifications underwent surgery. The surgical upstaging rate of DCIS to invasive disease was 16% (n=161). Of 161 upgrades, 35% (n=57) were upstaged to microinvasive disease and 65% (n=104) to non-microinvasive disease. The features associated with upstaging to any invasive disease (microinvasive or non-microinvasive) were menopause above the age of 50, breast MR imaging, and intermediate or high nuclear grade of DCIS at biopsy (all p<0.05). The only feature associated with upstaging to non-microinvasive disease was breast MR imaging (p=0.004). The optimism-corrected AUCs for both models were 0.63 (95% CI of 0.56-0.67 and 95% CI of 0.56-0.69, respectively).

CLINICAL RELEVANCE/APPLICATION

Identification of patient, imaging, and pathological features associated with higher surgical upstaging risk of DCIS could be used to exclude certain women with high-risk DCIS from AS trials.

SDP-BR-45   Contrast Enhanced Spectral Mammography Guided Biopsy: Single Institute Initial Clinical Experience

Participants
Maya Grisaru, MD, London, Ontario (*Presenter*) Nothing to Disclose

PURPOSE

Contrast Enhanced Spectral Mammography (CESM) relies on dual-energy exposure after contrast Iodine is injected intravenously. Suspicious enhancing lesions detected by CESM, and not seen on ultrasound or mammography, are typically biopsied under breast Magnetic Resonance Imaging (MRI) guidance. A new biopsy technique which was recently developed enables dual-energy exposure to be combined with stereotactic guided biopsy (namely, CESM-guided biopsy) with either a vertical or horizontal approach. The purpose of this abstract is to describe our initial clinical experience with 34 patients. This prospective study was approved by Health Canada and the Western University Research Ethics Board and is funded by GE Healthcare.*Methods and Materials A total of 905 CESM exams June 2020- April 2021 were performed on 874 women. Thirty-four/874 women with 35 lesions were enrolled in this trial. Three lesions were initially detected by MRI and then by CESM.*Results Patients ages ranged between 38-82. Average breast density was heterogeneous (BI-RADS category C). Lesion size ranged 3-24 mm (mean 14 mm; 7 foci, 4 masses, 24 non-mass enhancement). CESM-guided biopsy was completed in 30/35 lesions (86%, 6 malignant, 7 high risk, 17 benign), 22 (63%) were subjectively less enhancing compared to the reference CESM exam. Horizontal approach was used in 19/30 lesions. Five lesions (14%) did not enhance (4 benign lesions were subsequently biopsied/excised, 1 lost for follow-up). In 17 patients standard ipsilateral CESM exam was used instead of standard mammography to confirm the placement of tissue markers, at 21-46 minutes after the injection; in 14 lesions (82%) enhancement was still noted.*Conclusions Satisfactory initial experience using CESM-guided biopsy. Lesions that did not enhance were usually benign. Cancellation rate is similar to what is reported with the use of MRI-guided biopsy.*Clinical Relevance/Application Initial experience with the use of a CESM-guided biopsy for enhancing lesions detected by CESM exam appears promising, showing similar results to what has previously been reported with breast MRI-guided biopsy.

RESULTS

Patients ages ranged between 38-82. Average breast density was heterogeneous (BI-RADS category C). Lesion size ranged 3-24 mm (mean 14 mm; 7 foci, 4 masses, 24 non-mass enhancement). CESM-guided biopsy was completed in 30/35 lesions (86%, 6 malignant, 7 high risk, 17 benign), 22 (63%) were subjectively less enhancing compared to the reference CESM exam. Horizontal approach was used in 19/30 lesions. Five lesions (14%) did not enhance (4 benign lesions were subsequently biopsied/excised, 1 lost for follow-up). In 17 patients standard ipsilateral CESM exam was used instead of standard mammography to confirm the placement of tissue markers, at 21-46 minutes after the injection; in 14 lesions (82%) enhancement was still noted.

CLINICAL RELEVANCE/APPLICATION

Initial experience with the use of a CESM-guided biopsy for enhancing lesions detected by CESM exam appears promising, showing similar results to what has previously been reported with breast MRI-guided biopsy.

SDP-BR-46   Performance Of Automated Breast Ultrasound Versus Handheld Breast Ultrasound In The Diagnostic Breast Imaging Clinic

Participants

Shinnhuey Chou, MD, Boston, Massachusetts (*Presenter*) Institutional research support, General Electric Company

PURPOSE

To compare performance between automated breast ultrasound (ABUS) and handheld breast ultrasound (HHUS) in the diagnostic breast imaging clinic.*Methods and Materials This IRB-approved HIPAA-compliant study included consecutive ABUS and HHUS diagnostic exams performed in patients referred to our diagnostic clinic from August 2020 to January 2021. Diagnostic ultrasound was performed on an ABUS unit (Invenia, GE Healthcare) by a trained sonographer or mammography technologist or on an HHUS unit (Logiq E9, GE Healthcare) by a sonographer or radiologist. All exams were interpreted by 1 of 7 fellowship-trained radiologists. Final Breast Imaging Reporting and Data System (BIRADS) assessments 0, 3, 4 and 5 were considered positive to calculate the abnormal interpretation rate (AIR), positive predictive values (PPV1), PPV2, PPV3, and cancer detection rate (CDR). Multivariable logistic regression models were fit to assess the association of performance metrics with ABUS and HHUS, adjusting for patient age, breast density, and exam indication. *Results A total of 900 exams in 894 women (61.6% symptomatic, e.g. lump, pain, nipple discharge; 38.4% asymptomatic, e.g. recall from screening, short-term follow-up) included 227 ABUS exams in 227 women (mean age 46.1±15.2 years) and 673 HHUS exams in 667 women (mean age 48.6±15.7 years, p=0.05). There was no evidence of differences in exam indication, breast density, and BIRADS assessments between ABUS and HHUS (all p>0.05). There was no evidence that performance metrics were different between ABUS and HHUS: AIR (31.3% [71/227] vs. 33.1% [223/673], p=0.61), PPV1 (18.3% [13/71] vs. 16.6 [37/223], p=0.74), PPV2 (50.0% [13/26] vs. 43.0% [37/86], p=0.53), PPV3 (50.0% [13/26] vs. 43.5% [37/85], p=0.56), and CDR (5.7% [13/227] vs. 5.5% [37/673], p=0.90). These results persisted after estimation of multivariable models (p>0.05).*Conclusions Our study demonstrates comparable performance of ABUS to HHUS in the diagnostic clinic. Integrating ABUS as a diagnostic modality provides a platform to increase access and availability of diagnostic breast ultrasound, particularly in settings without the presence of expert physician or sonographer.*Clinical Relevance/Application Many studies have demonstrated performance of ABUS in the screening setting. Our study provides robust evidence and support of comparable performance of ABUS to HHUS in the diagnostic setting.

RESULTS

A total of 900 exams in 894 women (61.6% symptomatic, e.g. lump, pain, nipple discharge; 38.4% asymptomatic, e.g. recall from screening, short-term follow-up) included 227 ABUS exams in 227 women (mean age 46.1±15.2 years) and 673 HHUS exams in 667 women (mean age 48.6±15.7 years, p=0.05). There was no evidence of differences in exam indication, breast density, and BIRADS assessments between ABUS and HHUS (all p>0.05). There was no evidence that performance metrics were different between ABUS and HHUS: AIR (31.3% [71/227] vs. 33.1% [223/673], p=0.61), PPV1 (18.3% [13/71] vs. 16.6 [37/223], p=0.74), PPV2 (50.0% [13/26] vs. 43.0% [37/86], p=0.53), PPV3 (50.0% [13/26] vs. 43.5% [37/85], p=0.56), and CDR (5.7% [13/227] vs. 5.5% [37/673], p=0.90). These results persisted after estimation of multivariable models (p>0.05).

CLINICAL RELEVANCE/APPLICATION

Many studies have demonstrated performance of ABUS in the screening setting. Our study provides robust evidence and support of comparable performance of ABUS to HHUS in the diagnostic setting.

SDP-BR-47 **Associations Between Immunohistochemistry And 18F-fmiso-pet/mri Parameters Of Hypoxia And Vascular Function In Er-positive Breast Cancer**

Participants

Julia Carmona-Bozo, MD, Cambridge, United Kingdom (*Presenter*) Nothing to Disclose

PURPOSE

To examine relationships between tumor hypoxia and perfusion metrics from 18F-fluoromisonidazole (18F-FMISO) PET/MRI and endogenous immunohistochemical (IHC) markers in estrogen receptor (ER)-positive breast cancer*Methods and Materials Women aged >18 years with treatment-naïve, ER-positive breast cancer underwent a 60-min PET/MR scan of the breasts 2 hours post-injection of 300 MBq 18F-FMISO. Tumor vascular parameters were derived from DCE-MRI using the extended Tofts' model, while hypoxia was assessed using the 18F-FMISO influx rate constant Ki determined by Patlak-plot analysis. The apparent diffusion coefficient in the darkest part of the tumor (dp-ADC) was obtained from DWI-MRI. Following surgical excision, tumor sections were stained with CD31, hypoxia-inducible factor (HIF)-1a and carbonic anhydrase IX (CAIX). The number of tumor micro-vessels, micro-vessel diameter, and micro-vessel density (MVD) were obtained from CD31 microarrays via computer-assisted analysis. HIF-1a and CAIX expression were scored according to the percentage of positive cells stained. The percentage of stromal tumor-infiltrating lymphocytes (sTIL) was derived from available hematoxylin and eosin (H&E) slides. Regression analysis was used to study associations between imaging and IHC variables.*Results Of the 23 lesions examined, 14/23 (61%) were ductal tumors, grade 2 or 3 (20/23; 88%), while 18/23 (78%) were HER2-negative. 18F-FMISO Ki was negatively associated with micro-vessel diameter (R^2=0.23, p<0.03), MVD (R^2=0.26, p<0.02) and CAIX expression (R^2=0.52, p=0.03). A positive association was observed between dp-ADC and CAIX expression (R^2=0.44, p=0.03), while no significant relationships were found between DCE-MRI metrics and IHC parameters (all p>0.05). HIF-1a and sTIL expression did not significantly associate with PET/MR metrics (all p>0.05)*Conclusions Tumor hypoxia measured by 18F-FMISO PET is significantly associated with increased CAIX expression, low MVD, and smaller vessel diameters in ER-positive breast cancer*Clinical Relevance/Application CAIX expression seems to be a reliable marker of hypoxia in ER-positive breast cancer whereas HIF-1a seems to be an unreliable hypoxia marker because it has other modulators apart from hypoxia

RESULTS

Of the 23 lesions examined, 14/23 (61%) were ductal tumors, grade 2 or 3 (20/23; 88%), while 18/23 (78%) were HER2-negative. 18F-FMISO Ki was negatively associated with micro-vessel diameter (R^2=0.23, p<0.03), MVD (R^2=0.26, p<0.02) and CAIX expression (R^2=0.52, p=0.03). A positive association was observed between dp-ADC and CAIX expression (R^2=0.44, p=0.03), while no significant relationships were found between DCE-MRI metrics and IHC parameters (all p>0.05). HIF-1a and sTIL expression did not significantly associate with PET/MR metrics (all p>0.05)

CLINICAL RELEVANCE/APPLICATION

CAIX expression seems to be a reliable marker of hypoxia in ER-positive breast cancer whereas HIF-1a seems to be an unreliable hypoxia marker because it has other modulators apart from hypoxia

SDP-BR-48   A Preoperative Model To Predict The Probability Of Low- Nuclear-grade Ductal Carcinoma In Situ

Participants
Hee Jung Moon, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To develop a preoperative model to predict low-nuclear-grade ductal carcinoma in situ (DCIS) and evaluate upshift rate of low-nuclear-grade DCIS on biopsy to intermediate-to-high grade on surgery.*Methods and Materials Between January 2010 and December 2015, a total of 477 primary pure DCIS lesions on surgical pathology in 470 patients were included. We divided total patients into training (n=330) and validation set (n=147) to develop preoperative model to predict low-grade DCIS using multivariate regression. The 477 DCIS lesions were classified into one of two groups based on the final nuclear grade; the lesions with low grade both on biopsy- and surgical-pathology reports were 'Low-grade' group, and 'Intermediate-to-high grade' group included the lesions with intermediate- or high-grade DCIS on either biopsy- or surgical-pathology reports. 'Upshift' was defined when the low grade DCIS on biopsy was changed to intermediate-to-high grade on surgery. We evaluated which clinical, radiological, pathological factors associated with upshift of low-grade DCIS using multivariate regression.*Results A preoperative model consisting of lesions presenting as mass only on ultrasound and no comedonecrosis on biopsy predicted low-grade DCIS with high AUC (Area Under the Receiver Operating Characteristics curve) as 0.970 in validation set. Upshift rate of low-grade DCIS on biopsy was 38.8% (50 of 129). Lesions presenting both on ultrasound and mammography and Ki-67 positivity were substantially associated with upshift of low-grade DCIS, (P=0.056 and 0.065).*Conclusions The upshift rate of low grade DCIS on biopsy to intermediate-to-high grade on surgery was 38.8%, which was non-negligibly high. However, DCIS presenting as a mass only on ultrasound and no comedonecrosis on biopsy pathology can predict low-grade DCIS on final pathology.*Clinical Relevance/Application DCIS presenting as a mass only on ultrasound and no comedonecrosis on biopsy pathology can preoperatively predict low-grade DCIS on final pathology.

RESULTS

A preoperative model consisting of lesions presenting as mass only on ultrasound and no comedonecrosis on biopsy predicted low-grade DCIS with high AUC (Area Under the Receiver Operating Characteristics curve) as 0.970 in validation set. Upshift rate of low-grade DCIS on biopsy was 38.8% (50 of 129). Lesions presenting both on ultrasound and mammography and Ki-67 positivity were substantially associated with upshift of low-grade DCIS, (P=0.056 and 0.065).

CLINICAL RELEVANCE/APPLICATION

DCIS presenting as a mass only on ultrasound and no comedonecrosis on biopsy pathology can preoperatively predict low-grade DCIS on final pathology.

SDP-BR-49   Biopsy-proven Stromal Fibrosis: What Is The Appropriated Management Approach?

Participants
Prasaanthan Gopee-Ramanan, MD, Brampton, Ontario (*Presenter*) Nothing to Disclose

PURPOSE

To determine the upgrade rate to malignancy of biopsy-proven stromal fibrosis and assess features associated with the upgrade on surgical excision.*Methods and Materials REB-approved retrospective imaging studies and patient's chart review of imaging-guided biopsy-proven stromal fibrosis carried out between April 2014 and December 2019. The upgrade rate of malignancy and the imaging features of the upgraded cases on surgical excision were recorded. The results were correlated with surgical histopathology as the ground truth or an uneventful clinical and radiological follow-up of at least 6 months. Predictors for malignancy were examined and appropriate statistical tests were applied.*Results Out of 9814 consecutive imaging-guided breast biopsies performed on women between April 2014 and December 2019, 470 patients (4.8%; median age 52 years) had biopsy-proven stromal fibrosis without atypia and fulfilled the inclusion criteria, representing the study cohort. Out of the 470 patients, 28 patients (5.9%) underwent excisional surgery due to the discordance between the imaging appearance and the pathology outcome or at the discretion of the patient/attending surgeon and 442 cases (94.1%) underwent clinical and imaging follow up of at least 6 months. Out of 470 cases with an initial diagnosis of stromal fibrosis, 6 cases (1.3%) were upgraded to malignancy consisting of 4/6 cases of invasive malignancy with in-situ component (67%) and 2/6 cases of invasive malignancy without in-situ disease (33%). The imaging features associated with upgrade to malignancy were suspicious mass or non-mass enhancement on MRI, coarse heterogeneous calcifications on mammography, and irregular mass on ultrasound.*Conclusions The lower rate of upgrade to malignancy when stromal fibrosis is diagnosed supports short-term imaging follow-up in this setting as a safe management recommendation, especially in the absence of certain atypical imaging features.*Clinical Relevance/Application The study results can impact the management of biopsy-proven stromal fibrosis, suggesting when additional excisional surgery is needed or when imaging follow-up is sufficient.

RESULTS

Out of 9814 consecutive imaging-guided breast biopsies performed on women between April 2014 and December 2019, 470 patients (4.8%; median age 52 years) had biopsy-proven stromal fibrosis without atypia and fulfilled the inclusion criteria, representing the study cohort. Out of the 470 patients, 28 patients (5.9%) underwent excisional surgery due to the discordance between the imaging appearance and the pathology outcome or at the discretion of the patient/attending surgeon and 442 cases (94.1%) underwent clinical and imaging follow up of at least 6 months. Out of 470 cases with an initial diagnosis of stromal fibrosis, 6 cases (1.3%) were upgraded to malignancy consisting of 4/6 cases of invasive malignancy with in-situ component (67%) and 2/6 cases of invasive malignancy without in-situ disease (33%). The imaging features associated with upgrade to malignancy were suspicious mass or non-mass enhancement on MRI, coarse heterogeneous calcifications on mammography, and irregular mass on ultrasound.

CLINICAL RELEVANCE/APPLICATION

The study results can impact the management of biopsy-proven stromal fibrosis, suggesting when additional excisional surgery is needed or when imaging follow-up is sufficient.

SDP-BR-5   A Simplified Scoring System For Preoperative Prediction Of Axillary Response To Neoadjuvant Chemotherapy In Node-positive Breast Cancer

Participants
Xiaomei Huang, Guangzhou, China (*Presenter*) Nothing to Disclose

PURPOSE

To develop a simplified scoring system based on MRI features and clinicopathologic variables to preoperatively predict axillary pathologic complete response (pCR) to neoadjuvant chemotherapy (NAC) in clinically node-positive breast cancer.*Methods and Materials In this retrospective study, 259 patients with clinically node-positive breast cancer who received NAC followed by surgery from June 2012 to February 2020 were included. The patients were split into a development cohort (n=183) and an independent validation cohort (n=76) according to sequencing the date of surgery. Pre- and post-NAC MRI features were analyzed. Univariate and multivariable logistic regression analysis were applied to identify independent predictors of axillary pCR in the development cohort. A simplified scoring system was constructed based on the regression coefficients of predictors in the multivariable logistic model. The predictive performance of the scoring system was assessed with the receiver operating characteristic (ROC) curve and calibration curve.*Results The axillary pCR rate was 51.9% (95 of 183) and 57.9% (44 of 76) in the development and validation cohort, respectively. The independent predictors of axillary pCR were progesterone receptor negativity, human epidermal growth factor receptor 2 positivity, higher values of apparent diffusion coefficient before NAC, clinical T0/T1 stage after NAC, absence of perinodal infiltration in pre- and post-NAC MRI, and absence of enhancement in the tumor bed in post-NAC MRI. The simplified scoring system incorporating these predictors achieved an AUC of 0.835 (95% confidence interval [CI]: 0.777-0.894) and 0.828 (95% CI: 0.736-0.920) in the development and validation cohort, respectively. The calibration curve also showed good calibration in both cohorts. The simplified score ranged from 0 to 13. When the patients had a simplified score of more than 10, the pCR rates was higher than 91% (21 of 23) in validation cohort.*Conclusions A simplified scoring system incorporating MRI features and clinicopathologic variables shows good predictive performance for axillary pCR, which has the potential to guide axillary management after NAC in patients with initially node-positive breast cancer.*Clinical Relevance/Application A simplified scoring system for prediction of axillary response to NAC may guide axillary management after NAC and reduce surgical complications in patients with initially node-positive breast cancer.

RESULTS

The axillary pCR rate was 51.9% (95 of 183) and 57.9% (44 of 76) in the development and validation cohort, respectively. The independent predictors of axillary pCR were progesterone receptor negativity, human epidermal growth factor receptor 2 positivity, higher values of apparent diffusion coefficient before NAC, clinical T0/T1 stage after NAC, absence of perinodal infiltration in pre- and post-NAC MRI, and absence of enhancement in the tumor bed in post-NAC MRI. The simplified scoring system incorporating these predictors achieved an AUC of 0.835 (95% confidence interval [CI]: 0.777-0.894) and 0.828 (95% CI: 0.736-0.920) in the development and validation cohort, respectively. The calibration curve also showed good calibration in both cohorts. The simplified score ranged from 0 to 13. When the patients had a simplified score of more than 10, the pCR rates was higher than 91% (21 of 23) in validation cohort.

CLINICAL RELEVANCE/APPLICATION

A simplified scoring system for prediction of axillary response to NAC may guide axillary management after NAC and reduce surgical complications in patients with initially node-positive breast cancer.

SDP-BR-50   Architectural Distortion On Digital Breast Tomosynthesis: Pathological Upgrade Rates Of Radial Scars And Other Benign Pathologies

Participants
Manisha Bahl, MD,MPH, Boston, Massachusetts (*Presenter*) Consultant, Lunit Inc;Advisory Board, Accolade Inc

PURPOSE

The integration of digital breast tomosynthesis (DBT) into clinical practice has led to increased detection and subsequent biopsy of architectural distortion, which may yield malignancy, radial scar, or other benign pathologies. However, the management of radial scars and other benign pathologies in this setting remains controversial. The purpose of this study is to determine pathological upgrade rates of radial scars and other benign pathologies diagnosed by image-guided core needle biopsy to malignancy at surgery, in order to guide management recommendations.*Methods and Materials In this HIPAA-compliant and IRB-approved retrospective study, consecutive cases of suspicious architectural distortion on mammography (coded as BI-RADS 4 or 5) from July 2017 to June 2019 were reviewed. Included cases underwent image-guided core needle biopsy and surgical excision or underwent core needle biopsy and had at least two-year imaging follow-up. Medical records were reviewed for core biopsy results, surgical outcomes, and imaging follow-up.*Results Suspicious architectural distortion was identified in 313 mammographic exams in 305 women (mean age 58 years, range 23-90 years). Of the 313 cases, 260 (83%) underwent both image-guided core needle biopsy and surgery (n=228) or underwent image-guided core needle biopsy only and had at least two-year imaging follow-up (n=32). These 260 mammographic exams in 255 women (mean age 58 years, range 23-90 years) comprise the study cohort. Of the 260 cases, 81% (n=210) were detected at screening mammography, and 56% (n=145) were biopsied under mammographic guidance. At biopsy, 57% (148/260) were malignant, 25% (65/260) were radial scars, and 18% (47/260) were other benign or high-risk pathologies. Of the 48 radial scars without associated atypia, only one case (2%) upgraded to malignancy at surgery (grade 2 ductal carcinoma in situ). Of the 34 benign cases without associated atypia (e.g., stromal fibrosis), only one case (3%), which was considered discordant, upgraded to malignancy at surgery (benign predominantly fatty breast tissue at biopsy and grade 1 invasive ductal carcinoma at surgery).*Conclusions In the DBT era, 25% of architectural distortion cases yield radial scar at biopsy and nearly 20% are other benign or high-risk pathologies. Of radial scars without atypia, only one case (2%) upgraded to ductal carcinoma in situ at surgery, and none upgraded to invasive malignancy at surgery. Of benign cases without atypia, only one discordant case (3%) upgraded to malignancy at surgery.*Clinical Relevance/Application Imaging follow-up rather than surgery can be considered for architectural distortion yielding (1) radial scar without atypia at biopsy and (2) other benign pathologies without atypia at biopsy.

RESULTS

Suspicious architectural distortion was identified in 313 mammographic exams in 305 women (mean age 58 years, range 23-90 years). Of the 313 cases, 260 (83%) underwent both image-guided core needle biopsy and surgery (n=228) or underwent image-guided core needle biopsy only and had at least two-year imaging follow-up (n=32). These 260 mammographic exams in 255 women (mean age 58 years, range 23-90 years) comprise the study cohort. Of the 260 cases, 81% (n=210) were detected at screening mammography, and 56% (n=145) were biopsied under mammographic guidance. At biopsy, 57% (148/260) were malignant, 25% (65/260) were radial scars, and 18% (47/260) were other benign or high-risk pathologies. Of the 48 radial scars without associated atypia, only one case (2%) upgraded to malignancy at surgery (grade 2 ductal carcinoma in situ). Of the 34 benign cases without associated atypia (e.g., stromal fibrosis), only one case (3%), which was considered discordant, upgraded to malignancy at surgery (benign predominantly fatty breast tissue at biopsy and grade 1 invasive ductal carcinoma at surgery).

CLINICAL RELEVANCE/APPLICATION

Imaging follow-up rather than surgery can be considered for architectural distortion yielding (1) radial scar without atypia at biopsy

Imaging follow-up rather than surgery can be considered for architectural distortion yielding (1) radial scar without atypia at biopsy and (2) other benign pathologies without atypia at biopsy.

SDP-BR-51 Performance Of Full Field Synthetic Mammography In The Detection Of Microcalcifications And How To Dismiss Pseudocalcifications.

Participants
Jose M. Net, MD, Miami Beach, Florida (*Presenter*) Nothing to Disclose

PURPOSE

To compare visibility of calcifications on FFDM, FFSM and DBT and how to dismiss those suspected to represent pseudocalcifications.*Methods and Materials This retrospective study included patients where magnification views were performed 10/1/2013-9/30/2016. Patients with Full Field Digital Mammogram (FFDM), Full Field Synthetic Mammogram (FFSM), Digital Breast Tomosynthesis (DBT) and magnification views were included. Images were reviewed by 2 board certified fellowship trained breast imagers with 5 and 10 years of experience who were blinded to results of the work up. Cases were scored for visualization of calcifications on FFDM, FFSM, DBT and magnification views. Biopsy results were recorded as benign, atypical or malignant. Years of follow up and cancer diagnoses were recorded.*Results 528 patients had magnifications views performed and all requisite imaging. Patient's age ranged 32-86 years, average 55.6 and median 55. Calcifications were visualized on FFDM, FFSM, DBT and magnification views in 470 patients. Of these, 229 were referred for biopsy of which 43 yielded DCIS, 11 IDC and 5 LIN but benign at excision, 1 ADH also benign at excision, 6 were lost to follow up and 164 were benign. Calcifications were visible only on FFSM, DBT and magnification views in 36 patients, of which 28 only had FFSM and DBT performed as our center moved to only acquiring FFSM/DBT in August 2015. Of these, 14 were referred for biopsy of which 1 yielded IDC, 4 DCIS, 1 ADH but benign at excision and 8 were benign. 14 patients had calcifications visible only on FFDM and magnification views. Of these, 6 were biopsied and all were benign. 8 were seen only on FFSM and no other technique; no cancers were detected in follow up. Patients were followed for an average of 2.28 years, median 3 years of follow up, range 0-5 years. After initial work up,19 patients were subsequently diagnosed with breast cancer of which 15 were in the contralateral breast, 4 were ipsilateral to calcifications in question, but in different quadrants.*Conclusions FFDM and FFSM demonstrated equivalent performance in demonstrating calcifications; all malignant lesions were seen on both techniques. None of the suspected calcifications seen only on FFSM were visible on magnification views and none of these patients developed breast cancer at follows up, thus representing pseudocalcifications. FFDM resulted in 6 benign biopsies which could have been avoided if FFDM was eliminated.*Clinical Relevance/Application FFSM identified all malignant calcifications; our results suggest those calcifications seen only on FFSM can safely be described as pseudocalcifications. Calcifications seen only on FFDM resulted in additional work up and biopsy which could have been avoided if only FFSM and DBT were performed.

RESULTS

528 patients had magnifications views performed and all requisite imaging. Patient's age ranged 32-86 years, average 55.6 and median 55. Calcifications were visualized on FFDM, FFSM, DBT and magnification views in 470 patients. Of these, 229 were referred for biopsy of which 43 yielded DCIS, 11 IDC and 5 LIN but benign at excision, 1 ADH also benign at excision, 6 were lost to follow up and 164 were benign. Calcifications were visible only on FFSM, DBT and magnification views in 36 patients, of which 28 only had FFSM and DBT performed as our center moved to only acquiring FFSM/DBT in August 2015. Of these, 14 were referred for biopsy of which 1 yielded IDC, 4 DCIS, 1 ADH but benign at excision and 8 were benign. 14 patients had calcifications visible only on FFDM and magnification views. Of these, 6 were biopsied and all were benign. 8 were seen only on FFSM and no other technique; no cancers were detected in follow up. Patients were followed for an average of 2.28 years, median 3 years of follow up, range 0-5 years. After initial work up,19 patients were subsequently diagnosed with breast cancer of which 15 were in the contralateral breast, 4 were ipsilateral to calcifications in question, but in different quadrants.

CLINICAL RELEVANCE/APPLICATION

FFSM identified all malignant calcifications; our results suggest those calcifications seen only on FFSM can safely be described as pseudocalcifications. Calcifications seen only on FFDM resulted in additional work up and biopsy which could have been avoided if only FFSM and DBT were performed.

SDP-BR-52 Prediction Models Of The Axillary Lymph Node Burden Combining Cone-beam Computerized Tomography And Ultrasound In T1-2 Breast Cancer Patients

Participants
Shen Chen, Guangzhou, China (*Presenter*) Nothing to Disclose

PURPOSE

To derive and validate predictive models for preoperatively evaluating lymph node burden to assist T1-2 breast cancer's surgical decision-making.*Methods and Materials Data on 1394 consecutive patients Academic Cancer Center for cone-beam computerized tomography (CBCT) examination was retrospectively collected. A total of 387 patients were included and randomly divided into training and validation cohorts. Clinical-pathological information of all patients was recorded and images were reinterpreted in this study. A bidirectional stepwise method followed by multivariable analysis incorporated preoperative features and built optimal model sets with the training cohort for prediction of model one (N0 versus N+) and model two (N<3 versus N=3). Receiver operating characteristic curves (ROC) of two models were generated with the training and validation cohorts and their calibration abilities were estimated with bootstrap resamples. Calibration analysis, the concordance index (C-index), decision curves and the clinical impact curves were plotted to verify the accuracy for further clinical application.*Results The areas under the ROC curves were 0.884 and 0.891 in the training cohort, 0.878 and 0.880 in the validation cohort for models one and two respectively. Calibration curves, decision curves and the clinical impact curves demonstrated that prediction of lymph node burden in both models show preferable discrimination performance. Delong's test demonstrated comparable performance in both training and validation cohorts.*Conclusions Our models were developed as reliable and noninvasive way of preoperative nodal prediction, and we hope that they can serve as useful tools for the early planning of treatment strategies for breast cancer patients.*Clinical Relevance/Application Coordination of CBCT with ultrasound parameters can achieve predictive value of axillary lymph node status and assisting noninvasive approaches for axillary surgical planning in early stage breast cancer.

RESULTS

The areas under the ROC curves were 0.884 and 0.891 in the training cohort, 0.878 and 0.880 in the validation cohort for models one and two respectively. Calibration curves, decision curves and the clinical impact curves demonstrated that prediction of lymph node burden in both models show preferable discrimination performance. Delong's test demonstrated comparable performance in both training and validation cohorts.

SDP-BR-53   Variability Of Post-lumpectomy Imaging Surveillance In Women With Personal Histories Of Breast Cancer

Participants
Derek Nguyen, MD, Baltimore, Maryland (*Presenter*) Nothing to Disclose

PURPOSE

This study assesses current imaging surveillance protocols used for breast cancer survivors after lumpectomy and aims to understand the influencing factors.*Methods and Materials An anonymous survey was distributed through email to national breast imaging radiologists by the Society of Breast Imaging on 12/17/20. Response collection concluded on 1/17/21. The survey queried breast imaging practice settings, post-lumpectomy surveillance protocols, and reasons behind their specific protocols. Differences in duration of surveillance imaging protocols between practices were compared using the Chi-squared test. Associations between practice characteristics and protocol reasoning were evaluated using univariate logistic regression.*Results A total of 381 responses were received with an overall response rate of 16.1% (381/2361). The majority of practices (72.2%) recommend diagnostic mammography (DM) for post-lumpectomy imaging surveillance ranging from 6 months to 5 years before returning to annual screening mammography (SM), with 2-3 years being the most common (31%). In contrast, smaller proportions of practices recommend returning immediately to annual SM (7.9%) or recommend DM surveillance indefinitely (4.7%). The most common influencing factors for a practice's protocol utilization were the preferences of referring clinicians (63.8%) and radiologists (50.9%). Within the United States, practices in the West were more likely to recommend immediate return to annual SM than practices in the South (OR 1.09, 95% CI 1.01-1.17). No differences were seen based on practice setting or within international practices. Referring clinician preference, financial benefit for the patient, and published literature/guidelines were the reasons more commonly cited for recommending immediate return to annual SM following lumpectomy.*Conclusions There is variability among national breast imaging practices regarding the type of mammographic imaging surveillance protocols recommended post-lumpectomy for breast cancer survivors. These variations most commonly result from referring clinician and radiologist preferences.*Clinical Relevance/Application Communication and collaboration between referring clinicians and breast radiologists can help to standardize the care and surveillance for post-lumpectomy breast cancer patients.

RESULTS

A total of 381 responses were received with an overall response rate of 16.1% (381/2361). The majority of practices (72.2%) recommend diagnostic mammography (DM) for post-lumpectomy imaging surveillance ranging from 6 months to 5 years before returning to annual screening mammography (SM), with 2-3 years being the most common (31%). In contrast, smaller proportions of practices recommend returning immediately to annual SM (7.9%) or recommend DM surveillance indefinitely (4.7%). The most common influencing factors for a practice's protocol utilization were the preferences of referring clinicians (63.8%) and radiologists (50.9%). Within the United States, practices in the West were more likely to recommend immediate return to annual SM than practices in the South (OR 1.09, 95% CI 1.01-1.17). No differences were seen based on practice setting or within international practices. Referring clinician preference, financial benefit for the patient, and published literature/guidelines were the reasons more commonly cited for recommending immediate return to annual SM following lumpectomy.

CLINICAL RELEVANCE/APPLICATION

Communication and collaboration between referring clinicians and breast radiologists can help to standardize the care and surveillance for post-lumpectomy breast cancer patients.

SDP-BR-54   Utilization Of Screening Mammography In Women Before 50: Cross-sectional Survey Results From The National Health Interview Survey

Participants
Corey A. Brown, MENG,BS, Scarborough, Ontario (*Presenter*) Nothing to Disclose

PURPOSE

While the Society of Breast Imaging and other national societies recommend annual screening mammography in average risk women starting at age 40, the US Preventive Services Task Force (USPSTF) recommends that routine screening mammography should be an individual decision before the age of 50, reflecting patient considerations about benefits and potential harms. Using a nationally representative cross-sectional survey, the purpose of this study is to evaluate patient reported reasons and predictors for foregoing screening mammography prior to age 50.*Methods and Materials HIPAA compliant data from survey respondents aged 40-49 in the 2018 National Health Interview Survey (NHIS) without history of breast cancer were included (survey response rate 64%). Participants reported sociodemographic variables and reasons they did not undergo a mammogram within the last two years. Multiple variable logistic regression analyses were performed to evaluate the association between sociodemographic characteristics and patient-reported screening mammography practices. Analyses were conducted to account for complex survey sampling design and to obtain statistically valid estimates for the civilian, noninstitutionalized US population. *Results 1,489 women between the ages of 40-49 were included. 79.8% reported getting a screening mammogram within the last two years, and 60.6% reported getting a screening mammogram within the last year. Most common reasons for not undergoing screening mammography in the last two years included: No reason (36.2%), Didn't need it (23.5%), Doctor didn't order it (13.3%), Other (6.8%), Put it off (5.6%), I'm too young (5.6%), Haven't had any problems (3.7%), Too expensive (1.6%), Don't have doctor (1.5%). Multiple variable analyses revealed that participants without health insurance (OR 0.35, 95% CI 0.22, 0.55, p <0.001) were less likely to report undergoing screening mammography in the last two years. Asian participants (OR 0.47, 95% CI 0.24, 0.89, p = 0.004) and participants without health insurance (OR 0.30, 95% CI 0.20, 0.45, p < 0.001) were less likely to report undergoing screening mammography in the last year.*Conclusions The decision to not engage in screening mammography prior to age 50 was most strongly associated with lack of access to health insurance.*Clinical Relevance/Application USPSTF recommendations relying on complex decision making processes requiring access to health care providers may exacerbate breast cancer disparities and limit access to screening mammography for women in their 40s, particularly those without health insurance.

RESULTS

1,489 women between the ages of 40-49 were included. 79.8% reported getting a screening mammogram within the last two years, and 60.6% reported getting a screening mammogram within the last year. Most common reasons for not undergoing screening

mammography in the last two years included: No reason (36.2%), Didn't need it (23.5%), Doctor didn't order it (13.3%), Other (6.8%), Put it off (5.6%), I'm too young (5.6%), Haven't had any problems (3.7%), Too expensive (1.6%), Don't have doctor (1.5%). Multiple variable analyses revealed that participants without health insurance (OR 0.35, 95% CI 0.22, 0.55, p <0.001) were less likely to report undergoing screening mammography in the last two years. Asian participants (OR 0.47, 95% CI 0.24, 0.89, p = 0.004) and participants without health insurance (OR 0.30, 95% CI 0.20, 0.45, p < 0.001) were less likely to report undergoing screening mammography in the last year.

CLINICAL RELEVANCE/APPLICATION

USPSTF recommendations relying on complex decision making processes requiring access to health care providers may exacerbate breast cancer disparities and limit access to screening mammography for women in their 40s, particularly those without health insurance.

SDP-BR-55 Factors Associated With Screening Mammography Participation In Canadian Women

Participants
Nayaar Islam, BSC, Ottawa, Ontario (*Presenter*) Nothing to Disclose

PURPOSE

To determine whether sociodemographic factors are associated with screening mammography participation among women in Canada.*Methods and Materials This study used Canadian Community Health Survey data from all available survey cycles (2001, 2003, 2005, 2007-2008, 2009-2010, 2012, 2013-2014, 2015-2016, and 2017-2018). Survey weights assigned to survey responses by Statistics Canada were accounted for in all statistical analyses. Odds ratios (OR) and 95% confidence intervals (CI) were computed using multivariable regression models to determine the impact of age, province or territory of residence, ethnicity, immigrant status, level of education, household income, having a regular healthcare provider, perceived health status, and marital status on participation in a screening mammogram in the last two years.*Results A total of 138,284 respondents representing 27,663,094 individuals across nine survey cycles were included. From 2001 to 2018, an average of 63% (range: 60-67) of women aged 40-74 participated in screening mammography. In the two most recent survey cycles (2015-2016 and 2017-2018): odds of participation were lower among non-white women (OR=0.78 [95%CI: 0.77-0.79] and 0.52 [0.50-0.54], respectively; p<0.001 for both); odds of participation were higher among women aged 50-74 vs 40-49 (OR=6.10 [6.06-6.14] and 2.85 [2.80-2.90], respectively), who had higher levels of education, higher levels of household income, had a regular health care provider (OR=2.35 [2.33-2.38] and 2.84 [2.77-2.91], respectively), and were married vs single (OR=1.22 [1.21-1.24] and 1.60 [1.56-1.65], respectively] or in a common-law relationship vs single (OR=1.19 [1.17-1.20] and 1.60 [1.56-1.65], respectively; p<0.001 for all). In 2015-2016, odds of participation were lower among women who were immigrants (OR=0.963 [0.953-0.973]) and women with poorer levels of perceived health (p<0.001 for all).*Conclusions Non-white race, younger age, lower education, lower income, not having a regular healthcare provider, being single, worse perceived health, and being an immigrant were associated with lower participation in breast cancer screening mammography in Canada.*Clinical Relevance/Application Healthcare practitioners should consider patients' sociodemographic characteristics and provide additional guidance on accessing routine screening mammography to women who are less likely to participate in screening programs.

RESULTS

A total of 138,284 respondents representing 27,663,094 individuals across nine survey cycles were included. From 2001 to 2018, an average of 63% (range: 60-67) of women aged 40-74 participated in screening mammography. In the two most recent survey cycles (2015-2016 and 2017-2018): odds of participation were lower among non-white women (OR=0.78 [95%CI: 0.77-0.79] and 0.52 [0.50-0.54], respectively; p<0.001 for both); odds of participation were higher among women aged 50-74 vs 40-49 (OR=6.10 [6.06-6.14] and 2.85 [2.80-2.90], respectively), who had higher levels of education, higher levels of household income, had a regular health care provider (OR=2.35 [2.33-2.38] and 2.84 [2.77-2.91], respectively), and were married vs single (OR=1.22 [1.21-1.24] and 1.60 [1.56-1.65], respectively] or in a common-law relationship vs single (OR=1.19 [1.17-1.20] and 1.60 [1.56-1.65], respectively; p<0.001 for all). In 2015-2016, odds of participation were lower among women who were immigrants (OR=0.963 [0.953-0.973]) and women with poorer levels of perceived health (p<0.001 for all).

CLINICAL RELEVANCE/APPLICATION

Healthcare practitioners should consider patients' sociodemographic characteristics and provide additional guidance on accessing routine screening mammography to women who are less likely to participate in screening programs.

SDP-BR-56 Factors Affecting Axillary LN Metastasis In Patients With Clinically T1-2 N0 Breast Cancers Who Has Negative Preoperative Axillary Ultrasound

Participants
Sung Eun Song, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Randomized controlled trials are currently under way to investigate whether sentinel lymph node (LN) biopsy could be safely omitted in patients with clinically T1-2 N0 breast cancers who has negative preoperative axillary ultrasound. The purpose of our study was to reveal factors affecting pathologic axillary LN metastasis using clinical-pathologic and imaging features.*Methods and Materials From October 2013 to October 2020, consecutive women with clinically T1-2 N0 breast cancers whose sonographic findings for axillary LN were negative and who were treated with breast conservation therapy were retrospectively included. Clinical-pathologic data such as age, symptom, menopause, family history of breast cancer, histologic type and grade, pathologic tumor stage, Ki-67 index, hormone receptor status were collected. Imaging features such as mammograms (presence of calcifications, parenchymal density, and tumor location), ultrasound (BI-RADS category), and MRI (tumor morphology, enhancement kinetics, and apparent diffusion coefficient at diffusion-weighted imaging) were analyzed. Logistic regression analyses were performed to identify independent factors associated with pathologic LN metastasis.*Results A total of 402 women were included (mean age ± standard deviation, 57.61 ± 11.58). The axillary LN metastasis rate on pathology was 20.4% (82 of 402). Among 82 cases with metastasis, 21 (25.6%) were suspected to be metastatic by MRI. False positive rate by MRI was 4.4% (14 of 320). At univariate analysis, tumor stage T2 and progesterone receptor (PR) positivity, and outer tumor location on mammography, BI-RADS category 5 assessment on ultrasound, and suspicious LN metastasis on MRI were significantly associated with pathologic axillary LN metastasis (all P < .05). At mutivariate analysis, independent predictors for axillary LN metastasis were suspicious LN metastasis on MRI (odds ratio [OR], 8.19 ; 95% CI: 3.69, 18.13; P < .001), PR positivity (OR, 2.77 ; 95% CI: 1.18, 6.48; P = .018), and BI-RADS category 5 on ultrasound (OR, 2.32 ; 95% CI: 1.37, 3.92; P = .002).*Conclusions Clinical-pathologic feature of PR positivity, and imaging feature of BI-RADS category 5 assessment on ultrasound and suspicious LN metastasis on MRI might be helpful for predicting

pathologic axillary LN metastasis in patients with T1-2 N0 breast cancers who has negative axillary ultrasound.*Clinical Relevance/Application In patients with clinically T1-2 N0 breast cancers who has negative preoperative axillary ultrasound, a predictive model that incorporates clinical-pathologic features and imaging features was able to identify those patients who will have pathologic axillary LN metastasis and can be suitable candidates for sentinel LN biopsy.

RESULTS

A total of 402 women were included (mean age ± standard deviation, 57.61 ± 11.58). The axillary LN metastasis rate on pathology was 20.4% (82 of 402). Among 82 cases with metastasis, 21 (25.6%) were suspected to be metastatic by MRI. False positive rate by MRI was 4.4% (14 of 320). At univariate analysis, tumor stage T2 and progesterone receptor (PR) positivity, and outer tumor location on mammography, BI-RADS category 5 assessment on ultrasound, and suspicious LN metastasis on MRI were significantly associated with pathologic axillary LN metastasis (all P < .05). At mutivariate analysis, independent predictors for axillary LN metastasis were suspicious LN metastasis on MRI (odds ratio [OR], 8.19 ; 95% CI: 3.69, 18.13; P < .001), PR positivity (OR, 2.77 ; 95% CI: 1.18, 6.48; P = .018), and BI-RADS category 5 on ultrasound (OR, 2.32 ; 95% CI: 1.37, 3.92; P = .002).

CLINICAL RELEVANCE/APPLICATION

In patients with clinically T1-2 N0 breast cancers who has negative preoperative axillary ultrasound, a predictive model that incorporates clinical-pathologic features and imaging features was able to identify those patients who will have pathologic axillary LN metastasis and can be suitable candidates for sentinel LN biopsy.

SDP-BR-57 Post-neoadjuvant Chemotherapy Axillary Lymph Node Staging Ultrasound; A Pathological Analysis Of Missed Cases

Participants
Sepideh Sefidbakht, MD, Powel, Ohio (*Presenter*) Nothing to Disclose

PURPOSE

To review pathological characteristics of lymph node metastases missed on post-neoadjuvant chemotherapy ultrasound; to compare residual malignancy size and original tumor receptors of LN metastases missed on post-neoadjuvant chemotherapy ultrasound with correctly diagnosed lymph nodes*Methods and Materials Institutional ethics committee approved this retrospective study. 165 patients with both pre and post NAC ultrasound available over the study period entered the study. Pathology reports and slides for patients with at least one lymph node with pathologically proven malignancy on post-NAC SLNB or ALND were reviewed. Size of the lymph node metastases and original tumor receptor status was compared between those with false negative post-neoadjuvant chemotherapy tumor residue and those with correctly diagnosed residual lymph node metastases.*Results Out of 113 patients with surgically proven LN metastases, 56 patients were correctly diagnosed and 57 patients were missed on post-neoadjuvant chemotherapy axillary staging. 15 of the missed lymph nodes were micrometastses less than 2 mm in diameter, 26 had metastases 2-5 mm in diameter and 16 had larger residual metastases. 22 patients had more than one positive lymph node. Residual malignancy could be seen pathologically in 12 patients in the same level presumably the same lymph node as seen in pre-NAC ultrasound. 11/57 cases with missed cancer and only 5/56 cases with correctly diagnosed cancer were either HER2+ or triple negative.*Conclusions There is an inherent limitation to ultrasound in axillary lymph node staging after neoadjuvant chemotherapy. Ultrasound can miss a significant number of residual malignancy in lymph nodes. Using color doppler ultrasound, marking the positive lymph nodes accurately and considering re-biopsy of previously positive lymph nodes should be considered to reduce the number of axillary lymph node dissections.*Clinical Relevance/Application Axillary Lymph node dissection can cause significant morbidity and disability in women who have been treated for breast cancer. Sentinel Lymph Node biopsy is among the newer surgical techniques used to limit this disability. Newer protocols allow avoiding Axillary Lymph Node Dissection if less than three lymph nodes are involved. Both over-diagnosis and under-diagnosis can significantly affect the treatment protocols, disease course and well-being of patients. Accurate diagnosis has thus gained increasing significance as treatment protocols evolve.

RESULTS

Out of 113 patients with surgically proven LN metastases, 56 patients were correctly diagnosed and 57 patients were missed on post-neoadjuvant chemotherapy axillary staging. 15 of the missed lymph nodes were micrometastses less than 2 mm in diameter, 26 had metastases 2-5 mm in diameter and 16 had larger residual metastases. 22 patients had more than one positive lymph node. Residual malignancy could be seen pathologically in 12 patients in the same level presumably the same lymph node as seen in pre-NAC ultrasound. 11/57 cases with missed cancer and only 5/56 cases with correctly diagnosed cancer were either HER2+ or triple negative.

CLINICAL RELEVANCE/APPLICATION

Axillary Lymph node dissection can cause significant morbidity and disability in women who have been treated for breast cancer. Sentinel Lymph Node biopsy is among the newer surgical techniques used to limit this disability. Newer protocols allow avoiding Axillary Lymph Node Dissection if less than three lymph nodes are involved. Both over-diagnosis and under-diagnosis can significantly affect the treatment protocols, disease course and well-being of patients. Accurate diagnosis has thus gained increasing significance as treatment protocols evolve.

SDP-BR-58 The Diagnostic Performance Of Lymphatic Contrast Enhanced Ultrasound Guided Fine Needle Biopsy In Preoperative Evaluation Of Sentinel Lymph Node In Breast Cancer Patients

Participants
Lifang Jin, MD, Shanghai, China (*Presenter*) Nothing to Disclose

PURPOSE

To explore the feasibility and accuracy of lymphatic contrast enhanced ultrasound (LCEUS) guided fine needle biopsy (FNA) in preoperative evaluation of sentinel lymph node in breast cancer patients.*Methods and Materials Seventy-two breast cancer patients were enrolled. One sentinel lymph node (SLN) was locked with LCEUS for each ipsilateral axilla and then punctured and aspirated with FNA. The lymph cells and breast cancer cells were identified by cytological analysis. The identification of lymph cells referred as accurate punctuation, and the identification of breast cancer cells referred as metastasis. The diagnostic accuracy of LCEUS guided FNA was validated by histopathology after the SLN was localized by wire and excised in operation.*Results LCEUS succeeded in 72 patients. Lymph cells were identified in 59/72 patients, and the success rate for lymph node punctuation was 81.9%. For SLN metastasis diagnosis, the sensitivity of LCEUS guided FNA was 81.3%, the specificity was 100%, and the accuracy was 94.9%.*Conclusions LCEUS guided FNA can be an accurate method to evaluate the SLNs in breast cancer patients preoperatively.*Clinical Relevance/Application LCEUS guided FNA can evaluate if the SLNs are metastatic in breast cancer patients

in a way at lowest trauma and relative high accuracy.

RESULTS

LCEUS succeeded in 72 patients. Lymph cells were identified in 59/72 patients, and the success rate for lymph node punctuation was 81.9%. For SLN metastasis diagnosis, the sensitivity of LCEUS guided FNA was 81.3%, the specificity was 100%, and the accuracy was 94.9%.

CLINICAL RELEVANCE/APPLICATION

LCEUS guided FNA can evaluate if the SLNs are metastatic in breast cancer patients in a way at lowest trauma and relative high accuracy.

SDP-BR-59 Screening Mammography During A Pandemic: Clinical Implementation Of Artificial Intelligence Model To Support Risk-based Return To Screening

Participants
Constance Lehman, MD,PhD, Boston, Massachusetts (*Presenter*) Institutional Grant, General Electric Company;Institutional Grant, Hologic, Inc;Co-founder, Clairity, Inc.

PURPOSE

Use of risk models was recommended to invite patients to return to mammography screening during the pandemic, without clear evidence this is an effective strategy for predicting patients with breast cancer in populations due for screening. We compared the accuracy of an artificial intelligence (AI) risk score, derived solely from a patient's prior mammogram, to traditional risk scores to predict patients with cancer in a large cohort due for screening.*Methods and Materials This was a prospective, multisite trial of consecutive patients undergoing screening mammography during early recovery post COVID closures. Breast cancer risk was estimated from a 5-year AI risk score from the prior mammogram and from traditional 5-year breast cancer risk models?[NCI Breast Cancer Risk Assessment Tool (NCI) and Tyrer-Cuzick?version 8/IBIS (TC8)], prior to?return to screening.?Cancer outcomes were linked through a regional tumor registry. Proportions invited to screen and cancers detected using NCI and TC8 risk model strategies, with and without screening women with a personal history of breast cancer, were compared to AI risk model using Pearson's Chi-squared test. Areas under the receiver-operating-characteristic curve (AUCs) were estimated for each risk score and compared with the DeLong test.*Results The study included?4,210 women who returned for screening mammography May 26-July 26, 2020. To identify >90% of cancers, the AI risk model required screening of?59.6% (95% CI: 58.1-61.1) patients,?compared to 74.9% (95% CI: 73.6-76.2) with?NCI and 84.1% (95% CI: 83.0-85.2) with TC8 models (P<0.001). Including patients with a personal history of breast cancer improved both traditional approaches. The 5-year AI model had increased performance (AUC=0.67) compared to both traditional 5-year models (NCI AUC=0.57, TC8 AUC=0.46).*Conclusions In this prospective trial of consecutive women undergoing screening mammography, an AI risk model based on the prior mammogram alone supported screening <60% of the population to identify >90% of breast cancers, compared to traditional models which required screening significantly more women to achieve equivalent cancer detection.*Clinical Relevance/Application An AI-based breast cancer risk model can identify women most likely to harbor breast cancer, supporting more effective screening and mitigating the risk of delayed diagnoses in peri-pandemic times.

RESULTS

The study included?4,210 women who returned for screening mammography May 26-July 26, 2020. To identify >90% of cancers, the AI risk model required screening of?59.6% (95% CI: 58.1-61.1) patients,?compared to 74.9% (95% CI: 73.6-76.2) with?NCI and 84.1% (95% CI: 83.0-85.2) with TC8 models (P<0.001). Including patients with a personal history of breast cancer improved both traditional approaches. The 5-year AI model had increased performance (AUC=0.67) compared to both traditional 5-year models (NCI AUC=0.57, TC8 AUC=0.46).

CLINICAL RELEVANCE/APPLICATION

An AI-based breast cancer risk model can identify women most likely to harbor breast cancer, supporting more effective screening and mitigating the risk of delayed diagnoses in peri-pandemic times.

SDP-BR-60 Role Of Shear Wave Elastography Of Axillary Nodes As An Adjunct To Ultrasonography In Predicting Nodal Metastasis In Breast Cancer Patients

Participants
Vishnu Prasad Pulappadi, MD,MBBS, New Delhi, India (*Presenter*) Nothing to Disclose

PURPOSE

To compare the diagnostic performance of quantitative shear wave elastography (SWE) of axillary nodes with B-mode ultrasonography (USG) and combination of both in diagnosing nodal metastasis in breast cancer patients with suspicious axillary nodes.*Methods and Materials Between June 2018 and August 2020, after obtaining Ethics Committee approval, a prospective observational study was performed on patients with biopsy proven breast carcinoma and having axillary nodes with cortical thickness greater than 3 mm on USG. SWE followed by core biopsy was performed on the node with maximum cortical thickness. B-mode USG features, including cortical thickness, effacement of fatty hilum and non-hilar blood flow, and SWE parameters of the cortex were compared with biopsy results to ascertain their diagnostic performances.*Results Of the 54 patients evaluated, stable elasticity maps were obtained in 49 nodes of 49 patients (mean age, 46.3 years [95% CI, 42.8-49.8 years]; females, 48/49 [98%]). Biopsy revealed metastasis in 38 nodes and reactive hyperplasia in 11 nodes. Median values of all SWE parameters were significantly higher in metastatic nodes than in reactive nodes- Emax (25.9 kPa vs 12.6 kPa, p=0.001), Emin (21.15 kPa vs 10.5 kPa, p=0.002), Emean (24.75 kPa vs 11.6 kPa, p=0.001) and ESD (1.6 kPa vs 0.9 kPa, p=0.032). Emax had the best diagnostic performance with area under the curve (AUC) of 0.831, sensitivity of 73.7% and specificity of 81.8% at a cut-off of 14.9 kPa. Amongst the B-mode USG features, cortical thickness had the best diagnostic performance at a cut-off of 6.7 mm with AUC of 0.878, sensitivity of 89.5% and specificity of 72.7%. On combining cortical thickness with Emax, specificity improved from 72.7% to 90.9%, although it was not statistically significant (p=0.157). Combination of all B-mode USG features had specificity of 90.9%, which increased to 100% on combining with Emax, although it was not statistically significant (p=0.317).*Conclusions SWE is useful in detecting nodal metastasis in breast cancer patients. Emax has the best diagnostic performance among SWE parameters and early experience suggests that it can improve the specificity of B-mode USG.*Clinical Relevance/Application B-mode USG features of metastatic nodes can overlap with that of reactive nodes and addition of SWE can help in increasing the specificity for diagnosing nodal metastasis in breast cancer patients.

RESULTS

Of the 54 patients evaluated, stable elasticity maps were obtained in 49 nodes of 49 patients (mean age, 46.3 years [95% CI, 42.8-49.8 years]; females, 48/49 [98%]). Biopsy revealed metastasis in 38 nodes and reactive hyperplasia in 11 nodes. Median values of all SWE parameters were significantly higher in metastatic nodes than in reactive nodes- Emax (25.9 kPa vs 12.6 kPa, p=0.001), Emin (21.15 kPa vs 10.5 kPa, p=0.002), Emean (24.75 kPa vs 11.6 kPa, p=0.001) and ESD (1.6 kPa vs 0.9 kPa, p=0.032). Emax had the best diagnostic performance with area under the curve (AUC) of 0.831, sensitivity of 73.7% and specificity of 81.8% at a cut-off of 14.9 kPa. Amongst the B-mode USG features, cortical thickness had the best diagnostic performance at a cut-off of 6.7 mm with AUC of 0.878, sensitivity of 89.5% and specificity of 72.7%. On combining cortical thickness with Emax, specificity improved from 72.7% to 90.9%, although it was not statistically significant (p=0.157). Combination of all B-mode USG features had specificity of 90.9%, which increased to 100% on combining with Emax, although it was not statistically significant (p=0.317).

CLINICAL RELEVANCE/APPLICATION

B-mode USG features of metastatic nodes can overlap with that of reactive nodes and addition of SWE can help in increasing the specificity for diagnosing nodal metastasis in breast cancer patients.

SDP-BR-61 Factors Influencing Trainees' Interest In Breast Imaging

Participants
Wyanne Law, MD, Toronto, Ontario (*Presenter*) Nothing to Disclose

PURPOSE

To gauge the level of interest in breast imaging and to determine factors potentially impacting trainees' decision to pursue this subspecialty.*Methods and Materials An IRB approved survey study was conducted from November 2020 to February 2021 on Canadian radiology residents and medical students regarding their interests in breast imaging. Training, actual vs. preferred timing of breast rotations, fellowship choices, perceived positive and negative attributes of breast imaging and opinion of how Artificial Intelligence (AI) will impact breast imaging were collected. Chi-square and Fisher's exact tests, and univariate logistic regression were performed to determine the association between trainees' perceptions with interest in pursuing breast or women's imaging fellowships, and with level of training.*Results A total of 157 responses (77 medical students and 80 radiology residents) were collected. The top 3 fellowship subspecialties desired by residents were breast or women's imaging (36%), abdominal imaging (35%), and interventional radiology (25%). A quarter of the medical students (25%) were unsure due to lack of exposure. The most common reason residents found breast imaging appealing was procedures (59%), which was associated with increased odds of being interested in breast/women's fellowships (OR, 3.2, 95% CI,1.2-8.6, p=.021). However, significantly fewer medical students considered procedures as a reason to pursue breast imaging (16%, p<.001). The most common reason that both residents and medical students found breast imaging unappealing was repetitiveness (20%), which was associated with decreased odds of being interested in pursuing a breast/women's fellowships (OR, 0.25, 95% CI, 0.1-0.6, p=.021). Almost half (48%) of the radiology residents had their first breast imaging rotation in their third year. Forty percent of the residents reported that starting breast rotations in first or second year would affect their fellowship choice. AI was deemed by 51% of the respondents to improve breast imaging. Those who were interested in breast/women's imaging were enthusiastic in connecting with a mentor in this field (p<.001).*Conclusions Trainees have variable perceptions and exposures to breast imaging that may influence their interest in breast /women's fellowships.*Clinical Relevance/Application There is a shortage of breast imagers. Our study demonstrated that earlier exposure to breast imaging/procedures, increasing visibility of breast radiologists, and mentorship opportunities are key factors in the choice of breast imaging careers.

RESULTS

A total of 157 responses (77 medical students and 80 radiology residents) were collected. The top 3 fellowship subspecialties desired by residents were breast or women's imaging (36%), abdominal imaging (35%), and interventional radiology (25%). A quarter of the medical students (25%) were unsure due to lack of exposure. The most common reason residents found breast imaging appealing was procedures (59%), which was associated with increased odds of being interested in breast/women's fellowships (OR, 3.2, 95% CI,1.2-8.6, p=.021). However, significantly fewer medical students considered procedures as a reason to pursue breast imaging (16%, p<.001). The most common reason that both residents and medical students found breast imaging unappealing was repetitiveness (20%), which was associated with decreased odds of being interested in pursuing a breast/women's fellowships (OR, 0.25, 95% CI, 0.1-0.6, p=.021). Almost half (48%) of the radiology residents had their first breast imaging rotation in their third year. Forty percent of the residents reported that starting breast rotations in first or second year would affect their fellowship choice. AI was deemed by 51% of the respondents to improve breast imaging. Those who were interested in breast/women's imaging were enthusiastic in connecting with a mentor in this field (p<.001).

CLINICAL RELEVANCE/APPLICATION

There is a shortage of breast imagers. Our study demonstrated that earlier exposure to breast imaging/procedures, increasing visibility of breast radiologists, and mentorship opportunities are key factors in the choice of breast imaging careers.

SDP-BR-62 Axillary Lymphadenopathies Demonstrated By Ultrasound After Sars-cov-2 Vaccination

Participants
Myriam F. Montes, MD, Madrid, Spain (*Presenter*) Nothing to Disclose

PURPOSE

To assess the incidence of axillary lymphadenopathies after SARS-CoV-2 vaccination by axillary ultrasound.*Methods and Materials Observational prospective cohort study to estimate the incidence of axillar lymphadenopathies after SARS-CoV-2 vaccination in adult volunteers. Ultrasound scan was performed in day 3-7 after immunization. Information about presence, laterality, size, andsonographic characteristics of lymph nodes was collected.*Results Lymphadenopathies were detected in 93/109 (82.6%; 95% confidence interval 77.5% - 90.8%) cases. We did not find significant differences in age, gender, previous history of Covid-19 infection or the presence of axillar pain/palpable node after vaccination. Up to 34.5% of thenodes showed suspicious morphology consisting in focal cortical enlargement and absent hilum.*Conclusions Axillary ultrasound shows enlargement and changes in morphology of the axillary nodes after receiving the mRNA SARS-CoV-2 vaccine in most of the recipients.*Clinical Relevance/Application Radiologists must know the high incidence of lymphadenopathies after SARS-CoV-2 vaccination by imaging to avoid misleading in oncological imaging check-ups and breast cancer screening that led to unnecessary biopsies.

RESULTS

Lymphadenopathies were detected in 93/109 (82.6%; 95% confidence interval 77.5% - 90.8%) cases. We did not find significant

Lymphadenopathies were detected in 93/109 (82.6%; 95% confidence interval 77.5% - 90.8%) cases. We did not find significant differences in age, gender, previous history of Covid-19 infection or the presence of axillar pain/palpable node after vaccination. Up to 34.5% of thenodes showed suspicious morphology consisting in focal cortical enlargement and absent hilum.

CLINICAL RELEVANCE/APPLICATION

Radiologists must know the high incidence of lymphadenopathies after SARS-CoV-2 vaccination by imaging to avoid misleading in oncological imaging check-ups and breast cancer screening that led to unnecessary biopsies.

SDP-BR-63 Deep Learning For Detecting Early-stage Invasive Breast Cancer At Magnetic Resonance Imaging : A Preliminary Study

Participants
Jihe Lim, MD, Hwaseong-si, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To develop a deep learning model for detecting early-stage invasive breast cancer from multicenter breast MRI data.*Methods and Materials A total of 1860 women (mean age: 53.7 years) with T1 breast cancer were obtained from five medial centers, which included dynamic contrast-enhanced breast MRI prior to surgery between 2012 and 2020. All patients had a newly diagnosed single-site invasive breast cancer measuring 2 cm or less in size on pathology. Enhancing masses on early phase postcontrast T1-weighted images (with 15057 labeled cancer images and 1635 labeled benign images) served as the ground truth. The whole dataset was divided into three sets: training (1346 [72%] women from three centers), internal test (90 [5%] women from three centers), and external test (424 [23%] women from two centers). To develop a deep learning-based automatic detection algorithm for identifying malignant masses, the single phase was performed using a regional-based You Only Look Once (YOLOv2) model. Statistical analysis included the detection sensitivity and average false-positive rate.*Results On the external dataset, the deep learning model achieved a sensitivity of 85.1% (95% confidence intervals [CIs]: 81.4%, 88.4%) and average false-positive rate of 30.0% (95% CI: 25.7%, 34.6%). On the internal dataset, the model achieved a sensitivity of 93.2% (95% CI: 85.6%, 97.6%) and average false-positive rate of 41.1% (95% CI: 30.6%, 52.2%).*Conclusions This MRI-based deep learning model has a potential in the early detection of invasive breast cancer.*Clinical Relevance/Application Deep learning algorithms can be used for the detection of malignant enhancing masses on single early postcontrast T1-weighted imaging. Further study is warranted to compare the performance of deep learning and breast radiologists in the detection of early breast cancer with MRI.

RESULTS

On the external dataset, the deep learning model achieved a sensitivity of 85.1% (95% confidence intervals [CIs]: 81.4%, 88.4%) and average false-positive rate of 30.0% (95% CI: 25.7%, 34.6%). On the internal dataset, the model achieved a sensitivity of 93.2% (95% CI: 85.6%, 97.6%) and average false-positive rate of 41.1% (95% CI: 30.6%, 52.2%).

CLINICAL RELEVANCE/APPLICATION

Deep learning algorithms can be used for the detection of malignant enhancing masses on single early postcontrast T1-weighted imaging. Further study is warranted to compare the performance of deep learning and breast radiologists in the detection of early breast cancer with MRI.

SDP-BR-64 Deep Learning-based Heterogeneous Model Improve Diagnostic Performance Of Ultrasound For Axillary Metastasis Of Early Breast Cancer

Participants
Jingwen Zhou, Guangzhou, China (*Presenter*) Nothing to Disclose

PURPOSE

Pre-treatment evaluation of axillary lymph node (ALN) metastasis is critical for treatment planification of early-stage breast cancer. To improve the diagnostic performance of traditional ultrasound, we develop a deep learning-based heterogeneous model (DLHM) to reveal the medical characteristics from ultrasonic images and assist pre-treatment evaluation of ALN.*Methods and Materials A total of 214 eligible patients were prospectively recruited. 220 breast lesions were identified and the ipsilateral axillae underwent ultrasound elastography (UE) evaluation. Image data of the UE including B-mode ultrasonography and shear wave elastography (SWE) and related clinic-pathological characteristics of the 220 target ALNs, that defined as the most suspicious node according the radiologist criteria from the corresponding ipsilateral axilla, were collected and divided randomly at a ratio of 7:4 for training and testing cohort. UE based on radiological criteria that combined B-mode morphological characteristics and elastic values, and DLHM that combined radiomics features, B-mode deep features, and SWE deep features were established to predict metastatic and non-metastatic axilla. Performance was compared between UE and DLHM in terms of areas under the receiver operating characteristics curve (AUC), sensitivity, specificity, accuracy, negative predictive value, and positive predictive value for predicting ALN metastasis in both training and testing cohorts.*Results The DLHM achieved excellent performance for both the training cohort and testing cohort in predicting ALN metastasis. In the testing cohort, the DLHM demonstrated significantly improved performance in identifying metastatic ALNs compared to UE (AUC: 0.911 [95% confidence interval (CI): 0.826, 0.963] vs. 0.707 [95% CI: 0.595, 0.804]; P<0.001).*Conclusions The DLHM demonstrated promising ability as an effective, accurate, and non-invasive pre-treatment method for assisting the diagnosis of ALN metastasis in patients with early breast cancer.*Clinical Relevance/Application The DLHM presented a non-invasive method to identify the involved axilla and could serve as a pre-treatment routine practice for patients with early stage breast cancer. Moreover, different from UE based on the subjective diagnoses of radiologists, DLHM automatically extracts relevant features from B-mode and SWE images for diagnosis and avoid the inter-, or intro-observers inconsistencies. With a trend of reduced axillary surgery in the modern management of breast cancer, it is increasingly important to accurately identify metastatic burden. DLHM provided the basis for accurate axillary ultrasound staging with artificial intelligence for patients with early breast cancer.

RESULTS

The DLHM achieved excellent performance for both the training cohort and testing cohort in predicting ALN metastasis. In the testing cohort, the DLHM demonstrated significantly improved performance in identifying metastatic ALNs compared to UE (AUC: 0.911 [95% confidence interval (CI): 0.826, 0.963] vs. 0.707 [95% CI: 0.595, 0.804]; P<0.001).

CLINICAL RELEVANCE/APPLICATION

The DLHM presented a non-invasive method to identify the involved axilla and could serve as a pre-treatment routine practice for

patients with early stage breast cancer. Moreover, different from UE based on the subjective diagnoses of radiologists, DLHM automatically extracts relevant features from B-mode and SWE images for diagnosis and avoid the inter-, or intro-observers inconsistencies. With a trend of reduced axillary surgery in the modern management of breast cancer, it is increasingly important to accurately identify metastatic burden. DLHM provided the basis for accurate axillary ultrasound staging with artificial intelligence for patients with early breast cancer.

SDP-BR-65 Comparison Of Two Contrast-enhanced Spectral Mammography (cesm) Systems Regarding Background Enhancement And Its Possible Impact On Diagnostic Accuracy

Participants
Daniel Wessling, MD, Tuebingen, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the impact of the digital mammography imaging system on the overall background enhancement on recombined contrast-enhanced spectral mammography (CESM) images, the overall background enhancement of two different mammography systems was compared.*Methods and Materials We evaluated CESM images of female patients who underwent CESM in the between 2016 and 2019 with regard to the background enhancement. For this purpose, we compared the images of the mammography system Senographe EssentialTM, GE Healthcare, Chicago, IL, USA (machine A) and those of the Selenia ® Dimensions ® system, Hologic, Marlborough, MA, USA (machine B). Background enhancement was assessed qualitatively by using a Likert-scale from 1 (minimal overall background enhancement) to 4 (marked overall enhancement) and quantitatively by placing a region of interest (ROI) and measuring the pixel density. The background parenchymal enhancement as well as the overall image background enhancement were considered in the evaluation, excluding known artefacts and suspicious findings.*Results The quantitative image analysis revealed differences in background enhancement measurements, both for the first (1.72 vs 2.29) and the second reader (1.74 vs 2.35), which proved to be statistically significant (p<0.001). No relevant differences between the first and the second reader could be observed (p=0.8852). In concordance with the quantitative analysis, the qualitative evaluation also shows statistically significant differences in background enhancement (p<0.001) with an average difference of 75.69 pixels (99%-CI [74.37, 77.02]).*Conclusions Mammography machines seem to have a significant impact on the overall background enhancement qualitatively and quantitatively, thus having a possible impact on the diagnostic accuracy.*Clinical Relevance/Application Similar to MRI, in CESM there is a certain background enhancement of the benign breast parenchyma, even if the date of examination is timed to the menstrual cycle. In both imaging modalities, CESM and breast MRI, a high level of background enhancement can influence the radiological qualitative analysis and interpretation and thereby the diagnostic accuracy. Therefore, it is essential to identify possible influencing factors on the background enhancement.

RESULTS

The quantitative image analysis revealed differences in background enhancement measurements, both for the first (1.72 vs 2.29) and the second reader (1.74 vs 2.35), which proved to be statistically significant (p<0.001). No relevant differences between the first and the second reader could be observed (p=0.8852). In concordance with the quantitative analysis, the qualitative evaluation also shows statistically significant differences in background enhancement (p<0.001) with an average difference of 75.69 pixels (99%-CI [74.37, 77.02]).

CLINICAL RELEVANCE/APPLICATION

Similar to MRI, in CESM there is a certain background enhancement of the benign breast parenchyma, even if the date of examination is timed to the menstrual cycle. In both imaging modalities, CESM and breast MRI, a high level of background enhancement can influence the radiological qualitative analysis and interpretation and thereby the diagnostic accuracy. Therefore, it is essential to identify possible influencing factors on the background enhancement.

SDP-BR-66 Quantitative T2 Mapping Combined With The ADC Metric From Diffusion Weighted Imaging Improves Lesion Characterization In Breast MRI

Participants
Isabella Bolengo, MD, Rozzano, Italy (*Presenter*) Nothing to Disclose

PURPOSE

We explored the hypothesis that quantitative analysis of T2 relaxation time could be a useful addition to diffusion weighted imaging (DWI) with the calculation of an apparent diffusion coefficient (ADC) in characterizing enhancing lesions in breast MRI*Methods and Materials This IRB-approved retrospective single-centre study included all patients presenting with contrast-enhancing lesions on consecutive breast MRI examinations performed due to BIRADS 0, 4 or 5 findings at our Institution between February 2018 and December 2019. Histological verification was defined as the reference standard and patients undergoing neoadjuvant chemotherapy were excluded. Examinations were performed at 3T in line with international recommendations and included a DWI and a T2 mapping sequence with five different echo times. For malignant lesions, ki67 count was recorded. MRI evaluation of T2 relaxation time and ADC values for each breast lesion was performed by a fellow in breast imaging. Two other readers (an experienced breast radiologist and a second breast imaging fellow) independently repeated the measurements. Statistical analysis included the calculation of Spearman correlation coefficients and ROC-analysis. Multivariable combination of T2 and ADC values was done using 10-fold cross-validated classification and regression trees (CRT).*Results The study included 85 female patients, mean age 53.3 ±15.3, range 18-88 years, presenting with 88 enhancing breast lesions (35 benign and 53 malignant). T2 measurements showed a significant correlation between readers (0.55 and 0.74, P<0.001 respectively); ADC values also correlated significantly (0.43-0.71, P<0.001, respectively). A significant positive correlation was found between ki67 and T2 (P< 0.03) but not between ki67 and ADC values (P>0.05). CRT revealed significant contributions of both T2 and ADC to the model (P<=0.002). The area under the ROC curve was 0.770 for T2, 0.861 for ADC and 0.900 for the combined CRT model. The latter provided operating points both ruling-out and ruling-in malignancy.*Conclusions Combining quantitative T2 measurements with ADC provides additional value in the characterization of breast lesions as a part of a mp (multiparametric) MRI study. Besides improved diagnosis of malignant lesions, there is a significant correlation between T2 relaxation time and ki67 as a surrogate marker of cancer aggressiveness.*Clinical Relevance/Application The addition of the quantitative analysis of T2 relaxation time to ADC can improve characterization of enhancing lesions as a part of a mpMRI study. T2 relaxation time has also shown to correlate significantly with Ki67, providing important information about breast cancer aggressiveness.

RESULTS

The study included 85 female patients, mean age 53.3 ±15.3, range 18-88 years, presenting with 88 enhancing breast lesions (35 benign and 53 malignant). T2 measurements showed a significant correlation between readers (0.55 and 0.74, P<0.001

respectively); ADC values also correlated significantly (0.43-0.71, P<0.001, respectively). A significant positive correlation was found between ki67 and T2 (P< 0.03) but not between ki67 and ADC values (P>0.05). CRT revealed significant contributions of both T2 and ADC to the model (P<=0.002). The area under the ROC curve was 0.770 for T2, 0.861 for ADC and 0.900 for the combined CRT model. The latter provided operating points both ruling-out and ruling-in malignancy.

CLINICAL RELEVANCE/APPLICATION

The addition of the quantitative analysis of T2 relaxation time to ADC can improve characterization of enhancing lesions as a part of a mpMRI study. T2 relaxation time has also shown to correlate significantly with Ki67, providing important information about breast cancer aggressiveness.

SDP-BR-67 Discharging Nipple: Does It Really Matter ?

Participants
Hannah L. Chung, MD, Houston, Texas (*Presenter*) Nothing to Disclose

PURPOSE

To assess the role of imaging in patients presenting with nipple discharge.*Methods and Materials This was a retrospective, single-institution, IRB approved study of patients who underwent breast imaging evaluation for symptom of nipple discharge between November 2015 to October 2018. A total of 356 patients were identified from the EHR. After excluding 89 patients with < 1 year imaging or clinical follow up, 267 patients with biopsy results and/or follow up constituted the study cohort.*Results Of the 267 cases, discharge was unilateral in 220 and bilateral in 47. Color was bloody in 103, clear in 95, all other in 61, and not specified in 8. The following incidences were observed: cancers (38/267,14.2%), atypical histologies (14/267, 5.3%), papilloma without atypia (58/267,21.7%), nonspecific benign (42/267, 15.7%) and benign on imaging or clinical follow up (115 (43.1%). Among the 38 cancers (13 DCIS and 25 invasive), the median age was 52 with range 26-80. Discharge was unilateral in 35 (92.1%), spontaneous in 32 (84.2%), bloody in 27 (71.0%), clear in 8 (21.1%), associated with a palpable lump in 12 (31.6%). Cancer diagnosis was obtained by image guided needle biopsy in 35; skin punch biopsy in 1; surgical excisional biopsy in 2. Eight cancers (21.1%) were upstaged at surgery from an atypical high risk lesion at needle biopsy.*Conclusions Imaging evaluation of all nipple discharge yielded a malignant diagnosis in 14.2% and atypias in 5.3%. The upgrade rate of atypias in the setting of nipple discharge was 21.1%, so surgical excision should be performed.*Clinical Relevance/Application Nipple discharge is a common breast complaint. One in 5 nipple discharge cases are pathologic (due to malignancy or atypia) and do not always present with unilateral, spontaneous, bloody or clear discharge or with an associated palpable lump.

RESULTS

Of the 267 cases, discharge was unilateral in 220 and bilateral in 47. Color was bloody in 103, clear in 95, all other in 61, and not specified in 8. The following incidences were observed: cancers (38/267,14.2%), atypical histologies (14/267, 5.3%), papilloma without atypia (58/267,21.7%), nonspecific benign (42/267, 15.7%) and benign on imaging or clinical follow up (115 (43.1%). Among the 38 cancers (13 DCIS and 25 invasive), the median age was 52 with range 26-80. Discharge was unilateral in 35 (92.1%), spontaneous in 32 (84.2%), bloody in 27 (71.0%), clear in 8 (21.1%), associated with a palpable lump in 12 (31.6%). Cancer diagnosis was obtained by image guided needle biopsy in 35; skin punch biopsy in 1; surgical excisional biopsy in 2. Eight cancers (21.1%) were upstaged at surgery from an atypical high risk lesion at needle biopsy.

CLINICAL RELEVANCE/APPLICATION

Nipple discharge is a common breast complaint. One in 5 nipple discharge cases are pathologic (due to malignancy or atypia) and do not always present with unilateral, spontaneous, bloody or clear discharge or with an associated palpable lump.

SDP-BR-68 Prospectively Evaluating The Cost Of Modalities For Breast Cancer Screening And Diagnosis Using Time-driven Activity-based Costing Method

Participants
Aamir Ali, MBBS, Boston, Massachusetts (*Presenter*) Nothing to Disclose

PURPOSE

To calculate and compare the cost of performing breast imaging or procedures with different modalities using the time-driven activity-based costing (TDABC) method.*Methods and Materials This IRB-approved, prospective study was performed in 80 female patients who presented for breast imaging or breast procedures at a single institution from July 2020 to April 2021. Data were collected for 5 patients for each screening and diagnostic modality and procedure which included 2D and 3D mammography, breast ultrasound (US), breast MRI and contrast-enhanced mammography (CEM), and stereotactic, US-guided, and MRI-guided biopsy. For diagnostic 3D mammography, data for an additional 15 patients were collected to subdivide this exam into unilateral vs bilateral 3D mammography and 3D mammography followed by US exam and without US exam. TDABC process maps recorded all steps involved in patient care from check-in to check-out time. Capacity cost rates (cost per minute) for all personnel staff and fixed equipment were calculated. Capacity cost rates were multiplied with time utilized by a resource in minutes to calculate the cost of a resource. TDABC cost of exam was the sum of the cost of personnel staff, fixed equipment and consumables. The cost of image interpretation was not included in this study.*Results The cost of screening breast MRI was $249, whereas the cost of screening CEM, breast US, 3D and 2D mammography were 48% ($120), 33% ($83), 11% ($28) and 12% ($30) of the cost of the MRI exam. Personnel staff cost was the major contributor (60-88%) of the total cost of exam for all screening modalities except MRI exam in which 62% of the total cost was attributed to the fixed equipment cost. Only 3-14%, of the total exam cost was attributed to consumables in all screening modalities. For diagnostic breast exams, the cost of MRI was $241. The cost of diagnostic CEM, US and 2D mammography were 51% ($123), 29% ($71) and 18% ($43) of the cost of the MRI exam. The total cost of unilateral and bilateral 3D mammography exams followed by additional US exam were $99 and $125, respectively. For biopsy procedures, the cost of US guided biopsy was $356 which was 43% ($827) of stereotactic biopsy and 22% ($1,611) of MRI guided biopsy. Consumables contributed 40-50% and personnel staff contributed 31-56% to the total cost of biopsy procedures.*Conclusions TDABC provides a granular assessment of the true cost of performing breast imaging procedures. Personnel costs accounted for the majority of the total cost of screening, diagnostic, and biopsy procedures.*Clinical Relevance/Application Prospectively assessed TDABC provides a granular and accurate assessment of breast imaging costs, which can be used to improve efficiency in value-based alternative payment models.

RESULTS

The cost of screening breast MRI was $249, whereas the cost of screening CEM, breast US, 3D and 2D mammography were 48% ($120), 33% ($83), 11% ($28) and 12% ($30) of the cost of the MRI exam. Personnel staff cost was the major contributor (60-

88%) of the total cost of exam for all screening modalities except MRI exam in which 62% of the total cost was attributed to the fixed equipment cost. Only 3-14%, of the total exam cost was attributed to consumables in all screening modalities. For diagnostic breast exams, the cost of MRI was $241. The cost of diagnostic CEM, US and 2D mammography were 51% ($123), 29% ($71) and 18% ($43) of the cost of the MRI exam. The total cost of unilateral and bilateral 3D mammography exams followed by additional US exam were $99 and $125, respectively. For biopsy procedures, the cost of US guided biopsy was $356 which was 43% ($827) of stereotactic biopsy and 22% ($1,611) of MRI guided biopsy. Consumables contributed 40-50% and personnel staff contributed 31-56% to the total cost of biopsy procedures.

CLINICAL RELEVANCE/APPLICATION

Prospectively assessed TDABC provides a granular and accurate assessment of breast imaging costs, which can be used to improve efficiency in value-based alternative payment models.

SDP-BR-69   Performance In Consecutive Mammography Screenings Following Digital Breast Tomosynthesis Screening: Results From A Large, Prospective Trial

Participants
Sophia Zackrisson, Malmo, Sweden (*Presenter*) Speaker, Siemens AG;Consultant, Collective Minds Radiology AB

PURPOSE

To evaluate if the new screening modality, digital breast tomosynthesis (DBT), contributes to early detection of breast cancer by assessing recall rates (RR), cancer detection rates (CDR), and fraction of invasive cancers in consecutive routine digital mammography (DM).*Methods and Materials A paired, prospective trial, *****, including 14848 women between 2010 and 2015 where both DBT and DM were performed at one screening occasion showed increased CDR compared to routine DM. In this study, we followed the women included in the trial through their first (DM1, n=12876) and second (DM2, n=10880) consecutive DM screenings. In line with the national screening program DM1 took place 18-24 and DM2 36-48 months after the trial screening. Cancer diagnoses were identified through record linkages. Screening RRs and CDRs were calculated with 95% confidence intervals (CI).*Results The RRs in the trial were 2.5/100 women (CI(95%) 2.2-2.8) for DM and 3.6/100 (CI(95%) 3.3-3.9) for DBT. In both DM1 and DM2 the RR was 2.1 (CI(95%) 1.8-2.3). Compared to CDRs in the trial, 6.5/1000 (CI(95%)5.2-7.9) for DM and 8.7/1000 women (CI(95%)7.3-10.3) for DBT,CDR was lower in DM1 (4.6/1000 women, CI(95%)3.6-5.9), and in DM2 (5.5/1000, CI(95%)4.2-7.1). In the trial 139 tumors were detected, 85% of which were invasive, corresponding numbers for DM1 were 59 and 66%, and for DM2 60 and 83%.*Conclusions Following the trial, numbers of CDR and fraction of invasive cancers were lower at DM1 and then increasing at DM2, indicating that relevant invasive cancers were detected with DBT in the trial. Recall rates remained quite stable over time for DM. More rigorous statistical analyses will be performed and data on tumor characteristics will be provided.*Clinical Relevance/Application Analysis of how DBT screening affects consecutive screening performance is important in order to evaluate future value of DBT.

RESULTS

The RRs in the trial were 2.5/100 women (CI(95%) 2.2-2.8) for DM and 3.6/100 (CI(95%) 3.3-3.9) for DBT. In both DM1 and DM2 the RR was 2.1 (CI(95%) 1.8-2.3). Compared to CDRs in the trial, 6.5/1000 (CI(95%)5.2-7.9) for DM and 8.7/1000 women (CI(95%)7.3-10.3) for DBT,CDR was lower in DM1 (4.6/1000 women, CI(95%)3.6-5.9), and in DM2 (5.5/1000, CI(95%)4.2-7.1). In the trial 139 tumors were detected, 85% of which were invasive, corresponding numbers for DM1 were 59 and 66%, and for DM2 60 and 83%.

CLINICAL RELEVANCE/APPLICATION

Analysis of how DBT screening affects consecutive screening performance is important in order to evaluate future value of DBT.

SDP-BR-7   Development And Validation Of Nomogram For Prediction Of Pathologic Response After Neoadjuvant Chemotherapy In Triple-negative Breast Cancer Using Pretreatment Dynamic Contrast-enhanced MRI

Participants
Yanbo Li, Tianjin, China (*Presenter*) Nothing to Disclose

PURPOSE

To develop a nomogram based on pretreatment dynamic contrast-enhanced magnetic resonance imaging (DCE-MRI) to predict pathologic complete response (pCR) to neoadjuvant chemotherapy (NAC) in patients with triple-negative breast cancer (TNBC).*Methods and Materials A total of 108 female patients with TNBC who underwent completed neoadjuvant chemotherapy followed by surgery between January 2017 and October 2020 were enrolled. The patients were divided into the primary cohort (n=87) and the validation cohort (n=21). The pretreatment DCE-MRI and clinicopathological features were reviewed and recorded. Univariate analysis and multivariate logistic regression analyses were used to determine the independent predictors of pCR in primary cohort. A nomogram was developed based on the predictors, and its predictive performance was evaluated by the area under the curve (AUC) of receiver operating characteristics (ROC). The validation cohort was used to test the predictive model.*Results Tumor volume measured on DCE-MRI, time to peak (TTP), and androgen receptor (AR) status was identified as an independent predictor of pCR. The AUC of the nomogram was 0.84 (95% CI: 0.75-0.93) and 0.79 (95% CI: 0.59-0.99) in the primary cohort and validation cohort, respectively.*Conclusions Pretreatment DCE-MRI could predict pCR to NAC in TNBC. The nomogram can be used to predict the probability of pCR and might apply for individualized treatment approach-making.*Clinical Relevance/Application To apply for individualized treatment approach-making in patients with triple-negative breast cancer.

RESULTS

Tumor volume measured on DCE-MRI, time to peak (TTP), and androgen receptor (AR) status was identified as an independent predictor of pCR. The AUC of the nomogram was 0.84 (95% CI: 0.75-0.93) and 0.79 (95% CI: 0.59-0.99) in the primary cohort and validation cohort, respectively.

CLINICAL RELEVANCE/APPLICATION

To apply for individualized treatment approach-making in patients with triple-negative breast cancer.

SDP-BR-8   Outcomes Of Using Artificial Intelligence-based Computer-assisted Detection For Mammography: A Retrospective Simulation Study With A Screening Cohort

Participants
Jung Hyun Yoon, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Little has been reported on applying artificial intelligence-based computer-assisted detection/diagnosis (AI-CAD) in real-world screening mammograms. In this study we retrospectively evaluated the outcomes and analyze the abnormality features detected by AI-CAD when applied to real-world screening mammograms.*Methods and Materials From January 2016 to December 2017, 5479 screening mammograms of 4362 women were collected from a single screening facility. Mammograms were interpreted individually by three radiologists, according to the American College of Radiology Breast Imaging Reporting And Data System lexicon (ACR BI-RADS). A commercially-available AI-CAD for mammography was used for mammography analysis. Mammography features at the AI-CAD marks were reviewed. Ground truth in terms of cancer, benign diagnosis or absence of abnormality was confirmed according to histopathologic diagnosis via biopsy/surgery or at least 1 year of follow-up.*Results Of the 5479 mammograms, 34 (0.6%) were cancers, 175 (3.2%) benign lesions, and 5270 (96.2%) were negative. Among the 34 cancers, 23 (67.6%) were detected as abnormal findings by the interpreting radiologists. Six (17.6%, 6 of 34) of the 11 cancers initially overlooked by the radiologists had abnormality scores =10% with abnormal findings at the AI-CAD marks on retrospective review. Asymmetry (255 of 570, 44.7%) was the most common finding on the AI-CAD marks. Approximately 75.4% (430 of 570) of false-positive AI-CAD findings were interpreted as benign on retrospective review.*Conclusions AI-CAD detected 17.6% additional cancers that were initially overlooked by the radiologists in a screening population. Asymmetry was the most common false-positive AI-CAD finding, of which 75.4% were confidently interpreted as benign at the retrospective review.*Clinical Relevance/Application AI-CAD detected 17.6% additional cancers that were initially overlooked by the radiologists in a screening population. Asymmetry was the most common false-positive AI-CAD finding, of which 75.4% were confidently interpreted as benign at the retrospective review.

RESULTS

Of the 5479 mammograms, 34 (0.6%) were cancers, 175 (3.2%) benign lesions, and 5270 (96.2%) were negative. Among the 34 cancers, 23 (67.6%) were detected as abnormal findings by the interpreting radiologists. Six (17.6%, 6 of 34) of the 11 cancers initially overlooked by the radiologists had abnormality scores =10% with abnormal findings at the AI-CAD marks on retrospective review. Asymmetry (255 of 570, 44.7%) was the most common finding on the AI-CAD marks. Approximately 75.4% (430 of 570) of false-positive AI-CAD findings were interpreted as benign on retrospective review.

CLINICAL RELEVANCE/APPLICATION

AI-CAD detected 17.6% additional cancers that were initially overlooked by the radiologists in a screening population. Asymmetry was the most common false-positive AI-CAD finding, of which 75.4% were confidently interpreted as benign at the retrospective review.

SDP-BR-9   Can Artificial Intelligence Replace Ultrasound As A Complementary Tool To Mammogram For The Detection And The Diagnosis Of The Breast Cancer?

Participants
Sahar Mansour, MD, Cairo, Egypt (*Presenter*) Nothing to Disclose

PURPOSE

to study the impact of artificial intelligence (AI) on the performance of mammogram with regards the discrimination not just the detection of breast cancer in correlation mammograms aided with ultrasound.*Methods and Materials Ethics committee approval was obtained in this prospective analysis. The study included 2000 mammograms. The mammograms were interpreted by the radiologists, breast ultrasound was performed for all cases and the Breast Imaging Reporting and Data System (BI-RADS) score was applied accordingly. Each breast side was individually assessed with the aid of AI scanning in the form of targeted heat-map and a probability of malignancy (abnormality scoring percentage) was obtained. Operative data were the gold standard.*Results Normal assigned cases (BI-RADS 1) with no lesions were excluded from the statistical evaluation. The study included 538 benign and 642 malignant category breasts (n=1180, 59%). ACR BI-RADS categories for the breast lesions as regards the combined evaluation of the digital mammogram and ultrasound were assigned BI-RADS 2 (Benign) in 385 lesions with AI median value of the abnormality scoring percentage of 10, (n=385/1180, 32.6%), and BI-RADS 5 (malignant) in 471, that had showed median percentage AI value of 88 (n=471/1180, 39.9%). AI abnormality scoring of 59% yielded a sensitivity of 96.8% and specificity of 90.1% in the discrimination of the breast lesions detected on the included mammograms.*Conclusions Artificial intelligence (AI) could be considered as an optional reliable complementary tool to the digital mammogram for the evaluation of the breast lesions. The color hue and the abnormality scoring percentage presented a credible method for the detection and discrimination of breast cancer comparable to the breast ultrasound. So consequently, AI- mammogram combination could be used as a one setting method to discriminate between cases that require further imaging or biopsy from those that need only time interval follow up.*Clinical Relevance/Application Recently, the indulgence of AI in the work up for the detection of breast cancer and the probability that it could help the diagnosis, the choice of the treatment, the patient's outcome, and the workflow areas in the field of radiology became seriously considered. In the current work, the performance of the artificial intelligence was studied with regard the diagnosis not just the detection of breast cancer in lesions detected on mammography.

RESULTS

Normal assigned cases (BI-RADS 1) with no lesions were excluded from the statistical evaluation. The study included 538 benign and 642 malignant category breasts (n=1180, 59%). ACR BI-RADS categories for the breast lesions as regards the combined evaluation of the digital mammogram and ultrasound were assigned BI-RADS 2 (Benign) in 385 lesions with AI median value of the abnormality scoring percentage of 10, (n=385/1180, 32.6%), and BI-RADS 5 (malignant) in 471, that had showed median percentage AI value of 88 (n=471/1180, 39.9%). AI abnormality scoring of 59% yielded a sensitivity of 96.8% and specificity of 90.1% in the discrimination of the breast lesions detected on the included mammograms.

CLINICAL RELEVANCE/APPLICATION

Recently, the indulgence of AI in the work up for the detection of breast cancer and the probability that it could help the diagnosis, the choice of the treatment, the patient's outcome, and the workflow areas in the field of radiology became seriously considered. In the current work, the performance of the artificial intelligence was studied with regard the diagnosis not just the detection of breast cancer in lesions detected on mammography.

CH01-A5   **Leveraging Serial CT Scans In Deep-feature Reinforcement Learning Model For Improvement Of Early Diagnosis Of Lung Cancer**

Participants
Yifan Wang, ANN ARBOR, Michigan (*Presenter*) Nothing to Disclose

PURPOSE

To develop a deep reinforcement learning (D-RL) model with serial CT scans to improve early diagnosis of lung cancer at the baseline CT scan.*Methods and Materials We formulated the classification of malignant and benign lung nodules as a Markov decision process, and used the RL method to learn stochastic policies that make a sequence of decisions according to serial screening exams by mapping the state (the features characterized nodule patterns) to the nodule's risk of malignancy (decision). Our customary mapping was designed based on a value function that represents the expected cumulative reward associated with the lung cancer risk. The functional values were increased when the nodules were diagnosed as malignant and vice versa, or no change when follow-ups were required in the next annual exam. With access permission from the National Lung Screening Trial (NLST) project, a data set of 653 cases was randomly selected as the training set. Of the 653 cases, 260 were diagnosed with lung cancer and 393 were negative. The subjects had 1 to 3 years of CT exams from baseline to diagnosis or stayed negative in the 3-year study period, resulting in a total of 1345 CT scans. We trained a VGG deep learning network as an encoder to extract 64 features to characterize the patterns for each nodule in each CT scan. As lung cancer biologically progresses over time, the RL method served as the decoder to map the evolving patterns for malignant or benign nodules in the serial scans. We finally trained the new D-RL model using 1,345 CT scans from all available years, and another D-RL model using only 653 scans from the baseline year for comparison. The models were deployed to 300 first-year baseline CT scans in an independent test set containing 150 malignant and 150 benign cases. The area under the receiver operating characteristic (ROC) curve (AUC) was used for performance evaluation.*Results Our D-RL model trained with serial scans achieved a test AUC of 0.856 ± 0.025 while the D-RL model trained with only baseline scan achieved a test AUC of 0.825 ± 0.021.*Conclusions The D-RL model trained with 3-year serial CT screening scans could achieve higher accuracy in diagnosing lung cancer 1 or 2 years earlier in baseline CT exams.*Clinical Relevance/Application Accurate early diagnosis is crucial for lung cancer screening program. The serial-exam-trained reinforcement learning model has the potential to improve early diagnosis, allowing better treatment options.

RESULTS

Our D-RL model trained with serial scans achieved a test AUC of 0.856 ± 0.025 while the D-RL model trained with only baseline scan achieved a test AUC of 0.825 ± 0.021.

CLINICAL RELEVANCE/APPLICATION

Accurate early diagnosis is crucial for lung cancer screening program. The serial-exam-trained reinforcement learning model has the potential to improve early diagnosis, allowing better treatment options.

CH01-A6   **Automated Segmentation Of Pleural Effusion Subtypes In Computed Tomography Using Deep Learning**

Participants
Raphael Sexauer, MD, Basel, Switzerland (*Presenter*) Nothing to Disclose

PURPOSE

Pleural effusion is a common finding in cross-sectional imaging, but is currently reported in a qualitative, non-standardized way. Quantification is feasible but usually not performed in clinical routine, since manual segmentation is time-consuming. Therefore, the aims of this study were to develop an algorithm on CT scans to 1) detect 2) segment and 3) quantify pleural effusions.*Methods and Materials All written radiological reports from 01/2016 to 01/2021 with pleural effusions were queried for the following terms: "blood", "loculation", "pleural enhancement or pleural thickening", "pleural plaques, calcification or nodularity", "gas bubbles or pneumothorax", "chest tube" and "subdiaphragmatic fluid". Studies including none of these terms were rated as "no finding", studies with one term as "one finding", two or more terms as "findings". Assuming a normal distribution (n = 2659), we randomly selected 6% of the data for the semi-manual segmentation of the pleural space (n = 160; no finding = 106; one finding = 27; findings = 27). We also added 160 patients without pleural effusion as a negative cohort. Deep convolutional neural network algorithms were trained and cross-validated using semi-automatically (lung) and manually (effusion) generated segmentations (n = 224; 70%) and tested on a separate test subset (n = 96; 30%). To measure performance we used sensitivity, specificity and ROC curves for detection and Dice coefficient, Jaccard and volume analysis for the segmentation task.*Results The sensitivity and specificity to detect effusion was 99% and 98% (n=96, AUC: 99,6, test data). The algorithm showed a robust segmentation (Dice coefficient median: 88.9, mean: 83.8, CI 80.1-87.5), irrespective of volume, pleural complexity or contrast phase.*Conclusions Using a heterogeneous data set, a robust model was developed that detects pleural effusions, quantifies effusion volume and classifies subtypes. This implementation will improve clinical workflows by adding automated quantification.*Clinical Relevance/Application The model can be used in the clinical routine for the detection and quantification of pleural effusions (ml).

RESULTS

The sensitivity and specificity to detect effusion was 99% and 98% (n=96, AUC: 99,6, test data). The algorithm showed a robust segmentation (Dice coefficient median: 88.9, mean: 83.8, CI 80.1-87.5), irrespective of volume, pleural complexity or contrast phase.

CLINICAL RELEVANCE/APPLICATION

The model can be used in the clinical routine for the detection and quantification of pleural effusions (ml).

CH01-A7   Idiopathic Pulmonary Fibrosis: A Radiology Resident's Guide

Participants
Nidhi Reddy, MD, Wauwatosa, Wisconsin (*Presenter*) Nothing to Disclose

TEACHING POINTS

Identify high-resolution CT (HRCT) findings commonly seen in Interstitial Lung Disease (ILD), with specific attention to Usual Interstitial Pneumonia (UIP) and Idiopathic Pulmonary Fibrosis (IPF) using an image-rich approach from our institution's database Review the American Thoracic Society clinical practice guidelines for the Diagnosis of IPF published in 2018, with emphasis on the radiologist's role in diagnostic evaluation of patients with suspected ILD/IPF Troubleshoot probable or indeterminate UIP cases and guide clinicians in next steps of work-up Narrowing the differential when an alternative diagnosis is suggested based on HRCT findings and their distribution

TABLE OF CONTENTS/OUTLINE

Introduction and epidemiology Clinical presentation and diagnostic criteria for IPF • Physical exam findings • Pulmonary function tests • Serology Diagnosis of IPF: ATS Guidelines 2018 • HRCT parameters/protocol • Findings and distribution in definite, probable, indeterminate, and alternative UIP patterns • Case review Histopathologic Diagnosis • Surgical biopsy • Endobronchial tissue sampling/bronchoalveolar lavage Clinical management • Acute IPF exacerbation • Antifibrotics Mimics of UIP/IPF • Non-specific interstitial pneumonia • Chronic hypersensitivity pneumonitis • Connective-tissue related interstitial lung disease

NPM03-C1   Racial Inequities In The Use Of Diagnostic Imaging: A Systematic Review

Participants
Rebecca Colwell, La Crosse, Wisconsin (*Presenter*) Nothing to Disclose

PURPOSE

Diagnostic imaging plays a fundamental role in modern medical practice. Disparities in access to imaging based on patient race and ethnicity have been documented in multiple studies across a wide range of clinical practice settings and may play a role in other racial inequities in the health care system. The aim of this study was to summarize the existing literature on race-based inequities in diagnostic imaging and highlight priority areas for further research.*Methods and Materials Using key words focused on diagnostic imaging, race/ethnicity, and health disparities, we performed a systematic review of the literature in Medline, Cochrane, Web of Science, and Scopus for the years 2000 to the present. Citations were reviewed for relevance by title and abstract and then full text review. Papers were included if they compared rates of diagnostic imaging use by patient race and ethnicity. The included articles underwent data extraction including title, country of origin, publication year, number of participants, participant demographics, data source, clinical care setting, article conclusion, and whether health outcomes or strategies to promote health equity were evaluated.*Results The search strategy returned 2908 non-duplicate papers of which 2510 were removed by title/abstract review and 224 by full text review leaving 174 meeting inclusion criteria. 86% of studies (n=149) were conducted in the United States and over half (52%, n=91) used nationally representative data from government administered surveys or insurance claims. The majority (57%, n=99) were focused on breast cancer screening followed by general diagnostic imaging (10%, n=17), neurologic imaging (7%, n=12), cancer care (6%, n=10), and a variety of other less represented topics. 70% (n=121) of studies found disparities in imaging use in some or all of the minority groups evaluated. 10% (n=17) of studies reported health outcomes and 8% (n=14) evaluated strategies to mitigate race-based imaging disparities.*Conclusions Disparities based on patient race and ethnicity exist in multiple care settings within diagnostic radiology. Many of the existing studies are clustered on a narrow range of topics, and only a small minority of studies evaluated patient health outcomes or tested strategies to mitigate disparities suggesting that these may be avenues for future research.*Clinical Relevance/Application Although there is substantial existing literature on racial disparities in diagnostic radiology, much remains unknown. Radiologists are well-equipped to better evaluate disparities across a variety of care settings, connect inequities in imaging to patient health outcomes, and identify and evaluate strategies to promote equity in radiologic care.

RESULTS

The search strategy returned 2908 non-duplicate papers of which 2510 were removed by title/abstract review and 224 by full text review leaving 174 meeting inclusion criteria. 86% of studies (n=149) were conducted in the United States and over half (52%, n=91) used nationally representative data from government administered surveys or insurance claims. The majority (57%, n=99) were focused on breast cancer screening followed by general diagnostic imaging (10%, n=17), neurologic imaging (7%, n=12), cancer care (6%, n=10), and a variety of other less represented topics. 70% (n=121) of studies found disparities in imaging use in some or all of the minority groups evaluated. 10% (n=17) of studies reported health outcomes and 8% (n=14) evaluated strategies to mitigate race-based imaging disparities.

CLINICAL RELEVANCE/APPLICATION

Although there is substantial existing literature on racial disparities in diagnostic radiology, much remains unknown. Radiologists are well-equipped to better evaluate disparities across a variety of care settings, connect inequities in imaging to patient health outcomes, and identify and evaluate strategies to promote equity in radiologic care.

NPM03-C2   Understanding How Patients Define Value With Respect To Imaging Center Attributes And Radiologist Interaction

Participants
Kayla Berigan, MD, Burlington, Vermont (*Presenter*) Nothing to Disclose

PURPOSE

In the value-based care era, providers are accountable for patient experience, and radiology societies encourage radiologists to be more patient-facing. Gaps remain, however, in understanding the attributes of imaging services that matter to patients and the type of interaction they desire with radiologists. This study assessed patient prioritization of some of these attributes using a discrete choice experiment (DCE).*Methods and Materials A representative sample of US adults was asked to consider a hypothetical urgent x-ray encounter. Participants indicated their preferences for a set of hypothetical imaging locations with different combinations of attributes. Attributes included image-interpreting doctor specialty, PCP recommendation, wait time to results, out of pocket cost, travel time, wait time to appointment, staff sensitivity, Medicare star rating, and online scheduling availability. Data were analyzed using a mixed logit model. Participant understanding of a radiologist's role and preferences for interaction with radiologists and ordering providers were also assessed.*Results Presented herein are preliminary data from 121 of the 400 total participants in the study. Image-interpreting doctor specialty, PCP recommendation, staff sensitivity, reputation, and online scheduling increased preference for a location, whereas higher out of pocket cost decreased preference. Models estimated a

willingness to pay of $99 for interpretation by a sub-specialty radiologist, $78 for PCP recommendation, $19 for staff sensitivity, and $29 for an additional CMS star. Only 32.47% of participants correctly identified the role of a radiologist from a list of options. Preferences for interaction with radiologists and ordering providers varied somewhat across respondents. Overall, there was a strong preference for going over results and discussing next steps with ordering providers, with relatively low priority placed on meeting the radiologist in person.*Conclusions Patients place high value on subspecialty reads and recommendations of imaging centers by PCPs, factors not captured by existing quality metrics for Radiology. Staff sensitivity, a focus of current patient experience metrics, may be of less importance to patients. Finally, patient education about the radiologist role is needed before preferences for radiologist interaction can reliably be assessed.*Clinical Relevance/Application Insight into what patients value when it comes to their imaging experiences and their interactions with radiologists will inform the ongoing transition to patient-centered care in Radiology.

RESULTS

Presented herein are preliminary data from 121 of the 400 total participants in the study. Image-interpreting doctor specialty, PCP recommendation, staff sensitivity, reputation, and online scheduling increased preference for a location, whereas higher out of pocket cost decreased preference. Models estimated a willingness to pay of $99 for interpretation by a sub-specialty radiologist, $78 for PCP recommendation, $19 for staff sensitivity, and $29 for an additional CMS star. Only 32.47% of participants correctly identified the role of a radiologist from a list of options. Preferences for interaction with radiologists and ordering providers varied somewhat across respondents. Overall, there was a strong preference for going over results and discussing next steps with ordering providers, with relatively low priority placed on meeting the radiologist in person.

CLINICAL RELEVANCE/APPLICATION

Insight into what patients value when it comes to their imaging experiences and their interactions with radiologists will inform the ongoing transition to patient-centered care in Radiology.

NPM03-C3 Women Utilizing Computers For Healthcare Tasks Are More Likely To Undergo Breast Cancer Screening: Digital Divide Widening Healthcare Disparities

Participants
Patricia Balthazar, MD, Atlanta, Georgia (*Presenter*) Nothing to Disclose

PURPOSE

We aimed to 1) identify patient characteristics associated with utilization of computers to schedule an appointment with a health care provider; and 2) determine if patients utilizing computers for healthcare-related tasks are more likely to utilize breast cancer screening.*Methods and Materials A retrospective analysis was conducted of female respondents aged 40-74 years without history of breast cancer to the 2018 National Health Interview Survey, a large publicly available cross-sectional survey database representative of the non-institutionalized, civilian, United States population. We compared sociodemographic characteristics of survey respondents who reported using a computer to schedule an appointment with a health care provider with respondents who did not report using a computer to schedule an appointment with a health care provider. Multivariable logistic regression was used to evaluate the potential association between computer utilization (including the following healthcare-related tasks: look up health information on the Internet, fill a prescription, schedule an appointment with a health care provider, communicate with a health care provider by email) in the last 12 months and reported utilization of screening mammography within the last year.*Results Among 6,511 women meeting inclusion criteria, 1,100 (18.6%) reported using a computer to schedule an appointment with a health care provider. These women were more frequently younger (53.4 vs. 56.3 years; p<0.001), White (73% vs. 65%; p<0.001), from a higher mean household income ($112,627 vs. $80,162; p<0.001), more educated (85% college level or above vs. 61%; p<0.001), married (76% vs. 73%; p= 0.031), insured (96% vs. 90%; p<0.001), and employed (73% vs. 59%; p<0.001). Utilization of screening mammography was positively associated with computer utilization for all the evaluated healthcare-related tasks: look up health information on the Internet (OR 1.3 [95% CI 1.1-1.5]), fill a prescription (1.6 [1.3-1.9], schedule an appointment with a health care provider (1.3 [1.1-1.6]), communicate with a health care provider by email (1.5 [1.3-1.8]).*Conclusions Female participants who used computers for health care related tasks were more likely to be white, higher income, employed, insured, and have higher levels of education. Female participants who used computers for health care related tasks were more likely to report breast cancer screening.*Clinical Relevance/Application Reliance on digital portals and online scheduling may exacerbate health disparities.

RESULTS

Among 6,511 women meeting inclusion criteria, 1,100 (18.6%) reported using a computer to schedule an appointment with a health care provider. These women were more frequently younger (53.4 vs. 56.3 years; p<0.001), White (73% vs. 65%; p<0.001), from a higher mean household income ($112,627 vs. $80,162; p<0.001), more educated (85% college level or above vs. 61%; p<0.001), married (76% vs. 73%; p= 0.031), insured (96% vs. 90%; p<0.001), and employed (73% vs. 59%; p<0.001). Utilization of screening mammography was positively associated with computer utilization for all the evaluated healthcare-related tasks: look up health information on the Internet (OR 1.3 [95% CI 1.1-1.5]), fill a prescription (1.6 [1.3-1.9], schedule an appointment with a health care provider (1.3 [1.1-1.6]), communicate with a health care provider by email (1.5 [1.3-1.8]).

CLINICAL RELEVANCE/APPLICATION

Reliance on digital portals and online scheduling may exacerbate health disparities.

MS04-A1   **CT Imaging In Pregnant Trauma: Findings Of Uterine And Placental Injury**

Participants
Kacie Steinbrecher, MD, Saint Louis, Missouri (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this study was to assess the diagnostic performance of computed tomography (CT) in the diagnosis of placental abruption and determine which imaging findings correlate with clinical diagnosis.*Methods and Materials Sixty-five pregnant patients (mean gestational age, 23.8 weeks [range 4-39 weeks]; mean age, 26.3 years [range 18-44 years]) underwent CT for the evaluation of trauma between 2010 and 2019. Two radiologists independently and retrospectively reviewed each case. Various imaging characteristics were correlated with clinical outcome. The reference standard for clinical abruption was non-reassuring fetal status requiring early delivery. The standard for pathologic placental abruption was the presence of fibrin and clots within the placenta.*Results Incidence of clinical abruption in the present study was 18% (13 patients). In these patients, the mean percentage of placental enhancement was 46% in the clinically-abrupted group versus 87% for the non-clinically abrupted group (p < 0.05) Nine of 13 patients (79%) with clinical abruption demonstrated full thickness enhancement defects whereas 14 of 52 patients (27%) without clinical abruption also demonstrated full thickness enhancement defects of the placenta.*Conclusions Contrary to popular teaching, full thickness placental enhancement defects were found to be both insensitive and non-specific for both the clinical and pathologic diagnosis of placental abruption. In contrast, the percentage of placental enhancement may be a more useful diagnostic tool as there was a statistically significant difference between the means.*Clinical Relevance/Application As CT is often avoided in pregnancy to prevent unnecessary radiation exposure, lack of familiarity with both the normal and abnormal placental appearance can add to diagnostic confusion. In this study, we determined that percentage of placental enhancement was the imaging finding best correlate to the diagnosis of placental abruption in trauma. In assessing for this finding, diagnostic radiologists can suggest the possibility of placental abruption and expedite triage and care of pregnant trauma patients.

RESULTS

Incidence of clinical abruption in the present study was 18% (13 patients). In these patients, the mean percentage of placental enhancement was 46% in the clinically-abrupted group versus 87% for the non-clinically abrupted group (p < 0.05) Nine of 13 patients (79%) with clinical abruption demonstrated full thickness enhancement defects whereas 14 of 52 patients (27%) without clinical abruption also demonstrated full thickness enhancement defects of the placenta.

CLINICAL RELEVANCE/APPLICATION

As CT is often avoided in pregnancy to prevent unnecessary radiation exposure, lack of familiarity with both the normal and abnormal placental appearance can add to diagnostic confusion. In this study, we determined that percentage of placental enhancement was the imaging finding best correlate to the diagnosis of placental abruption in trauma. In assessing for this finding, diagnostic radiologists can suggest the possibility of placental abruption and expedite triage and care of pregnant trauma patients.

SDP-NPM-1 **Sociodemographic And Geographic Disparities In Obstetrical Ultrasound Imaging Utilization: A Population-based Study**

Participants
Scott Adams, MD, Saskatoon, Saskatchewan (*Presenter*) Nothing to Disclose

PURPOSE

Obstetrical ultrasound imaging is an important part of prenatal care, though not all patients have readily available access to ultrasound services. This study aimed to assess the relationship between sociodemographic and geographic factors and (1) having a second trimester complete obstetrical ultrasound and (2) overall obstetrical ultrasound utilization.*Methods and Materials All pregnancies and obstetrical ultrasound exams billed from 2014-2018 in Saskatchewan, Canada were identified from province-wide databases. Generalized estimating equation models with binomial and Poisson distributions were used to identify factors associated with having a second trimester ultrasound and overall obstetrical ultrasound utilization, respectively.*Results 80,536 pregnancies from 57,881 individuals were included. Of 57,186 pregnancies carried to =23 weeks, a second trimester ultrasound was performed in 50,180 (87.7%). Patients living in higher income neighbourhoods (adjusted odds ratio [aOR], 1.86 for highest vs. lowest quintile; 95% confidence interval [CI], 1.63-2.12; p<0.0001) were more likely to have a second trimester ultrasound. Patients living in rural areas (aOR, 0.70; 95% CI, 0.64-0.77; p<0.0001), remote areas (aOR, 0.49 for greatest vs. least remoteness level; 95% CI, 0.42-0.59; p<0.0001), and status First Nations individuals (aOR, 0.49; 95% CI, 0.46-0.53; p<0.0001) were less likely to have a second trimester ultrasound. Poisson regression analysis demonstrated these same factors, except rural residence, were associated with overall obstetrical ultrasound utilization.*Conclusions Substantial disparities in obstetrical ultrasound utilization exist among patients in remote geographic areas, Indigenous peoples, and patients in low income neighbourhoods. Addressing barriers which these demographic groups face in accessing ultrasound imaging is critical to ensure health equity.*Clinical Relevance/Application Significant variation in obstetrical ultrasound utilization across the health system suggests there is a need for radiology leaders to develop targeted approaches to ensure equitable access to obstetrical ultrasound for specific demographic groups, including patients in remote communities, Indigenous peoples, and low-income patients. Potential solutions to reduce disparities in obstetrical ultrasound utilization may include culturally-safe outreach, a culturally-safe clinic environment, sonographer recruitment and retention in rural and remote communities, telerobotic ultrasound technology, and increased collaboration with referring clinicians.

RESULTS

80,536 pregnancies from 57,881 individuals were included. Of 57,186 pregnancies carried to =23 weeks, a second trimester ultrasound was performed in 50,180 (87.7%). Patients living in higher income neighbourhoods (adjusted odds ratio [aOR], 1.86 for highest vs. lowest quintile; 95% confidence interval [CI], 1.63-2.12; p<0.0001) were more likely to have a second trimester ultrasound. Patients living in rural areas (aOR, 0.70; 95% CI, 0.64-0.77; p<0.0001), remote areas (aOR, 0.49 for greatest vs. least remoteness level; 95% CI, 0.42-0.59; p<0.0001), and status First Nations individuals (aOR, 0.49; 95% CI, 0.46-0.53; p<0.0001) were less likely to have a second trimester ultrasound. Poisson regression analysis demonstrated these same factors, except rural residence, were associated with overall obstetrical ultrasound utilization.

CLINICAL RELEVANCE/APPLICATION

Significant variation in obstetrical ultrasound utilization across the health system suggests there is a need for radiology leaders to develop targeted approaches to ensure equitable access to obstetrical ultrasound for specific demographic groups, including patients in remote communities, Indigenous peoples, and low-income patients. Potential solutions to reduce disparities in obstetrical ultrasound utilization may include culturally-safe outreach, a culturally-safe clinic environment, sonographer recruitment and retention in rural and remote communities, telerobotic ultrasound technology, and increased collaboration with referring clinicians.

SDP-NPM-10 **Leadership Titles In Radiology: Usage Of Non-inclusive Terminology Among Academic Radiology Departments And Societies**

Participants
Alan Shan, MD, Los Angeles, California (*Presenter*) Nothing to Disclose

PURPOSE

Non-inclusive terminology, including gender-specific titles like "chairman" and potentially culturally-insensitive terms like "chief," have traditionally been used to describe leaders of academic radiology departments and/or divisions. These terms are problematic, as they may reinforce historical gender hierarchies and racial biases. However, the prevalence of these terms has not yet been systematically evaluated.The purpose of this study was to characterize the use of gender-specific (chairman) and non-inclusive terminology (chief) to describe departmental and divisional/sectional leadership within academic radiology department and radiological society websites.*Methods and Materials From a total of 157 unique institutions identified, we gathered a list of 123 departments with functioning websites. We screened for use of the terms "chairman" and "chief" on departmental home pages, welcome messages, faculty listings, and residency program pages, noting location on websites and alternative terms, if present. We also assessed for use of "chairman" through a list of 14 radiological society websites. The overall usage of these terms was determined and the relationships between geographic region, faculty gender, and use of terminology were assessed.*Results

"Chairman" is common among radiology department websites, with 42.1% (51/121) of websites using the term at least once. Usage of "chairman" was higher in departments whose chairs were men (OR 4.32, 95% CI: 1.36-13.69) and lower in those located in the Midwest (versus Northeast, OR 0.34, 95% CI: 0.12-0.96). Use of "chief" is extremely common among departments listing divisional leadership, at 82.7% (67/81). Alternative terms used included "chair," "head," "chairperson," and "director." Among departments, the proportion of women in leadership roles is low, representing 19.7% (22/122) of chairs and 31.1% (272/874) of other leadership. Radiological societies were unlikely to use "chairman," with only one website using the term.*Conclusions Use of "chairman" and "chief" is frequent among academic radiology departments. Radiological societies, in contrast, seldom used "chairman," suggesting a more progressive approach to leadership titles in these professional groups. Further efforts should be made to assess the usage of non-inclusive terminology and its potential impact within academic radiology departments with consideration of alternative terms, such as "head" or "chair" (Table 1).*Clinical Relevance/Application We highlight the high prevalence of non-inclusive terminology in leadership titles in radiology departments. The use of these terms, such as "chairman" and "chief" should be reconsidered, as they may perpetuate gender and racial biases.

RESULTS

"Chairman" is common among radiology department websites, with 42.1% (51/121) of websites using the term at least once. Usage of "chairman" was higher in departments whose chairs were men (OR 4.32, 95% CI: 1.36-13.69) and lower in those located in the Midwest (versus Northeast, OR 0.34, 95% CI: 0.12-0.96). Use of "chief" is extremely common among departments listing divisional leadership, at 82.7% (67/81). Alternative terms used included "chair," "head," "chairperson," and "director." Among departments, the proportion of women in leadership roles is low, representing 19.7% (22/122) of chairs and 31.1% (272/874) of other leadership. Radiological societies were unlikely to use "chairman," with only one website using the term.

CLINICAL RELEVANCE/APPLICATION

We highlight the high prevalence of non-inclusive terminology in leadership titles in radiology departments. The use of these terms, such as "chairman" and "chief" should be reconsidered, as they may perpetuate gender and racial biases.

SDP-NPM-11 Health Disparities In Systemic Staging Of Rectal Cancer

Participants
Jessica Colin Escobar, Irvine, California (*Presenter*) Nothing to Disclose

PURPOSE

To assess health disparity in initial systemic staging of rectal cancer in race, ethnicity, insurance coverage, socioeconomic status.*Methods and Materials We reviewed consecutive rectal adenocarcinoma cases at a high volume colorectal academic institution from 2013-2019. Patients with indeterminant workup history, or initial work up performed outside of United States were excluded. We recorded the date of diagnosis, date of systemic staging imaging exam, type of systemic staging, CT vs PET/CT, if CT, whether chest abdomen and pelvis were performed or only CT abdomen and pelvis were performed, age, gender, insurance type, residence zip-code. Chi square and t-tests, as well as linear and logistic regression models were utilized for analysis.*Results 266 subjects were included. Racial/ethnic categories were non-Hispanic white were 49.8%, Hispanic 22.5%, Asian 19.5%, and African-American 2.6%. Insurance coverage was private in 49.8% and public in 48.2%. 40.4% were from zip code income median family income greater than 100,000$ per year. 96.6% had some type of systemic imaging evaluation at initial staging. 63.4% had CT chest, abdomen and pelvis, as recommended by NCCN guidelines. 33. 9% had PET/CT. 12.4% had only CT abdomen and pelvis, with no CT chest. Hispanics had higher rate of incomplete systemic evaluation compared to non Hispanic whites, odd ratio (OR) = 3.7 (95 % confidence interval [CI] 1.6 to 8.6, P = 0.003). Lower socioeconomic status also had a lower rate of completing systemic staging, odd ratio (OR) = 3.8 (95% confidence interval [CI] 1.6 to 8.8, P = 0.002). No significant difference was noted between public vs. private insurance coverage, odd ratio (OR) = 1.18 (95% confidence interval [CI] 0.58 to 2.4, P = 0.64).Among private insurance and Medicare-covered 8.3% and 9.0% had both CT chest, abdomen and pelvis and PET/CT. None of the 48 Medicaid patients had both modality. Non-Hispanic white had shorter time interval between the date of diagnosis compared to Hispanic, average days, 21.2 ± SD 28.1 days compared to 32.6 ± SD 50.7 days(P=0.07). Private insurance coverage had shorter time interval between diagnosis and exam, average 19.0 ± SD 32.9 days days compared to Medicaid 25.9 ± SD 36.3 days (P=0.27).*Conclusions Significant disparity was present in systemic initial staging evaluation for rectal cancer, between race/ethnicity and socioeconomic status.*Clinical Relevance/Application Health disparity in initial systemic staging rectal cancer, associated with minority race/ethnicity, lower socioeconomic status and inadequate insurance coverage, is a gap that needs to be addressed in order to achieve to health equity and improved population outcome.

RESULTS

266 subjects were included. Racial/ethnic categories were non-Hispanic white were 49.8%, Hispanic 22.5%, Asian 19.5%, and African-American 2.6%. Insurance coverage was private in 49.8% and public in 48.2%. 40.4% were from zip code income median family income greater than 100,000$ per year. 96.6% had some type of systemic imaging evaluation at initial staging. 63.4% had CT chest, abdomen and pelvis, as recommended by NCCN guidelines. 33. 9% had PET/CT. 12.4% had only CT abdomen and pelvis, with no CT chest. Hispanics had higher rate of incomplete systemic evaluation compared to non Hispanic whites, odd ratio (OR) = 3.7 (95 % confidence interval [CI] 1.6 to 8.6, P = 0.003). Lower socioeconomic status also had a lower rate of completing systemic staging, odd ratio (OR) = 3.8 (95% confidence interval [CI] 1.6 to 8.8, P = 0.002). No significant difference was noted between public vs. private insurance coverage, odd ratio (OR) = 1.18 (95% confidence interval [CI] 0.58 to 2.4, P = 0.64).Among private insurance and Medicare-covered 8.3% and 9.0% had both CT chest, abdomen and pelvis and PET/CT. None of the 48 Medicaid patients had both modality. Non-Hispanic white had shorter time interval between the date of diagnosis compared to Hispanic, average days, 21.2 ± SD 28.1 days compared to 32.6 ± SD 50.7 days(P=0.07). Private insurance coverage had shorter time interval between diagnosis and exam, average 19.0 ± SD 32.9 days days compared to Medicaid 25.9 ± SD 36.3 days (P=0.27).

CLINICAL RELEVANCE/APPLICATION

Health disparity in initial systemic staging rectal cancer, associated with minority race/ethnicity, lower socioeconomic status and inadequate insurance coverage, is a gap that needs to be addressed in order to achieve to health equity and improved population outcome.

SDP-NPM-12 Trends In Medicare Part B Payments And Utilization For Imaging Services Between 2009 And 2019

Participants
Monica Kassavin, Cleveland, Ohio (*Presenter*) Nothing to Disclose

PURPOSE

In 2019, the total National Healthcare Expenditure (NHE) reached $3.8 trillion, or nearly 20% of the total Gross Domestic Product (GDP). This represents a 4-fold increase in its GDP share since 1960. Given the magnitude and growth of such expenditures, healthcare cost containment is central to the country's financial sustainability. Moreover, as Medicare represents nearly 20% of the total NHE, it is a primary target for piloting, implementing and scaling initiatives that reduce expenditures.The purpose of this study is to assess trends in Medicare Physician Fee Schedule for Service (Part B) payments and utilization for Imaging relative to other services from 2009 through 2019.*Methods and Materials We conducted a retrospective observational study of annual expenditures and utilization of imaging services using data from Centers for Medicare and Medicaid Services (CMS) Medicare Part B. Data was grouped according to the Berenson-Eggers Type of Service Classification. The values were adjusted for inflation and we calculated the annual changes and the compound annual growth rates and the price elasticity of supply.*Results For the 10-year period, Imaging represented on average 8% of the total Medicare Part B expenditures, an equivalent of 1.4% of total Medicare expenditures or 0.05% of the NHE. While NHE, overall Medicare and overall Part B had positive growth rates of total expenditures, Imaging did not. Moreover, Imaging had the most negative CAGR compared to all other categories, including Drugs, Procedures, Evaluation and Management and Durable Medical Equipment.*Conclusions Imaging did not contribute to the increase in Medicare Part B expenditures, and it might have been disproportionately affected by cost containment policies.*Clinical Relevance/Application While annual adjustments in physician fees are aiming for budget neutrality as a final goal, the impact on categories (e.g., Imaging) and specialties (e.g., Radiology) may not be effectively assessed with the current CMS strategy.

RESULTS

For the 10-year period, Imaging represented on average 8% of the total Medicare Part B expenditures, an equivalent of 1.4% of total Medicare expenditures or 0.05% of the NHE. While NHE, overall Medicare and overall Part B had positive growth rates of total expenditures, Imaging did not. Moreover, Imaging had the most negative CAGR compared to all other categories, including Drugs, Procedures, Evaluation and Management and Durable Medical Equipment.

CLINICAL RELEVANCE/APPLICATION

While annual adjustments in physician fees are aiming for budget neutrality as a final goal, the impact on categories (e.g., Imaging) and specialties (e.g., Radiology) may not be effectively assessed with the current CMS strategy.

SDP-NPM-2   A Telerobotic Ultrasound Clinic Model Of Ultrasound Service Delivery To Improve Access To Imaging In Rural And Remote Communities

Participants
Scott Adams, MD, Saskatoon, Saskatchewan (*Presenter*) Nothing to Disclose

PURPOSE

Patients living in many rural and remote areas do not have readily available access to ultrasound services due to a lack of sonographers and radiologists in these communities. As a potential solution to improve access to ultrasound imaging, telerobotic ultrasound is a technology which allows a sonographer or radiologist to remotely manipulate an ultrasound probe and control ultrasound machine settings, allowing sonographers and radiologists to remotely perform an ultrasound exam. The purpose of this study was to determine the feasibility of using telerobotic ultrasound to establish a service delivery model to remotely provide diagnostic ultrasound services in rural and remote communities.*Methods and Materials Telerobotic ultrasound clinics were developed in three remote communities more than 500 km away from our academic medical centre. Sonographers remotely performed all ultrasound exams using telerobotic ultrasound systems and exams were subsequently interpreted by radiologists at an academic medical centre. A mixed-methods approach was used to evaluate telerobotic ultrasound as a potential service delivery model to remotely provide ultrasound services, with consideration given to diagnostic assessment, patient experience, and health system and radiology practice integration. Diagnostic performance was assessed by each interpreting radiologist using a standardized reporting form. Patient experience was assessed through quantitative and qualitative analysis of survey responses and operational challenges and solutions were identified.*Results Eighty-seven telerobotic ultrasound exams were remotely performed and included in this study, with the most frequent exam types being abdominal (n=35), first trimester obstetrical (n=26), and second trimester complete obstetrical (n=12). Across all exam types, 70% of telerobotic ultrasound exams were sufficient for diagnosis, minimizing travel or reducing wait times for these patients. Ninety-five percent of patients would be willing to have another telerobotic ultrasound exam in the future. Operational challenges were related to technical infrastructure, human resources, and coordination between clinic sites.*Conclusions Telerobotic ultrasound can provide access to diagnostic ultrasound services for patients in underserved rural and remote communities without regular ultrasound services, thereby reducing disparities in access to care and improving health equity.*Clinical Relevance/Application Radiology practices may wish to consider implementing telerobotic ultrasound technology in underserved rural and remote communities in their region to improve patient access to ultrasound imaging.

RESULTS

Eighty-seven telerobotic ultrasound exams were remotely performed and included in this study, with the most frequent exam types being abdominal (n=35), first trimester obstetrical (n=26), and second trimester complete obstetrical (n=12). Across all exam types, 70% of telerobotic ultrasound exams were sufficient for diagnosis, minimizing travel or reducing wait times for these patients. Ninety-five percent of patients would be willing to have another telerobotic ultrasound exam in the future. Operational challenges were related to technical infrastructure, human resources, and coordination between clinic sites.

CLINICAL RELEVANCE/APPLICATION

Radiology practices may wish to consider implementing telerobotic ultrasound technology in underserved rural and remote communities in their region to improve patient access to ultrasound imaging.

SDP-NPM-3   Demographic, Socioeconomic Status (SES) And Nodule Risk Can Accurately Predict Adherence To Follow Up Of Incidental Pulmonary Nodules

Participants
Eduardo J. Mortani Barbosa JR, MD, Philadelphia, Pennsylvania (*Presenter*) Research Consultant, FLUIDDA nv;Research Grant, Siemens AG

PURPOSE

Incidental pulmonary nodules (IPNs) are commonly found in chest imaging, however are often not followed up appropriately. We assessed a large cohort of patients to identify which demographic and socioeconomic status (SES), clinical context (CC) and

nodule characteristics (NC) variables are most predictive of adequate follow up.*Methods and Materials We reviewed electronic medical record and U.S. Census data for 1,843 patients diagnosed with IPNs identified on chest CT in a tertiary healthcare system in 2016, and examined their follow-up adherence until 2019. We collected variables including: demographics/SES (age, sex, race, employment, mean income , educational attainment, the latter 2 via geocoding based on U.S. Census block data from 2019), CC (smoking history, encounter context) and NC via risk assessment by the interpreting radiologist using a coding scheme based on Fleischner society guidelines. Our outcome was whether patients did not receive a specific recommendation for follow up (#1), received a recommendation but never obtained follow up (#2), obtained follow up delayed by more than 2 months (#3), or obtained follow up timely (#4). We performed chi-square univariate (CSU), multivariate logistic regression (MLR) and bootstrap forest (BF) analyses to predict the outcome.*Results 6 variables were statistically significant predictors of non-adherence via CSU (p<0.005, CSU likelihood ratio 99.2 - 408.3): black race, not employed status, current smoker, non-outpatient setting, medicaid or no insurance, and lower risk nodules. MLR ordered nodule risk, patient context, smoking status and race as the four best predictors, with whole model ROC AUC of 0.729 - 0.881. BF obtained ROC AUC of 0.674-0.944.*Conclusions Our models not only can accurately identify patients at greatest risk of not obtaining adequate follow up of IPNs, but more importantly can delineate which variables are most predictive and the magnitude of their influence. Demographic/SES variables dominate model prediction, though nodule risk assessment is also a key predictor.*Clinical Relevance/Application Our research has major implications for clinical practice, by characterizing the most vulnerable patients at risk for non-adherence to follow up of IPNs, which can inform policy interventions to improve patient outcomes.

RESULTS

6 variables were statistically significant predictors of non-adherence via CSU (p<0.005, CSU likelihood ratio 99.2 - 408.3): black race, not employed status, current smoker, non-outpatient setting, medicaid or no insurance, and lower risk nodules. MLR ordered nodule risk, patient context, smoking status and race as the four best predictors, with whole model ROC AUC of 0.729 - 0.881. BF obtained ROC AUC of 0.674-0.944.

CLINICAL RELEVANCE/APPLICATION

Our research has major implications for clinical practice, by characterizing the most vulnerable patients at risk for non-adherence to follow up of IPNs, which can inform policy interventions to improve patient outcomes.

SDP-NPM-4 Increasing Diversity And Inclusion In Diagnostic Radiology Residency: A Survey Of Program Directors

Participants
Arif Musa, MS, Detroit, Michigan (*Presenter*) Research Grant, Stryker Corporation;Contract, WebMD Health Corp (WebMD, Inc)

PURPOSE

Diagnostic radiology residency training programs historically lack trainees from under-represented backgrounds. The goal of this study was to determine which methods were endorsed by radiology residency program directors to increase under-represented minorities and female applicants.*Methods and Materials A cross-sectional study of diagnostic radiology residency training program directors was performed via an electronic survey that listed strategies to increase minority and female representation. Level of agreement or disagreement was converted to a weighted average (WA) for each strategy (1 = disagree, 2 = somewhat disagree, 3 = neutral, 4 = somewhat agree, 5 = agree). Responses were collected from January to April 2021. A lottery incentive was included.*Results A total of 30 responses were obtained from 181 program directors (16.6%). The most supported strategies to increase diversity were promoting mentorship by female and minority faculty (WA = 4.6), recruiting female and minority medical students (WA = 4.6), increasing the number of female and minority faculty (WA = 4.5), implementing unconscious bias training (WA = 4.5), increasing female and minority interviewers (WA = 4.4), analyzing successful diversity initiatives (WA = 4.3), conducting holistic application reviews (WA = 4.3), cultural bias training (WA = 4.3), and establishing Women in Radiology or similar groups (WA = 4.3). Other highly supported methods included increasing funding for diversity initiatives (WA = 4.2), including diversity in the program mission statement (WA = 4.2), establishing an office of diversity (WA = 4.2), and having a webpage dedicated to diversity and inclusion (WA = 4.1). Establishing a safe space (WA = 3.9), conducting diversity research (WA = 3.8), establishing a pipeline program for female and minority applicants (WA = 3.8), and advertising at medical schools with historically diverse students (WA = 3.8) were also endorsed. Other strategies included establishing a diversity subcommittee (WA = 3.3), accepting more international medical graduates (WA = 2.8), accepting a minimum number of female or minority applicants (WA = 2.8), deemphasizing USMLE scores (WA = 2.7), and removing applicant photos, gender, and ethnicity from applications (WA = 2.7).*Conclusions Diagnostic radiology residency training program directors endorsed a wide variety of methods to increase diversity and inclusion. These strategies affected resident recruitment, interviewing, training, and program structure.*Clinical Relevance/Application Diagnostic radiology residency training program directors should be aware of what strategies are most supported by their peers to increase the number of female and minority residents.

RESULTS

A total of 30 responses were obtained from 181 program directors (16.6%). The most supported strategies to increase diversity were promoting mentorship by female and minority faculty (WA = 4.6), recruiting female and minority medical students (WA = 4.6), increasing the number of female and minority faculty (WA = 4.5), implementing unconscious bias training (WA = 4.5), increasing female and minority interviewers (WA = 4.4), analyzing successful diversity initiatives (WA = 4.3), conducting holistic application reviews (WA = 4.3), cultural bias training (WA = 4.3), and establishing Women in Radiology or similar groups (WA = 4.3). Other highly supported methods included increasing funding for diversity initiatives (WA = 4.2), including diversity in the program mission statement (WA = 4.2), establishing an office of diversity (WA = 4.2), and having a webpage dedicated to diversity and inclusion (WA = 4.1). Establishing a safe space (WA = 3.9), conducting diversity research (WA = 3.8), establishing a pipeline program for female and minority applicants (WA = 3.8), and advertising at medical schools with historically diverse students (WA = 3.8) were also endorsed. Other strategies included establishing a diversity subcommittee (WA = 3.3), accepting more international medical graduates (WA = 2.8), accepting a minimum number of female or minority applicants (WA = 2.8), deemphasizing USMLE scores (WA = 2.7), and removing applicant photos, gender, and ethnicity from applications (WA = 2.7).

CLINICAL RELEVANCE/APPLICATION

Diagnostic radiology residency training program directors should be aware of what strategies are most supported by their peers to increase the number of female and minority residents.

SDP-NPM-5 Readability Of Patient Education Materials Related To Radiation Safety And The Implications For Patient-centred Radiology Care

Participants

Francis Delaney, MD, Dublin, Ireland (*Presenter*) Nothing to Disclose

PURPOSE

Patients increasingly rely on Web-based resources for healthcare information on which they base decisions about their medical care. Radiation safety is an issue that can be misunderstood by patients and clinicians and lead to patient anxiety. Online patient education materials are frequently written at a higher than recommended reading level. We aimed to assess the readability of currently available online patient educational materials (PEMs) related to radiation safety.*Methods and Materials The readability of 84 articles pertaining to radiation safety from 14 well-known online resources were assessed using 8 readability formulae. The mean reading grade level (RGL) of each article was compared to the recommended reading level for PEMs (6th grade) and the average adult reading level (8th grade). The mean RGL of each website's articles were also compared. In addition, a comparison was made between academic and non-profit resources.*Results The cumulative mean RGL for all 84 articles was 13.3 (range = 8.6-17.4). No article (0%) was written at or below either the 6th or 8th grade reading level. The cumulative mean RGL exceeded the 6th grade reading level by an average of 7.3 levels (95% CI, 6.8-7.8; P<0.001) and the 8th grade level by an average of 5.3 grade levels (95% CI, 4.8-5.8; P<0.001). The mean Flesch Reading Ease Score was 39/100 which is classified as 'difficult'. There was no statistically significant difference between academic and non-profit resources. On comparison of our results to prior studies, there has been no substantial improvement in the readability of PEMs on radiation safety in recent years.*Conclusions Currently available online PEMs related to radiation safety are still written at higher than recommended reading levels. Radiation safety is a topic in which the specialist knowledge of radiologists is crucial in providing guidance to clinicians and education to patients. Addressing the readability of online PEMs may help to improve health literacy and enhance radiology-patient communication as part of the shift to a more patient-centred model of practice.*Clinical Relevance/Application The readability of online patient education materials is a significant factor in health literacy in modern medical practice. Improving the readability of materials pertaining to radiation safety is important for radiologists to help guide clinical practice and enable informed decision-making between clinicians and patients in the era of patient-centred care.

RESULTS

The cumulative mean RGL for all 84 articles was 13.3 (range = 8.6-17.4). No article (0%) was written at or below either the 6th or 8th grade reading level. The cumulative mean RGL exceeded the 6th grade reading level by an average of 7.3 levels (95% CI, 6.8-7.8; P<0.001) and the 8th grade level by an average of 5.3 grade levels (95% CI, 4.8-5.8; P<0.001). The mean Flesch Reading Ease Score was 39/100 which is classified as 'difficult'. There was no statistically significant difference between academic and non-profit resources. On comparison of our results to prior studies, there has been no substantial improvement in the readability of PEMs on radiation safety in recent years.

CLINICAL RELEVANCE/APPLICATION

The readability of online patient education materials is a significant factor in health literacy in modern medical practice. Improving the readability of materials pertaining to radiation safety is important for radiologists to help guide clinical practice and enable informed decision-making between clinicians and patients in the era of patient-centred care.

SDP-NPM-6 Practical Preventive Strategies For Extravasation Of Contrast Media During CT: What The Radiology Team Can Do

Participants
Shinsuke Shigematsu, Kumamoto, Japan (*Presenter*) Nothing to Disclose

PURPOSE

This study aimed to assess the practical preventive strategies (i.e. venous vulnerability assessment and prevention scan protocol rules) for extravasation of contrast media (ECM) during CT.*Methods and Materials 73,931 patients who underwent contrast-enhanced CT scans between January 2013 and December 2019 were retrospectively included. Venous vulnerability assessment by the radiology team (radiology nurses, radiology technicians, and radiologists) began in 2015, and prevention scan protocol rules for the prevention of ECM were added in 2017. We defined each period as follows: 2013-2014, no prevention period (Period A); 2015-2016, prevention period (Period B, venous vulnerability assessment only); 2017-2019: prevention period (Period C, venous vulnerability assessment with prevention scan protocol rules). The incident reports, radiology reports, and medical records of patients in whom ECM occurred were reviewed. We compared the frequency of ECM during each period.*Results ECM occurred in 0.39% (292/73,931) of patients. The frequencies of ECM for Period A, Period B, and Period C were 0.62% (121/19,505), 0.43% (89/20,847), and 0.24% (82/33,579), respectively. There was a significant difference in the frequency of ECM during each period (Chi-squared test, p<0.01).*Conclusions Venous vulnerability assessment and prevention scan protocol rules by the radiology team can be practical and simple solutions for ECM during CT.*Clinical Relevance/Application Venous vulnerability assessment and prevention scan protocol rules by the radiology team can play an important role in the prevention of ECM during CT.

RESULTS

ECM occurred in 0.39% (292/73,931) of patients. The frequencies of ECM for Period A, Period B, and Period C were 0.62% (121/19,505), 0.43% (89/20,847), and 0.24% (82/33,579), respectively. There was a significant difference in the frequency of ECM during each period (Chi-squared test, p<0.01).

CLINICAL RELEVANCE/APPLICATION

Venous vulnerability assessment and prevention scan protocol rules by the radiology team can play an important role in the prevention of ECM during CT.

SDP-NPM-7 The 2020 Radiology Residency Match: Preferences And Success Rates Of Applicants

Participants
Faranak Rafiee, MD, Shiraz, Iran, Islamic Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

The preferences and success rates of different applicant pools in the different specialties of the NRMP residency match may determine future applications to those specialties. The competition for spots can influence the constitution of the applicant pool.*Methods and Materials The NRMP web site was accessed to review the candidate pools and success rates of specialties by reviewing the online "Results and Data of the 2020 Main Residency Match" and "Charting Outcomes in the Match: International Medical Graduates" reports site (www.nrmp.org/about-match-data). Success rates were determined by calculating the number of

applicants applying to a specialty to the number that matched. Raw data were used to determine specialty preferences.*Results Among US medical school (USMD) seniors, Diagnostic Radiology (DR) was the 8th most popular specialty after internal medicine, pediatrics, emergency medicine, family medicine, general surgery, obstetrics and gynecology, and anesthesiology. The success rate for USMD seniors applicants in DR (75.9%) was less than that for Pediatrics (89.1%), EM (88.5%), IM (84.6%), FM (84.6%) and OB-GYN (84.3%) but was higher than Anesthesiology (68.2%) and general surgery (74.9%). By comparison, among Doctor of Osteopathy (DO) seniors, DR was the 10th most popular specialty (Psychiatry and physical medicine rehab surpassed radiology). However the success rate for DOs in applying to DR fell to 66.1% with only PMR (29.1%), general surgery (59.4%), anesthesiology (60.5%) and OB-GYN (65.4%) more competitive. USMD and DO seniors (total 795) and graduates (total 45) filled 840 (84.8%) of 990 DR spots offered. 127 International medical graduates matched to DR (the 8th most popular specialty among IMGs). However 210 USMD and 69 DO senior applicants did not match in DR.*Conclusions The competition for DR spots in the NRMP residency match is more difficult for DO seniors than USMD seniors with success rates for applicants of 66.1% and 75.9% respectively. Despite this, diagnostic radiology is in the top 10 of specialties applied to, being surpassed largely by the clinical primary care specialties.*Clinical Relevance/Application Diagnostic Radiology is a popular specialty in the NRMP match. USMD seniors are 75.9% successful in securing spots, surpassing DOs (66.1%) and IMGs, but many fail to match in DR. The competitiveness for positions suggests a high quality resident pool.

RESULTS

Among US medical school (USMD) seniors, Diagnostic Radiology (DR) was the 8th most popular specialty after internal medicine, pediatrics, emergency medicine, family medicine, general surgery, obstetrics and gynecology, and anesthesiology. The success rate for USMD seniors applicants in DR (75.9%) was less than that for Pediatrics (89.1%), EM (88.5%), IM (84.6%), FM (84.6%) and OB-GYN (84.3%) but was higher than Anesthesiology (68.2%) and general surgery (74.9%). By comparison, among Doctor of Osteopathy (DO) seniors, DR was the 10th most popular specialty (Psychiatry and physical medicine rehab surpassed radiology). However the success rate for DOs in applying to DR fell to 66.1% with only PMR (29.1%), general surgery (59.4%), anesthesiology (60.5%) and OB-GYN (65.4%) more competitive. USMD and DO seniors (total 795) and graduates (total 45) filled 840 (84.8%) of 990 DR spots offered. 127 International medical graduates matched to DR (the 8th most popular specialty among IMGs). However 210 USMD and 69 DO senior applicants did not match in DR.

CLINICAL RELEVANCE/APPLICATION

Diagnostic Radiology is a popular specialty in the NRMP match. USMD seniors are 75.9% successful in securing spots, surpassing DOs (66.1%) and IMGs, but many fail to match in DR. The competitiveness for positions suggests a high quality resident pool.

SDP-NPM-8 Radiology Residency Match Criteria: Program Directors' 2020 Survey

Participants
Parisa Khoshpouri, MD, Coquitlam, British Columbia (*Presenter*) Nothing to Disclose

PURPOSE

The national residency match program (NRMP) provides the results of program director (PD) survey to assess and identify the factors that PDs use to rank residency applicants for all specialties each year. Our study aims to describe the important factors provided by PDs for the Radiology residency match of 2020.*Methods and Materials We reviewed the official published data of 2020 NRMP Program Director (PD) Survey in its website (https://mk0nrmp3oyqui6wqfm.kinstacdn.com/wp-content/uploads/2020/08/2020-PD-Survey.pdf). This survey evaluates (1) the number of applicants that were received, reviewed and eventually ranked, (2) the frequency of interviewing and ranking by programs, (3) test scores, and (4) factors used for applicant selection pre-interview and post-interview.*Results Of all 195 Radiology PDs, 36 (18.5%) responded to the survey. The results included 38 factors important in selecting applicants (pre-interview) and 44 factors in ranking applicants (post-interview). The most important criteria by which candidates were assessed for being selected for interviews were: USMLE Step 1 score (100%), Medical Student Performance Evaluation (MSPE/Dean's Letter) (93%), personal statement (89%), Class ranking/quartile (89%), letters of recommendation in the specialty (81%), failed USMLE (81%), and USMLE Step 2 CK scores (78%). The factors important in ranking applicants after interviews were: Interpersonal skills (93%), Interactions with faculty during the interview (93%), Interactions with housestaff during the interview(93%), Medical Student Performance Evaluation (MSPE/Dean's Letter) (85%), Feedback from current residents (81%) and USMLE Step 1 score (81%). 70% of PDs require obtaining a target score for Step 1 and 41% of PDs will not consider applicants who fail Step 1.*Conclusions Multiple factors are weighed by radiology program directors in selecting residents for an interview, but if an applicant passes the initial criteria successfully, the PDs prioritize interpersonal skills and personal traits at the interview. However USMLE Step 1 scores play a large role in both processes.*Clinical Relevance/Application USMLE Step 1 plays an important role in considering an applicant for matching into radiology, which currently seems like the best accessible filter.

RESULTS

Of all 195 Radiology PDs, 36 (18.5%) responded to the survey. The results included 38 factors important in selecting applicants (pre-interview) and 44 factors in ranking applicants (post-interview). The most important criteria by which candidates were assessed for being selected for interviews were: USMLE Step 1 score (100%), Medical Student Performance Evaluation (MSPE/Dean's Letter) (93%), personal statement (89%), Class ranking/quartile (89%), letters of recommendation in the specialty (81%), failed USMLE (81%), and USMLE Step 2 CK scores (78%). The factors important in ranking applicants after interviews were: Interpersonal skills (93%), Interactions with faculty during the interview (93%), Interactions with housestaff during the interview(93%), Medical Student Performance Evaluation (MSPE/Dean's Letter) (85%), Feedback from current residents (81%) and USMLE Step 1 score (81%). 70% of PDs require obtaining a target score for Step 1 and 41% of PDs will not consider applicants who fail Step 1.

CLINICAL RELEVANCE/APPLICATION

USMLE Step 1 plays an important role in considering an applicant for matching into radiology, which currently seems like the best accessible filter.

SDP-NPM-9 Estimating Population Reach Of Global Health Radiology Outreach Using Geographic Information Systems Analysis

Participants
David Gage, BSC,MD, Baltimore, Maryland (*Presenter*) Nothing to Disclose

PURPOSE

According to the World Health Organization, widespread scarcity of radiology and medical imaging resources is generally estimated at one-half to two-thirds of the world, but difficult to specifically quantify at the facility and regional level. Geographic Information Systems (GIS) research has accelerated real-time monitoring of health data for identifying populations and measuring the impact of interventions. The purpose of this study was to design, develop and test GIS methods for nonprofit global health radiology outreach planning and quantifying potential impact of interventions on medically underserved populations.*Methods and Materials The study developed and tested GIS methodology using publicly available databases used by the global health radiology nonprofit organization, RAD-AID International. The data collection targeted the regions and populations served by seventy-eight (78) low-resource medical facilities partnered with RAD-AID in 30 low and middle-income countries (LMICs). Three constraints were used to measure proximity for approximating patient's level of geographic access to healthcare: 1) one-hour driving time, 2) one-hour walking time, and 3) ten-mile circular radius. To calculate the population within each constraint, a GIS analysis used geospatial input data sources including a global digital elevation model, population and land cover data, and roads at country level from OpenStreetMap. Demographic and health data from the World Health Organization were also incorporated to provide insight into further characteristics of the covered population.*Results Total population served by all RAD-AID sites as measured by driving time, walking time, and ten-mile radius was 189,241,193 (47.8% female), 26,190,117 (48.7% female), and 110,884,095(48.1% female), respectively. For individual locations, the median population within one-hour driving time was found to be 1,795,977 (range: 8,742—30,630,800; interquartile range [IQR]: 537,808—4,192,237), with an average life expectancy of 68.4 (range: 54.0—78.3; standard deviation: ±5.8) years. Median child mortality before age five was 3.8% (range: 0.9—8.3%; IQR: 2.0—5.7%), and median HIV prevalence was 3.1% (range: 0.7—10.9%; IQR: 2.0—4.8%).*Conclusions This study demonstrates the role of geographic information systems analysis for estimating total global health outreach, which can be used for resource allocation and planning.*Clinical Relevance/Application Given heightened needs for measuring reach of global health strategies, this GIS-based method and variables for approximating geographic access to health institutions may be useful for analysis, outreach planning, and resource allocation among medical outreach organizations.

RESULTS

Total population served by all RAD-AID sites as measured by driving time, walking time, and ten-mile radius was 189,241,193 (47.8% female), 26,190,117 (48.7% female), and 110,884,095(48.1% female), respectively. For individual locations, the median population within one-hour driving time was found to be 1,795,977 (range: 8,742— 30,630,800; interquartile range [IQR]: 537,808—4,192,237), with an average life expectancy of 68.4 (range: 54.0—78.3; standard deviation: ±5.8) years. Median child mortality before age five was 3.8% (range: 0.9—8.3%; IQR: 2.0—5.7%), and median HIV prevalence was 3.1% (range: 0.7—10.9%; IQR: 2.0—4.8%).

CLINICAL RELEVANCE/APPLICATION

Given heightened needs for measuring reach of global health strategies, this GIS-based method and variables for approximating geographic access to health institutions may be useful for analysis, outreach planning, and resource allocation among medical outreach organizations.

IR05-A1   Minimally Invasive Treatment For Unicameral Bone Cysts With Chemical Sclerosis And Bone Graft Substitute: A Preliminary Report.

Participants
Shankar Rajeswaran, MD, Chicago, Illinois (*Presenter*) Nothing to Disclose

PURPOSE

Unicameral bone cysts (UBCs) are benign lesions that primarily occur in childhood and can present with pain, pathologic fracture and growth disturbances. Existing treatment approaches for the management of UBCs are highly variable and recurrence is not uncommon. This study seeks to evaluate an image-guided, minimally invasive combination of chemical sclerotherapy and synthetic grafting as a novel outpatient management treatment option for UBCs.*Methods and Materials Retrospective evaluation from August 2018 through July 2020 of fourteen pediatric patients, ages 5-14 years, undergoing treatment for a UBC, at a single institution. All UBCs were treated in a single, minimally invasive, image guided procedure using percutaneous needle access into the UBC followed by chemical sclerotherapy and injection of regenerative synthetic graft. Patients were followed clinically and with serial radiographs to evaluate for healing and complications, with an average follow-up of 13.7 months and descriptive statistics were performed.*Results 12 of 14 (85.7%) patients showed Neer classification class 1 or 2 healed cysts at their most recent follow-up and there was one case of recurrence noted at 3 months. Patients were pain-free and returned to normal physical activity on average within 2.0 months, and all patients remained asymptomatic at the most recent follow-up. There were no complications related to the procedures.*Conclusions Image guided chemical sclerosis and bone grafting is a minimally invasive treatment option for unicameral bone cysts and compares favorably to other existing treatment options.*Clinical Relevance/Application Given the high efficacy and low morbidity of this treatment approach, the preliminary findings of this technique are promising as an alternative management option for UBCs.

RESULTS

12 of 14 (85.7%) patients showed Neer classification class 1 or 2 healed cysts at their most recent follow-up and there was one case of recurrence noted at 3 months. Patients were pain-free and returned to normal physical activity on average within 2.0 months, and all patients remained asymptomatic at the most recent follow-up. There were no complications related to the procedures.

CLINICAL RELEVANCE/APPLICATION

Given the high efficacy and low morbidity of this treatment approach, the preliminary findings of this technique are promising as an alternative management option for UBCs.

IR05-A2   Sex Disparities In Survival After Transjugular Intrahepatic Portosystemic Shunt Placement

Participants
Ryan Lokken, MD, San Francisco, California (*Presenter*) Consultant, Neptune Medical Inc

PURPOSE

To compare transplant-free survival (TFS) between women and men after transjugular intrahepatic portosystemic shunt (TIPS) creation in patients with similar Model for End Stage Liver Disease (MELD) scores.*Methods and Materials This multi-center retrospective cohort study was approved by the Institutional Review Board. A total of 717 patients underwent primary TIPS placement between November 1998 and June 2020. After excluding patients on dialysis and with emergent indications, 520 patients (221 women, 42.5%; 299 men, 57.5%; mean age 56 years) met study criteria. 53.6% were White, 25.4% Hispanic, 12.5% categorized as Other, 6.5% Black and 1.9% Asian. 65% of cases were for refractory ascites or hydrothorax, 29% for non-emergent bleeding and 6% for other indications. MELD scores and TFS were tabulated. Kaplan-Meier survival curves were obtained and Harrington-Fleming tests performed to compare overall, 30-day, 90-day and 365-day survival based on indication and sex. Comparisons were also made in three MELD subcategories: 10 or less, 11 - 18 and 19 - 25.*Results Overall median survival was 5.5 years for females and 4.1 years for males. At a MELD score of 10 or less, median survival was 3.4 years for females and 11.5 years for males. In the overall cohort, no difference was observed in overall TFS ($p = 0.4$), survival at 1 year ($p = 0.8$), survival at 90 days ($p = 0.7$) and survival at 30 days ($p = 0.9$) between the sexes. At a MELD score of 10 or less, overall TFS was slightly better for men compared to women after TIPS ($p = 0.05$). At MELD scores between 11 - 18 ($p = 0.3$) and 18 - 25 ($p = 0.2$), no difference was observed in overall TFS between sexes. There was no difference in TFS based on indication between the sexes ($p = 0.3$).*Conclusions For patients with a MELD score of 10 or less, women had poorer TFS after TIPS compared to men. The findings suggest that MELD underestimates disease severity in women relative to men.*Clinical Relevance/Application Developed to estimate mortality after TIPS placement, the MELD score is now factored into liver transplant allocation algorithms. Liver transplant waitlist outcomes (allocation and death) are worse for females compared to males. A proposed reason for this disparity is that MELD systematically underestimates disease severity in women because of the incorporation of serum creatinine. On average, women with the same creatinine level as men have worse renal function because of lower mean muscle mass. While the relationship between MELD and aspects of liver transplant has been explored, sex-related differences based on MELD in regard to TIPS outcomes remain understudied. This study provides further evidence that MELD is a less adequate prognostic index for women

compared to men. MELD adjustment based on sex is worthy of further investigation.

RESULTS

Overall median survival was 5.5 years for females and 4.1 years for males. At a MELD score of 10 or less, median survival was 3.4 years for females and 11.5 years for males. In the overall cohort, no difference was observed in overall TFS (p = 0.4), survival at 1 year (p = 0.8), survival at 90 days (p = 0.7) and survival at 30 days (p = 0.9) between the sexes. At a MELD score of 10 or less, overall TFS was slightly better for men compared to women after TIPS (p = 0.05). At MELD scores between 11 - 18 (p = 0.3) and 18 - 25 (p = 0.2), no difference was observed in overall TFS between sexes. There was no difference in TFS based on indication between the sexes (p = 0.3).

CLINICAL RELEVANCE/APPLICATION

Developed to estimate mortality after TIPS placement, the MELD score is now factored into liver transplant allocation algorithms. Liver transplant waitlist outcomes (allocation and death) are worse for females compared to males. A proposed reason for this disparity is that MELD systematically underestimates disease severity in women because of the incorporation of serum creatinine. On average, women with the same creatinine level as men have worse renal function because of lower mean muscle mass. While the relationship between MELD and aspects of liver transplant has been explored, sex-related differences based on MELD in regard to TIPS outcomes remain understudied. This study provides further evidence that MELD is a less adequate prognostic index for women compared to men. MELD adjustment based on sex is worthy of further investigation.

IR05-A3   Gastric Arterial Patency After Bariatric Embolization In A Swine Model.

Participants
Frank Yuan, MD, Morgantown, West Virginia (*Presenter*) Nothing to Disclose

PURPOSE

This study evaluates the vascular patency and the degree of left gastric artery revascularization after bariatric embolization with embolic microspheres of varying sizes in a swine model.*Methods and Materials Bariatric embolization was performed in 16 juvenile pigs with 31 left gastric arteries embolized. The selection of fundal arteries for bariatric embolization was based on celiac DSA Cone Beam CT (CBCT). On average, 1 to 3 arteries were embolized using one of three types of particle embolics: 50μm barium-alginate beads, 100-300μm or 300-500μm Embospheres. Repeat angiography was performed before sacrifice (50μm treated animals at 4-weeks; the rest at 16-weeks) to assess the rate and degree of arterial revascularization. Angiograms were scored for the degree of recanalization (complete or partial) or collateralization. Fisher exact test was performed to compare the groups.*Results Of the 11 arteries embolized in the 50μm group, 7 (63%) had complete recanalization, 3 (27%) had partial recanalization, and 1 (10%) had collateralization (no recanalization). In the 100-300μm group (n=10 arteries), 7 (70%) had complete recanalization and 3 (30%) had partial recanalization. In the 300-500μm group (n=10 arteries), 7 (70%) had complete recanalization, 1 (10 %) had partial recanalization and 2 (20%) had collateralization. No statistical difference in the degree of recanalization was present between the groups (Table 1; Figure 1).Table 1. Degree of revascularization per group pan style="font-family: "Times New Roman", serif; font-size: 12pt;">No difference in the degree of revascularization between the three groups (P=0.637).*Conclusions Overall, 90% (28/31) of the embolized arteries exhibited partial or complete arterial recanalization. New arterial collateral formation was observed in 9.7% (3/31) of previously embolized arteries. The embolic microsphere size did not appear to affect the degree of arterial revascularization. *Clinical Relevance/Application The findings from this study challenge the concern that bariatric embolization may preclude future bariatric surgery due to an increased risk for ischemia-related anastomotic dehiscence.

RESULTS

Of the 11 arteries embolized in the 50μm group, 7 (63%) had complete recanalization, 3 (27%) had partial recanalization, and 1 (10%) had collateralization (no recanalization). In the 100-300μm group (n=10 arteries), 7 (70%) had complete recanalization and 3 (30%) had partial recanalization. In the 300-500μm group (n=10 arteries), 7 (70%) had complete recanalization, 1 (10 %) had partial recanalization and 2 (20%) had collateralization. No statistical difference in the degree of recanalization was present between the groups (Table 1; Figure 1).Table 1. Degree of revascularization per group pan style="font-family: "Times New Roman", serif; font-size: 12pt;">No difference in the degree of revascularization between the three groups (P=0.637).

CLINICAL RELEVANCE/APPLICATION

The findings from this study challenge the concern that bariatric embolization may preclude future bariatric surgery due to an increased risk for ischemia-related anastomotic dehiscence.

IR05-A4   Using Intraoperative Neuromonitoring To Prevent Iatrogenic Peripheral Nerve Injury During Embolization Of High-flow Arteriovenous Malformations

Participants
Adham Khalil, MD, Baltimore, Maryland (*Presenter*) Nothing to Disclose

PURPOSE

To assess the efficacy of intraoperative neuromonitoring (IONM) as a method to minimize iatrogenic peripheral nerve injury during embolization of high-flow vascular malformations (HFVM).*Methods and Materials The authors retrospectively derived a study cohort of 21 symptomatic patients (mean age 25.4±17 years, range 2-65 years; 66.7% males) with peripherally located Arteriovenous Malformations (AVM) who underwent 80 image-guided embolization sessions (endovascular = 53; percutaneous = 29) using different sclerosants (e.g. Ethanol, Onyx, Glue, Sotradecol, and others) performed between 2012-2021. Provocative testing (PT) using Lidocaine 2% (20-40 mg per vessel; max. total dose 1 g/kg) was performed prior to each individual embolization. Areas with unremarkable PT were embolized. In these cases, IONM was also performed after embolic injection.*Results A total of 80 embolization sessions were performed (44 in lower extremities, 17 abdominopelvic, 15 in upper extremities, 7 in shoulders, and 7 gluteal). Ethanol was used in 45.3% (34/75) of sessions. The mean clinical and image follow-up durations were 34.1±28.6 months and 36.2±28.9 months (range: <1-91.4 months) from first embolization. Neuromonitoring modalities included somatosensory evoked potential (SSEP; N=72 sessions), transcranial motor evoked potentials (TcMEP; N=35 sessions) and/or motor nerve conduction studies (MNCS; N=33 sessions). Intraoperatively, 20% (16/80) of sessions showed signal changes after PT and the decision was made not to proceed with embolization at the corresponding site to avoid nerve damage. Overall, neuromonitoring signal changes were observed in 46.4% (32/69) of SSEP tests, 17.1% (6/35) of TcMEP test, and 34.4% (11/32) of MNCS tests. Of the IONM sessions with signal changes, signal recovery was noted in 11.4% (3/26) SSEP, 40% (2/5) TcMEP, and 28.6% (2/7) MNCS sessions. The overall neurologic complication rate was 6.3% (5/79). All of them were transient. No patient developed a permanent neurologic complication. Previous studies in the literature have reported complication rates ranging from 0% to 12.9% for transient neurologic

complications and rates ranging from 0% to 3.4% for permanent neurologic complications.*Conclusions IONM may improve the safety of embolization of HFVM by preventing permanent neurologic injury.*Clinical Relevance/Application IONM is a valuable tool for intra-procedural use during embolization of HFVMs to protect against iatrogenic peripheral nerve injury.

RESULTS

A total of 80 embolization sessions were performed (44 in lower extremities, 17 abdominopelvic, 15 in upper extremities, 7 in shoulders, and 7 gluteal). Ethanol was used in 45.3% (34/75) of sessions. The mean clinical and image follow-up durations were 34.1±28.6 months and 36.2±28.9 months (range: <1-91.4 months) from first embolization. Neuromonitoring modalities included somatosensory evoked potential (SSEP; N=72 sessions), transcranial motor evoked potentials (TcMEP; N=35 sessions) and/or motor nerve conduction studies (MNCS; N=33 sessions). Intraoperatively, 20% (16/80) of sessions showed signal changes after PT and the decision was made not to proceed with embolization at the corresponding site to avoid nerve damage. Overall, neuromonitoring signal changes were observed in 46.4% (32/69) of SSEP tests, 17.1% (6/35) of TcMEP test, and 34.4% (11/32) of MNCS tests. Of the IONM sessions with signal changes, signal recovery was noted in 11.4% (3/26) SSEP, 40% (2/5) TcMEP, and 28.6% (2/7) MNCS sessions. The overall neurologic complication rate was 6.3% (5/79). All of them were transient. No patient developed a permanent neurologic complication. Previous studies in the literature have reported complication rates ranging from 0% to 12.9% for transient neurologic complications and rates ranging from 0% to 3.4% for permanent neurologic complications.

CLINICAL RELEVANCE/APPLICATION

IONM is a valuable tool for intra-procedural use during embolization of HFVMs to protect against iatrogenic peripheral nerve injury.

IR05-A5   Prediction Of Complication Risk In CT-guided Thoracic Biopsy: A Prescription For Improving Procedure Safety

Participants
Hwan Lee, MD, Philadelphia, Pennsylvania (*Presenter*) Nothing to Disclose

PURPOSE

CT-guided trans-thoracic biopsy (CTTB) is a minimally invasive procedure with high diagnostic yield in the evaluation of a variety of thoracic diseases. In this study, we comprehensively assessed a large CTTB cohort to predict procedural and patient factors associated with risk of complication.*Methods and Materials e medical record and CT images of 1,430 patients who underwent CTTB were reviewed individually to obtain clinical information and technical factors of the procedure. Statistical analyses included descriptive and summary statistics, univariate analysis with Fisher's test, multivariate logistic regression, and machine learning methods.*Results The most common type of complication was pneumothorax (17.4% of the patients), followed by bleeding (5.9%). Only 26 patients (1.8%) developed a major complication (defined by SIR guidelines). On univariate analysis, significantly higher rate of complication was seen for lung lesions (OR 14.5 [6.4-32.9] for lung vs. non-lung). In addition, non-dependent position of the lesion (OR 4.2 [2.3-7.5]), vertical needle approach (OR 2.5 [1.8-3.6]), and involvement of a trainee (OR 1.3 [1.0-1.7]) increased risk of complication, whereas use of co-axial technique (OR 0.6 [0.4-0.7]) was a protective factor (shown as OR [95% CI]). Similar odd ratios were obtained when the patients with lung lesions (n=1,196) were analyzed separately. Presence of emphysema (P=0.32), patient position (P=0.32), and sex (P=0.40) were not linked to rate of complication. For non-lung lesions, trespassing the pleural space was highly predictive of complications (OR 82.7 [9.0-760.5]). On multivariate analysis, a support vector machine model achieved an AUC of 0.898 for prediction of complications on lung lesions (on validation cohort). A logistic regression model achieved AUC of 0.884, 0.723 and 0.745 for prediction of major, minor and no complications, respectively.*Conclusions Technical procedural factors that can be decided by the operator are highly predictive of the risk of complications on CTTB.*Clinical Relevance/Application Physicians may optimize their techniques to improve procedure safety and outcomes of CT-guided trans-thoracic biopsy.

RESULTS

The most common type of complication was pneumothorax (17.4% of the patients), followed by bleeding (5.9%). Only 26 patients (1.8%) developed a major complication (defined by SIR guidelines). On univariate analysis, significantly higher rate of complication was seen for lung lesions (OR 14.5 [6.4-32.9] for lung vs. non-lung). In addition, non-dependent position of the lesion (OR 4.2 [2.3-7.5]), vertical needle approach (OR 2.5 [1.8-3.6]), and involvement of a trainee (OR 1.3 [1.0-1.7]) increased risk of complication, whereas use of co-axial technique (OR 0.6 [0.4-0.7]) was a protective factor (shown as OR [95% CI]). Similar odd ratios were obtained when the patients with lung lesions (n=1,196) were analyzed separately. Presence of emphysema (P=0.32), patient position (P=0.32), and sex (P=0.40) were not linked to rate of complication. For non-lung lesions, trespassing the pleural space was highly predictive of complications (OR 82.7 [9.0-760.5]). On multivariate analysis, a support vector machine model achieved an AUC of 0.898 for prediction of complications on lung lesions (on validation cohort). A logistic regression model achieved AUC of 0.884, 0.723 and 0.745 for prediction of major, minor and no complications, respectively.

CLINICAL RELEVANCE/APPLICATION

Physicians may optimize their techniques to improve procedure safety and outcomes of CT-guided trans-thoracic biopsy.

IN05-B2   **Dynamic Priority Queues Improve Study Turnaround Times In A Radiology Worklist**

Participants
Thilakshan Kanesalingam, Atlanta, Georgia (*Presenter*) Nothing to Disclose

PURPOSE

The overuse of urgency on imaging studies (e.g., STAT) can place an undue burden on radiology departments where every study is now a top priority. In response, many hospitals have developed fine-grain priority levels and processes to better communicate studies that require immediate action. Unfortunately, this separation of priority levels into many separate queues can easily lead to the 'starvation' of imaging studies in lower priority groups. In this study we adapted a dynamic priority queue algorithm commonly used in network routing to improve the turnaround time for radiological interpretation across all modalities without adding new resources.*Methods and Materials We adopted a simulation approach to test the hypothetical performance gains of a dynamic priority queue over more common workflow management strategies such as a priority grouping coupled with first-in first-out. Our case study includes over 25,000 imaging studies derived from the operations of a large teleradiology firm. Our dynamic priority queue combined an 'earliest due date' and 'shortest processing time first' scheduling strategy to optimally allocate the next most important study to a given radiologist.*Results A dynamic priority queue improved three core measures in our simulated radiology department relative to a priority group first-in first-out strategy. First, it reduced the average turnaround time of imaging studies by 27% (252 to 184 minutes). Second, it increased the percentage of imaging studies returned by their deadline by 6.6% (77.6% to 84.2%). Third, it reduced the number of studies that required off-hours interpretations by 12.4% (22.7% to 10.3%).*Conclusions We saw resource starvation of lower priority studies anecdotally in our observation of a large teleradiology organization, but we also reproduced these results in a simulation of their operations. In our simulation around half of the caseload were routine studies, but only 63% of them were interpreted within 24 hours. This starvation was driven by a quarter of the caseload from the emergency department that required attention in that hour. Dynamic priority queueing jointly considers the study's deadline as well as its priority level. This more evenly distributed studies to radiologists to improve workflow efficiency and the reliability of turnaround time agreements.*Clinical Relevance/Application Improving workflow efficiency in radiology departments will have positive downstream impacts in emergency departments by reducing delays in critical treatments and report turnaround times.

RESULTS

A dynamic priority queue improved three core measures in our simulated radiology department relative to a priority group first-in first-out strategy. First, it reduced the average turnaround time of imaging studies by 27% (252 to 184 minutes). Second, it increased the percentage of imaging studies returned by their deadline by 6.6% (77.6% to 84.2%). Third, it reduced the number of studies that required off-hours interpretations by 12.4% (22.7% to 10.3%).

CLINICAL RELEVANCE/APPLICATION

Improving workflow efficiency in radiology departments will have positive downstream impacts in emergency departments by reducing delays in critical treatments and report turnaround times.

IN04-C2   Deep Learning For Detection Of Metal Dense Implants In X-ray Imaging

Participants
Hien Tran, MD, Freiburg, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Development of a robust algorithm for detection of metal dense implants such as osteosynthesis, prosthesis, screws or endobuttons in musculoskeletal x-ray imaging.*Methods and Materials MSK-Radiographs from our department from 2018-2019 were classified for presence or absence of implants. Reading was performed first by a medical student, followed by a junior and a senior radiologist. 13600 images were annotated and exported for the deep learning study; about 17% were showing implants. Data leakage was excluded by separating the data groups on a patient level, resulting in 8607 images for training, 3662 for validation and 1331 for result calculation. To develop the deep learning model, established convolutional neural networks, InceptionV3, ResNet50, and Densenet121 (results in that order) were modified with Keras to produce binary output, using a custom network-top on a fully trainable base model pretrained on Imagenet. Images were rescaled to 256*256 pixels and grayscale was augmented using the image, an inverted image, and an edge-optimized image to form a 3-level image. The data was randomized, balanced, and mildly augmented on the fly as batches were created. Deep learning was performed by using Tensorflow 2.4 with a standard graphics unit (Nvidia Tesla K80). Following parameters were used: 200 training epochs. AdaDelta as a solver type and the learning rate reducing from 0.1 to 0.005. The calculation and visualization of the results of the networks used sklearn and tf-explain.*Results The training of the CNNs took each around 3h. Image processing of all 1331 test-images took 144,116,107 seconds. The overall accuracy of the separate test sample is 99.0, 99.3, 99.3%. The sensitivity was 0.94, 0.96, 0.97 and specificity was for all 1.00.*Conclusions The algorithms created all show good detection and exclusion rates for metal-dense material in MSK radiographs. The best performance was achieved with a DenseNet121, although the results of the other two tested networks were almost comparable.*Clinical Relevance/Application For clinical acceptance, a major challenge in AI is to avoid misapplications that lead to incorrect results. With sorting algorithms as a precursor, optimized automated use of AI-based algorithms within clinical workflows becomes feasible.

RESULTS

The training of the CNNs took each around 3h. Image processing of all 1331 test-images took 144,116,107 seconds. The overall accuracy of the separate test sample is 99.0, 99.3, 99.3%. The sensitivity was 0.94, 0.96, 0.97 and specificity was for all 1.00.

CLINICAL RELEVANCE/APPLICATION

For clinical acceptance, a major challenge in AI is to avoid misapplications that lead to incorrect results. With sorting algorithms as a precursor, optimized automated use of AI-based algorithms within clinical workflows becomes feasible.

NPM01-B2   Is Radiology Lagging Behind Other Specialties In Education Scholarship Publications?

Participants

Elana Smith, MD, Baltimore, Maryland (*Presenter*) Nothing to Disclose

PURPOSE

To compare the numbers of educational scholarship publications per medical specialty. The authors hypothesized: 1. Percentage of educational scholarship publications is lower in highest impact factor (IF) radiology journals than in other specialties. 2. In radiology journals, the proportion of educational scholarship publications is negatively associated with journal IF.*Methods and Materials The Journal Citation Reports (JCR) database was used to select the 5 titles with the highest IFs in 19 medical specialties. For time period Jan 1, 2016-Jan 1, 2021, this PubMed search strategy was performed in top IF and all JCR-listed Radiology journals: (Education, Medical[MAJR] OR Education, Medical, Graduate[MAJR] OR Education, Medical, Undergraduate[MAJR] OR "medical education"[tiab] OR "graduate medical education"[tiab] OR "undergraduate medical education"[tiab]) AND "journal name"[TA] AND "2016/1/1"[dcom] : "2021/1/1"[dcom], followed by "journal name"[TA] AND "2016/1/1"[dcom] : "2021/1/1"[dcom]. To test hypothesis 1, an indicator variable for radiology journals vs. non-radiology journals was created. Fixed effects logistic regressions were implemented. To address hypothesis 2, mixed effects logistic regressions were implemented.*Results Neurosurgery and Radiation Oncology journals index with Surgery and Radiology journals respectively; 17 specialties were assessed. Radiology educational scholarship publications ranked 12/17 across specialties. The proportion of educational articles is significantly higher for non-radiology journals, 12.16 per 1000 articles [SE=0.31, 95% CI: [11.56, 12.78], compared to radiology journals, 4.94 per 1000 articles (SE=0.79, 95% CI: [3.61, 6.75]. IF was not associated with the proportion of educational scholarship publications in radiology journals (p=0.86). Educational scholarship: 0.41% of publications in top IF Radiology journals. 16/132 Radiology journals published >1% educational scholarship articles. Academic Radiology published 12.37%.41 radiology journals IF > 3. Of these, 85.4% (35/41) devoted <1% of their publications to educational scholarship.*Conclusions 1. Radiology lags behind most medical specialties in educational scholarship publications in top IF journals. 2. Many radiology journals with high IF do not emphasize educational scholarship.*Clinical Relevance/Application Educational publications are important to academic portfolios and career advancement for clinician educators. Fewer opportunities to publish educational scholarship negatively impacts Radiology faculty. Passive learning yields medical student disinterest and negatively affects radiology recruitment; innovative teaching engages students and assists in recruitment/retention.

RESULTS

Neurosurgery and Radiation Oncology journals index with Surgery and Radiology journals respectively; 17 specialties were assessed. Radiology educational scholarship publications ranked 12/17 across specialties. The proportion of educational articles is significantly higher for non-radiology journals, 12.16 per 1000 articles [SE=0.31, 95% CI: [11.56, 12.78], compared to radiology journals, 4.94 per 1000 articles (SE=0.79, 95% CI: [3.61, 6.75]. IF was not associated with the proportion of educational scholarship publications in radiology journals (p=0.86). Educational scholarship: 0.41% of publications in top IF Radiology journals. 16/132 Radiology journals published >1% educational scholarship articles. Academic Radiology published 12.37%.41 radiology journals IF > 3. Of these, 85.4% (35/41) devoted <1% of their publications to educational scholarship.

CLINICAL RELEVANCE/APPLICATION

Educational publications are important to academic portfolios and career advancement for clinician educators. Fewer opportunities to publish educational scholarship negatively impacts Radiology faculty. Passive learning yields medical student disinterest and negatively affects radiology recruitment; innovative teaching engages students and assists in recruitment/retention.

NPM01-B4   Conversion Factor: Converting An In-Person Didactic Rectal Cancer MRI Lecture Into An Interactive Online Experience

Participants

Jonathan Levine, MD, Chicago, Illinois (*Presenter*) Nothing to Disclose

TEACHING POINTS

The COVID-19 pandemic has pushed medical student and trainee education to the virtual world. New challenges for Radiology educators presenting digitally include limited participation, technology hiccups, absence of live feedback, and image quality limitations. However, online tools also provide new opportunities to go beyond simply converting an in-person lecture to a virtual one. In the time of COVID-19 and beyond, leveraging technology and learning theory can allow the educator to engage learners in a more meaningful interactive experience.

TABLE OF CONTENTS/OUTLINE

1. Goals and objectives 2. The traditional model for Radiology education and its shortcomings 3. A proposed new model incorporating virtual tools and lessons from learning theory 4. Specific ways to make a traditional Powerpoint presentation more interactive and meaningful in the virtual world: Scrollable cases instead of still images or GIFs, Polling software (RSNA Diagnosis

Live, Poll Everywhere) instead of "hot seat" questioning, Self-directed online modules instead of or to augment scheduled lectures 5. Lessons from learning theory and how the above techniques can improve knowledge retention over didactic lectures: Retrieval practice, Spaced learning, Reflection, Gamification, Interleaving 6. The authors' experience of converting a didactic lecture on Rectal Cancer MRI into an online learning experience, including results and lessons learned along the way 7. Continuing challenges for the Radiology educator in the virtual world

PH01-B10   Ultra-high Resolution And Area-detector CTs For Lung Density Evaluation: Capability For Radiation Dose Reduction With Two-types Of Iterative Reconstruction And Deep Learning Reconstruction At QIBA Phantom Study

Participants
Chika Shigemura, Toyoake, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To compare radiation dose reduction capability of ultra-high-resolution CT (UHR-CT) and area-detector CT (ADCT) for lung density assessment among hybrid-type and mode-based iterative reconstruction (IR) and developed deep learning reconstruction (DLR) at Quantitative Imaging Biomarkers Alliance (QIBA) recommended phantom study.*Methods and Materials QIBA recommended phantom (COPDGene II, Phantom Laboratory) was scanned by UHR-CT with normal resolution (NR: 0.5mm×80 rows/896 channels), high resolution (HR: 0.5mm×80 rows/1792 channels) and super-high resolution (SHR: 0.25mm×160 rows/1792 channels) and ADCT (0.5mm×80 rows/896 channels) at 400mA, 230mA, 100mA, 50mA, 20mA and 6mA in five times. Then, all CT data were reconstructed as 0.5mm and 1mm section thicknesses by each reconstruction. Then, CT values of all density forms and mean differences between measured CT value within lung density form and standard reference (?CT) were determined by ROI measurements in five times. Then, Pierson's correlation was analyzed between measured CT density and standard reference of each form on all CT protocols. To compare the capability for radiation dose reduction on each CT data with ADCT obtained by 400mA and reconstructed with hybrid-type IR (i.e. standard protocol), ?CT of each protocol was compared with that of standard protocol by paired t-test. In addition, the limits of agreements by Bland-Altman analyses were compared with QIBA profile for lung densitometry.*Results There was significant and excellent correlation with standard reference on each protocol (0.99<r<1, p<0.0001). When reconstructed as 0.5mm and 1mm section thicknesses, UHR-CT with SHR modes at 6mA and reconstructed by each method or UHR-CT with HR mode at 6mA and reconstructed with DLR had significant differences of ?CT with standard protocol (p<0.05). The limits of agreement on all CT protocols were ranged from -5.1HU to 5.4HU and small enough as compared with QIBA profile.*Conclusions For lung density assessment, hybrid-type and model-based IR as well as DLR on UHR-CT and ADCT can reduce 95% radiation dose with keeping accuracy as compared with standard CT protocol and QIBA profile.*Clinical Relevance/Application For lung density assessment, hybrid-type and model-based IR and DLR on UHR-CT and ADCT can reduce radiation dose at 5% level with keeping accuracy as compared with standard protocol and QIBA profile.

RESULTS

There was significant and excellent correlation with standard reference on each protocol (0.99<r<1, p<0.0001). When reconstructed as 0.5mm and 1mm section thicknesses, UHR-CT with SHR modes at 6mA and reconstructed by each method or UHR-CT with HR mode at 6mA and reconstructed with DLR had significant differences of ?CT with standard protocol (p<0.05). The limits of agreement on all CT protocols were ranged from -5.1HU to 5.4HU and small enough as compared with QIBA profile.

CLINICAL RELEVANCE/APPLICATION

For lung density assessment, hybrid-type and model-based IR and DLR on UHR-CT and ADCT can reduce radiation dose at 5% level with keeping accuracy as compared with standard protocol and QIBA profile.

PH01-B3   A Comparative Study Of CT Image Standardization Models In Non-small Cell Lung Cancer

Participants
Mauro Hanaoka, MD, Lexington, Kentucky (*Presenter*) Nothing to Disclose

PURPOSE

Due to the sensitivity of CT images to acquisition parameters, multicentric images studies across intra/inter manufacturers with different noise level, sharpness, edge enhancement and reconstruction algorithms often suffer from a lack of homogeneity in terms of statistical characteristics. There is a critical need for image-based standardization, making CT imaging more sensitive, specific and predictive, and improving clinical outcomes associated with image-based features. This study evaluates several CT image standardization techniques that translate heterogeneous images to match the statistical properties of a standard domain.*Methods and Materials Seven CT image standardization models, namely cGAN, CNN, GANai, STAN-CT, RadiomicGAN, CycleGAN, and CVS-CT were evaluated and compared using NSCLC patient data. The models required paired training data except CycleGAN and CVS-CT. CT images for training and testing were acquired in a Siemens Sensation Force using two different kernels (Br40, Bl64) and 1 mm slice thickness. The training data included a total of 33,406 CT image slices. The test data contains images from 13 NSCLC patients which includes a total 9,116 CT image slices. Approximately 1715 radiomics sub-features extracted from the lung nodule of each individual patient using IBEX were used to evaluate the performance of CT image normalization models. Concordance Correlation Coefficient (CCC) was employed to measure the level of reproducibility of radiomic features between the standardized images and target images.*Results The baseline images (before standardized) have an averaged CCC score 0.71&3;0.18 on NSCLC, and the RadiomicGAN has the best averaged CCC of 0.95&3;0.07 on NLCS. Overall, cGAN, CNN, GANai, STAN-CT, RadiomicGAN, CycleGAN, and CVS-CT improves the feature stability by 22.8%, 23.5%, 23.3%, 23.3%, 23.7%, 9.3% and 7.3%, respectively. Models that do not require paired training image data have significantly lower performance than the others probably due to high model

complexity.*Conclusions Image standardization reduces cross-domain variation and improves the stability of radiomic features. RadiomicGAN shows the best performance.*Clinical Relevance/Application Understanding CT standardization models can help advance the radiomic studies in NSCLC and improve clinical outcomes associated with image-based features.

RESULTS

The baseline images (before standardized) have an averaged CCC score 0.71&3;0.18 on NSCLC, and the RadiomicGAN has the best averaged CCC of 0.95&3;0.07 on NLCS. Overall, cGAN, CNN, GANai, STAN-CT, RadiomicGAN, CycleGAN, and CVS-CT improves the feature stability by 22.8%, 23.5%, 23.3%, 23.3%, 23.7%, 9.3% and 7.3%, respectively. Models that do not require paired training image data have significantly lower performance than the others probably due to high model complexity.

CLINICAL RELEVANCE/APPLICATION

Understanding CT standardization models can help advance the radiomic studies in NSCLC and improve clinical outcomes associated with image-based features.

PH01-B4   Use Of 7 Tesla MRI For Frameless Presurgical Planning With Skin-Adhesive Fiducials: Overcoming Image Geometric Distortion

Participants
Krystal Kirby, Baton Rouge, Louisiana (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate and correct image geometric distortion at the position of skin-adhesive fiducial markers in 7 Tesla (7T) MR images used for frameless stereotactic neurosurgical navigation.*Methods and Materials Three volunteers were imaged at 3T and 7T (Magnetom Prisma and Terra respectively, Siemens, Germany). 10 skin-adhesive fiducials were placed on the exposed skin surface of the volunteers, according to standard placement procedures, to facilitate patient-to-image registration in a commercial surgical planning system (StealthStation S8, Medtronic, USA). Imaging sequences included a magnetization-prepared rapid gradient echo (MPRAGE) with three receiver bandwidths (400, 690, and 1020 Hz/pixel) and a B0 field map. The vendor-provided distortion correction (DC) algorithm for gradient nonlinearity was used. A custom grid phantom was 3D printed to evaluate gradient scaling correction (GSC) factors. The phantom scans included a very high-bandwidth MPRAGE (1450 Hz/pixel) and high-resolution CT (Somatom Force, Siemens, Germany). GSC factors were determined by comparing three-axis measurements on the grid phantom through isocenter in MR and CT images. After rigid registration of in vivo images, a geometric distortion comparison was performed by measuring corresponding locations of the 10 fiducials in each volume with only the DC, after gradient scaling, and after correction via the B0 field map.*Results Scaling correction factors were X=101.1%, Y=102.2%, and Z=101.0%. With only the DC, differences between 3T and 7T MPRAGE with high/medium/low bandwidth were 2.2mm, 2.6mm, and 2.3mm. After the GSC, differences lowered (p<0.001) to 1.6mm, 1.3mm, and 1.0mm. Data from 4 fiducials was excluded due to patient positioning differences on 3T vs. 7T. Corrections with B0 field maps did not change these values significantly. 3T phantom data compared to CT had errors < 1.0mm.*Conclusions Geometric distortions in frameless 7T presurgical imaging can be reduced to a clinically relevant level (errors <~1mm) with no significant susceptibility-related distortions, by using high receiver bandwidth, ensuring gradients are properly calibrated, and placing skin fiducials in areas where distortions from patient positioning are minimal.*Clinical Relevance/Application Skin fiducial locations in 7T images yielded about 1mm distortion, without additional B0 correction. This facilitates the clinical implementation of 7T for frameless surgical guidance procedures.

RESULTS

Scaling correction factors were X=101.1%, Y=102.2%, and Z=101.0%. With only the DC, differences between 3T and 7T MPRAGE with high/medium/low bandwidth were 2.2mm, 2.6mm, and 2.3mm. After the GSC, differences lowered (p<0.001) to 1.6mm, 1.3mm, and 1.0mm. Data from 4 fiducials was excluded due to patient positioning differences on 3T vs. 7T. Corrections with B0 field maps did not change these values significantly. 3T phantom data compared to CT had errors < 1.0mm.

CLINICAL RELEVANCE/APPLICATION

Skin fiducial locations in 7T images yielded about 1mm distortion, without additional B0 correction. This facilitates the clinical implementation of 7T for frameless surgical guidance procedures.

PH01-B5   Miniaturized Head Tomography Imaging Using CNT X-ray Tubes - First Experimental Results

Participants
Brian Gonzales, PhD, SeaTac, Washington (*Presenter*) Scientist, Micro-X Ltd

PURPOSE

Stroke patients require rapid treatment due to the time-sensitive nature of the disease; Ischemic strokes can be directly treated with TPA if identified early. The use of TPA requires medical imaging to ensure there is no hemorrhage in the brain. Mobile Stroke Units using small head CT imaging units have shown significant improvement in patient outcomes by bringing CT imaging directly to patients, but these units are large, complex, expensive and difficult to deploy. We are investigating the use of CNT x-ray tubes to create an ultra-lightweight cost-effective stroke imaging tomography device that could be deployed in any ambulance to enable early imaging of patients suffering a stroke.*Methods and Materials We tested an early version of the concept using a digital x-ray device and a set of technical phantoms. We improved the early version through a series of simple geometric simulations and constructed a prototype fixed gantry cone beam wide angle Tomosynthesis scanner. Together with the Royal Melbourne Hospital, we imaged two cadavers and compared these images with scans taken using a conventional CT. We further tested the concept with a more detailed initial simulation study.*Results Early testing of the of the wide angle tomosynthesis showed accurate high resolution in the coronal plane, tangential to the array of CNT x-ray sources, but significant artifacts in the other planes. The second version significantly improved the resolution in the axial and sagittal planes, but the contrast within the brain was still low due to the number of sources and artifacts due to the skull. A unique dual-energy bone suppression approach was applied to suppress the skull artifacts in the projection slices and reconstructions showed improved soft-tissue contrast. Simulations showed further optimization of the array of x-ray tubes along with the dual-energy approach could enable the visualization of small hemorrhages down to a few mm in size.*Conclusions First testing demonstrated the potential effectiveness of a simple fixed gantry tomosynthesis imaging system using an array of CNT x-ray tubes to image patients suffering strokes, to rule out hemorrhages and enable early treatment with TPA. The unique fixed gantry approach allows for the use of simple dual energy bone suppression that significantly improves soft-tissue contrast. Further work is in progress via simulations and algorithm refinement to achieve a targeted 1mm bleed.*Clinical Relevance/Application Stroke is the second most common cause of death in individuals over sixty and the second most common cause of long-term disability globally. If early stroke imaging can be achieved in a low-cost system that is

easily deployed into any ambulance, millions of people every year could be helped, and thousands of lives saved.

RESULTS

Early testing of the of the wide angle tomosynthesis showed accurate high resolution in the coronal plane, tangential to the array of CNT x-ray sources, but significant artifacts in the other planes. The second version significantly improved the resolution in the axial and sagittal planes, but the contrast within the brain was still low due to the number of sources and artifacts due to the skull. A unique dual-energy bone suppression approach was applied to suppress the skull artifacts in the projection slices and reconstructions showed improved soft-tissue contrast. Simulations showed further optimization of the array of x-ray tubes along with the dual-energy approach could enable the visualization of small hemorrhages down to a few mm in size.

CLINICAL RELEVANCE/APPLICATION

Stroke is the second most common cause of death in individuals over sixty and the second most common cause of long-term disability globally. If early stroke imaging can be achieved in a low-cost system that is easily deployed into any ambulance, millions of people every year could be helped, and thousands of lives saved.

PH01-B6   Ultra Low Dose Whole-body Computed Tomography Protocol Optimization For Patients With Plasma Cell Disorders: Diagnostic Accuracy And Effective Dose Analysis From An Italian Reference Center

Participants
Giulio Strazzarino, MD, Torino, Italy (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the performances of a whole-body low dose CT protocol, evaluating diagnostic accuracy and patient effective dose reduction achievable with a latest generation CT scanner.*Methods and Materials The study was performed using a 256 slices CT scanner (Revolution CT, GE, USA). First WBLDCT examinations were performed in 2018 starting from a reference protocol with acquisition parameters set (120 kV, collimation 80 mm, rotation time, pitch, slice thickness 1,25 mm, noise index (NI) 25, iterative ASIR-V 50%). In February 2019, a phantom study was performed to investigate the minimum dose that allow to maintain an optimal diagnostic accuracy in lesion detection. This low dose protocol was implemented in clinical practice from April 2019 on 189 consecutive patients.Images were evaluated by three readers for image quality using a 5 point scale (1:non diagnostic; 5:excellent quality) and to detect lesions.*Results There was an overall very good agreement on image quality scores between the three readers for both groups as demonstrated by repeated measures ANOVA test with p values always superior to 0,05.An excellent inter-rater agreement for lesion detection was achieved evaluating both groups singularly and also considering the whole patient population,obtaining high values of Fleiss' kappa for all districts, ranging from 0,851 for humeral head to 1 for thoracic spine with values of p always <0,001.DLP median value for the original protocol was about 345 mGy cm (mean value 342,5 ± 102 mGy cm), with an interquartile range (IQR) of 302-408 mGy cm. With the optimized protocol, a 56% reduction of the median DLP was observed resulting in a value of 151 mGy cm (IQR 128-188 mGy cm, mean 160,5 ± 55 mGy cm). A dose reduction of about 60% was observed also for CTDIvol, from an initial median value of 2.2 mGy (IQR 1.9 - 2.7 mGy, mean 2,2 ± 0,6 mGy cm) down to a median CTDIvol of 0.9 mGy (IQR 0.8 - 1.2 mGy, mean 1 ± 0,4 mGy cm). Dose reduction was statistically significant for both DLP and CTDI vol (p < 0,001 in both cases).*Conclusions The lowest achievable dose for WBLDCT can be assessed with phantom studies and proper image quality metrics (including noise power spectrum, task transfer function and subjective image quality) thus demonstrating that routine ultra-low dose WBLDCT is feasible on latest generation CT scanners with a proper balance between tube current modulation parameters and iterative reconstruction strength resulting in excellent image quality and diagnostic accuracy with significant dose reduction for patients respecting the ALARA/ALARP principles (as low as reasonably achievable/as low as reasonably practicable).*Clinical Relevance/Application Optimization of Low Dose protocols in clinical practice starting from a phantom study.

RESULTS

There was an overall very good agreement on image quality scores between the three readers for both groups as demonstrated by repeated measures ANOVA test with p values always superior to 0,05.An excellent inter-rater agreement for lesion detection was achieved evaluating both groups singularly and also considering the whole patient population,obtaining high values of Fleiss' kappa for all districts, ranging from 0,851 for humeral head to 1 for thoracic spine with values of p always <0,001.DLP median value for the original protocol was about 345 mGy cm (mean value 342,5 ± 102 mGy cm), with an interquartile range (IQR) of 302-408 mGy cm. With the optimized protocol, a 56% reduction of the median DLP was observed resulting in a value of 151 mGy cm (IQR 128-188 mGy cm, mean 160,5 ± 55 mGy cm). A dose reduction of about 60% was observed also for CTDIvol, from an initial median value of 2.2 mGy (IQR 1.9 - 2.7 mGy, mean 2,2 ± 0,6 mGy cm) down to a median CTDIvol of 0.9 mGy (IQR 0.8 - 1.2 mGy, mean 1 ± 0,4 mGy cm). Dose reduction was statistically significant for both DLP and CTDI vol (p < 0,001 in both cases).

CLINICAL RELEVANCE/APPLICATION

Optimization of Low Dose protocols in clinical practice starting from a phantom study.

PH01-B7   Estimating Water-equivalent Diameter From CT Localizer

Participants
Christiane Burton, PhD, Boston, Massachusetts (*Presenter*) Nothing to Disclose

PURPOSE

Estimating water-equivalent diameter (WED) from CT localizer radiographs would allow it to be included into data-driven clinical workflows such as size adaptive protocol selection like diagnostic reference ranges (DRRs) which provide a minimum estimated patient dose. A calibration method to estimate WED from CT localizers was proposed. In this study we apply this method to patient data on 3 scanners and compare it to AAPM 220 results.*Methods and Materials CT axial and CT localizer images of the CTDIvol phantom with 1.0 (PMMA rod), 16, and 32 cm diameters and the ACR phantom were acquired on 3 scanners. Calibration curves were obtained for each scanner. Using patient data, the CT localizer-based WED was plotted as a function of the CT axial-based WED.*Results The calibration curves are linear on all scanners with R2<0.97, however the slope and y-intercepts vary. With the exception of outliers cause by truncation in the CT axial images, the CT localizer-based WED as a function of CT axial-based WED falls within the 95% confidence interval.*Conclusions The water-equivalent diameter can be estimated from the CT localizer radiograph.*Clinical Relevance/Application The water-equivalent diameter (WED) takes into account the attenuation of the patient when estimating dose prior to CT axial scanning.

RESULTS

The calibration curves are linear on all scanners with R2<0.97, however the slope and y-intercepts vary. With the exception of outliers cause by truncation in the CT axial images, the CT localizer-based WED as a function of CT axial-based WED falls within the 95% confidence interval.

CLINICAL RELEVANCE/APPLICATION

The water-equivalent diameter (WED) takes into account the attenuation of the patient when estimating dose prior to CT axial scanning.

PH01-B9   Comparison Of Two Deep Learning Image Reconstruction Algorithms on Chest CT Images: A Task-based Image Quality Assessment on Phantom Data

Participants
Joel Greffier, PhD, Nimes, France (*Presenter*) Nothing to Disclose

PURPOSE

To compare the effect of two Deep Learning Image Reconstruction (DLR) algorithms (AiCE and TrueFidelity) on task-based image quality.*Methods and Materials Acquisitions on an image quality phantom were acquired using six dose levels (CTDIvol: 10/7.5/5/2.5/1/0.5mGy) on two CT scanners. Raw data were reconstructed using the filtered back-projection (FBP) and the lowest/intermediate/highest DLR levels (L-DLR/M-DLR/H-DLR) of each algorithm. The noise power spectrum and task-based transfer function (TTF) were computed. The detectability index (d') was computed to model the detection of a low-contrast chest nodule, a ground-glass opacity, and a high contrast pulmonary lesion.*Results For the L-DLR and M-DLR levels, the noise magnitude was lower with TrueFidelity than with AiCE from 2.5 to 10mGy but the opposite for 1 and 0.5mGy. For all dose levels and H-DLR, noise magnitude was lower with AiCE than with TrueFidelity. For L-DLR and M-DLR, the average NPS spatial frequency (fav) values were higher for AiCE than for TrueFidelity for all dose levels except for 0.5mGy. For H-DLR levels, fav values were higher for TrueFidelity than for AiCE. Compared to TrueFidelity, TTF values at fifty percent were higher with AiCE for the air insert, and lower for the polyethylene insert. From 10 to 2.5mGy, d' values were higher for AiCE than for TrueFidelity for H-DLR for all simulated lesions, but were in the same range for L-DLR and M-DLR.*Conclusions DLR algorithms reduced the image noise and improved lesion detectability. The operation and properties of these algorithms impacted in different ways the noise texture and the spatial resolution.*Clinical Relevance/Application This study compared for the first time the two new DLR algorithms most used in clinical practice. We confirmed that these two algorithms reduced noise and improved the detectability of simulated chest lesions. We also showed that the operation and properties of these algorithms impacted in different ways the noise texture and spatial resolution. TrueFidelity had less impact on the spatial resolution and did not modify the image texture compared to AiCE. It should be noted that the choice of the DLR level has an impact on the metric results obtained.

RESULTS

For the L-DLR and M-DLR levels, the noise magnitude was lower with TrueFidelity than with AiCE from 2.5 to 10mGy but the opposite for 1 and 0.5mGy. For all dose levels and H-DLR, noise magnitude was lower with AiCE than with TrueFidelity. For L-DLR and M-DLR, the average NPS spatial frequency (fav) values were higher for AiCE than for TrueFidelity for all dose levels except for 0.5mGy. For H-DLR levels, fav values were higher for TrueFidelity than for AiCE. Compared to TrueFidelity, TTF values at fifty percent were higher with AiCE for the air insert, and lower for the polyethylene insert. From 10 to 2.5mGy, d' values were higher for AiCE than for TrueFidelity for H-DLR for all simulated lesions, but were in the same range for L-DLR and M-DLR.

CLINICAL RELEVANCE/APPLICATION

This study compared for the first time the two new DLR algorithms most used in clinical practice. We confirmed that these two algorithms reduced noise and improved the detectability of simulated chest lesions. We also showed that the operation and properties of these algorithms impacted in different ways the noise texture and spatial resolution. TrueFidelity had less impact on the spatial resolution and did not modify the image texture compared to AiCE. It should be noted that the choice of the DLR level has an impact on the metric results obtained.

CA04-C3   Assessment Of Dose Reduction Potential For Virtual Monoenergetic Coronary Artery Calcium Quantification With Dual-source Photon-counting CT: A Dynamic Phantom Study

Participants
Niels Van der Werf, MSc, Rotterdam, Netherlands (*Presenter*) Nothing to Disclose

PURPOSE

To assess the potential of coronary artery calcium (CAC) quantification on virtual monoenergetic images (VMI) at reduced radiation dose on a clinical dual source photon-counting detector (PCD) computed tomography (CT) system.*Methods and Materials A dynamic phantom with a cylindrical CAC (length:1.0 cm, diameter: 0.5 cm, density: 800 mg hydroxyapatite cm-3) was scanned with a clinical protocol for CAC scoring on a clinical dual-source PCD CT (NAEOTOM Alpha, Siemens Healthineers). The artery was moved in one direction at 60-75 beats per minute within a water compartment at the center of an anthropomorphic thorax phantom (QRM thorax, QRM). All acquisitions were repeated five times at 100% and 50% clinical radiation dose by adapting the tube current. VMI were reconstructed with filtered back projection at 40, 50, ?, 190 keV. For CAC quantification as Agatston scores, previously defined VMI energy level specific thresholds were used. Agatston scores were automatically calculated with a previously validated, in-house developed Python script. Agatston score deviations of >10% with the reference (ME 70 keV - 130 HU) were deemed to be clinically relevant. Contrast-to-noise ratios (CNR) were determined for each VMI level to assess CAC visualization.*Results Compared to the reference at 70 keV, deviations in median Agatston scores for clinical radiation dose were at most -6.4%, irrespective of VMI level. At reduced radiation dose, VMI at 40, 50 and 60 keV again showed comparable (maximum deviation -7.1%) median Agatston scores in comparison with the reference. Increased VMI levels showed clinically relevant in Agatston score up to 22%. Reference median (total range) CNR was at 18.6 (17.6;19.6) and 15.3 (14.8;15.5) for 100% and 50% radiation dose, respectively. CNR increased with decreasing VMI level, and decreased with increasing VMI level. At 40 keV, CNR was at 26.8 (26.0;27.9) and 21.9 (20.1;22.7) for 100% and 50% radiation dose, respectively. CNR at 190 keV was reduced to 7.4 (7.2;8.5) and 6.6 (5.8;7.2), respectively.*Conclusions With VMI level specific CAC thresholds, reduced VMI levels resulted in comparable Agatston scores with superior CNR at reduced radiation dose.*Clinical Relevance/Application For the first time, one can profit from both VMI and high temporal resolution with dual-source PCCT. A dose reduction for the CAC scoring protocol is feasible with VMI level specific CAC thresholds.

RESULTS

Compared to the reference at 70 keV, deviations in median Agatston scores for clinical radiation dose were at most -6.4%, irrespective of VMI level. At reduced radiation dose, VMI at 40, 50 and 60 keV again showed comparable (maximum deviation -7.1%) median Agatston scores in comparison with the reference. Increased VMI levels showed clinically relevant in Agatston score up to 22%. Reference median (total range) CNR was at 18.6 (17.6;19.6) and 15.3 (14.8;15.5) for 100% and 50% radiation dose, respectively. CNR increased with decreasing VMI level, and decreased with increasing VMI level. At 40 keV, CNR was at 26.8 (26.0;27.9) and 21.9 (20.1;22.7) for 100% and 50% radiation dose, respectively. CNR at 190 keV was reduced to 7.4 (7.2;8.5) and 6.6 (5.8;7.2), respectively.

CLINICAL RELEVANCE/APPLICATION

For the first time, one can profit from both VMI and high temporal resolution with dual-source PCCT. A dose reduction for the CAC scoring protocol is feasible with VMI level specific CAC thresholds.

IN01-B1   **Assessing Machine Learning Models: Pipeline For Validation And Comparison Of Multiple Models**

Participants
Bernardo Bizzo, MD,PhD, Newton, Massachusetts (*Presenter*) Consultant, Diagnosticos da America (Dasa)

PURPOSE

To design, build and test an objective evaluation pipeline to normalize performance measurement of three independently developed machine learning (ML) models for detection of lung nodules on chest CTs, using a common test imaging dataset.*Methods and Materials With IRB approval, we identified an enriched dataset of 100 chest CTs (n= 100 patients; age 19-92 years; male: female 46:54) from a pool of 2459 consecutive chest CTs and reports in our local clinical PACS archive. The majority opinion of three radiologists served as the ground-truth for the presence of nodules. All chest CTs were processed with three ML models for detecting lung nodules using our data-preprocessing and assessment pipeline chain. The pipeline included tools for image cohort creation and de-identification; report and image annotation for ground-truth labeling; server partitioning to receive vendor "black box" models and to enable model testing of selected 100 chest CTs within our security firewall; model validation and results visualization; and calculation of precision recall statistics for performance assessment of each model.*Results The evaluation was done without imaging data leaving our institutional firewall, and without our need to understand the black box of the third-party models that were being evaluated. The ground-truth radiologists annotated 243 nodules (127 solid; 76 ground glass; 40 part-solid) with a mean diameter of 7 (range 4-23) mm. There were significant variations (p<0.001) in true positives, false positives, false negatives, recall, and precision for detecting lung nodules among the tested ML models (Vendor-1: 194, 23, 49, 0.80, 0.89; Vendor-2: 182, 270, 61, 0.75, 0.40; Vendor-3: 75, 120, 168, 0.32, 0.39).*Conclusions Model performance varied greatly, overall underperforming compared with vendor advertisement and therefore justifying our premise that a standardized objective ML model evaluation process is needed. Our ML model validation pipeline tested the specific use case of detecting lung nodules in chest CTs, but is generalizable to other models and use cases.*Clinical Relevance/Application There is increasing availability of ML models for similar use cases. Prior to clinical use, ML models must be evaluated on local institutional data using standardized objective methods so that their performance can be normalized and compared.

RESULTS

The evaluation was done without imaging data leaving our institutional firewall, and without our need to understand the black box of the third-party models that were being evaluated. The ground-truth radiologists annotated 243 nodules (127 solid; 76 ground glass; 40 part-solid) with a mean diameter of 7 (range 4-23) mm. There were significant variations (p<0.001) in true positives, false positives, false negatives, recall, and precision for detecting lung nodules among the tested ML models (Vendor-1: 194, 23, 49, 0.80, 0.89; Vendor-2: 182, 270, 61, 0.75, 0.40; Vendor-3: 75, 120, 168, 0.32, 0.39).

CLINICAL RELEVANCE/APPLICATION

There is increasing availability of ML models for similar use cases. Prior to clinical use, ML models must be evaluated on local institutional data using standardized objective methods so that their performance can be normalized and compared.

MS03-A1   Blunt Cerebrovascular Injury (bcvi) In Ankylosed Cervical Spine: A Manual Review Of 5867 CT Angiographies At A Single Level 1 Traumacenter

Participants
Riku Vierunen, MD, Helsinki, Finland (*Presenter*) Nothing to Disclose

PURPOSE

To examine the incidence, location, and grade of blunt cerebrovascular injury (BCVI), and the concomitant strokes in patients with ankylosed cervical spine.*Methods and Materials Retrospective manual review of 5867 computed tomographic angiographies (CTA) of the craniocervical arteries obtained during nine years and six months revealed 153 patients with ankylosis of at least three consecutive cervical vertebrae. BCVI was the primary and concomitant brain infarction the secondary outcome. Predictive variables were facial, skull, and cervical spine fractures. Etiology and levels of ankylosis were recorded and compared to original reports from radiologists and clinicians. For correlation between cervical spine fracture and BCVI we used Chi-squared test, and for correlation between levels of ankylosis and concomitant fractured vertebrae and transversally disrupted intervertebral discs Spearman's ?. Interrater reliability for blinded review of BCVI between two musculoskeletal radiologists and one fellow in training had calculation by Krippendorf's alpha and percentage agreement, and for etiology of ankylosis by Cohen's ? between musculoskeletal radiologist and the trainee.*Results Of the 153 patients (M/F=111/42; median age 75 years) with ankylosed cervical spines, 28 (18.3%) had 34 BCVIs, of which 30 (88%) were located in the vertebral arteries. The most common level for BCVI was at C2. Biffl grade II (15) was most common, followed by grade IV (14), grade III (4) and grade V (1). In 28 patients, three BCVIs in vertebral arteries caused cerebellar, and two in carotid arteries caused cerebral infarctions. Most common mechanism of injury was a fall on ground level (81%). Cervical spine fractures correlated with BCVIs (P=.001), and the number of fractured vertebrae and intervertebral discs correlated with the number of ankylosed intervertebral discs (0.214, P<.01). Interrater reliability for BCVI was considered fair (37.56%, percentage agreement: 92.8-94.1) and for etiology of ankylosis substantial (0.728, P<.001). The original radiological reports revealed documentation of ankylosis in 82 patients (53%), of which clinicians noted 43 (28%), and in 59 (39%) ankylosis remained undocumented.*Conclusions In conclusion, ankylosis of the cervical spine is poorly recognized and falling on ground level predisposes patients to BCVI. Compared to nonspecified blunt trauma populations the relative risk for overall BCVI is increased tenfold and in vertebral arteries 33-fold.*Clinical Relevance/Application Detection of ankylosis in cervical spine of at least three consecutive vertebrae improves diagnostics of BCVI. Patients with ankylosed cervical spine require CTA after a fall on ground level for timely commencing of anticoagulation therapy.

RESULTS

Of the 153 patients (M/F=111/42; median age 75 years) with ankylosed cervical spines, 28 (18.3%) had 34 BCVIs, of which 30 (88%) were located in the vertebral arteries. The most common level for BCVI was at C2. Biffl grade II (15) was most common, followed by grade IV (14), grade III (4) and grade V (1). In 28 patients, three BCVIs in vertebral arteries caused cerebellar, and two in carotid arteries caused cerebral infarctions. Most common mechanism of injury was a fall on ground level (81%). Cervical spine fractures correlated with BCVIs (P=.001), and the number of fractured vertebrae and intervertebral discs correlated with the number of ankylosed intervertebral discs (0.214, P<.01). Interrater reliability for BCVI was considered fair (37.56%, percentage agreement: 92.8-94.1) and for etiology of ankylosis substantial (0.728, P<.001). The original radiological reports revealed documentation of ankylosis in 82 patients (53%), of which clinicians noted 43 (28%), and in 59 (39%) ankylosis remained undocumented.

CLINICAL RELEVANCE/APPLICATION

Detection of ankylosis in cervical spine of at least three consecutive vertebrae improves diagnostics of BCVI. Patients with ankylosed cervical spine require CTA after a fall on ground level for timely commencing of anticoagulation therapy.

MS03-A2   Multimodality Imaging Of Hamartomas: An Interactive Case Based Approach

Awards
Identified for RadioGraphics

Participants
Meghan G. Lubner, MD, Madison, Wisconsin (*Presenter*) Grant, Koninklijke Philips NV;Grant, Johnson & Johnson

TEACHING POINTS

1. Hamartomas are non-neoplastic masses that represent abnormal growth of normal tissue.2. Hamartomas may be seen in isolation or may be syndromic, with relevant syndromes including Cowden Syndrome, Tuberous Sclerosis, and Peutz-Jehgers syndrome.3. Hamartomas often have a characteristic imaging appearance depending on the specific organ system involved.4. Many of these masses are discovered incidentally and may be mistaken for neoplasm. Awareness of common location and multimodality imaging features can aid in appropriate diagnosis.

TABLE OF CONTENTS/OUTLINE

-Epidemiology and clinical features of hamartomas-Pathophysiology and pathologic features of hamartomas-Spectrum of imaging findings of hamartomas involving multiple organ systems-Interactive case examples-Emphasis on cross sectional imaging findings - Associated syndromes-Goals of Imaging-Mimics/Differential for hamartoma-Summary

NMMI03-B1 **Multiparametric Integrated 18F-FDG PET/MRI Based Radiomics For Prediction Of Therapy Response To Neoadjuvant Chemotherapy In Breast Cancer**

Participants
Julian Kirchner, Dusseldorf, Germany (*Presenter*) Nothing to Disclose

PURPOSE

This study investigated the performance of simultaneous 18F-FDG PET/MRI of the breast as a platform for comprehensive radiomics analysis to predict therapy response to neoadjuvant chemotherapy.*Methods and Materials 89 patients underwent simultaneous 18F-FDG PET/MRI. Breast tumors were segmented and radiomic features were extracted utilizing CERR software following the IBSI guidelines. LASSO regression was employed to select the most important radiomics features prior to model development. Five-fold cross validation was then utilzied alongside support vector machines, resulting in predictive models for various combinations of imaging data series.*Results Highest AUC and accuracy for differentiation between responders (partial or complete response) and non-responders (stable disease or progressive disease was achieved by all MR aand PET data (AUC 0.9; accuracy 84.3%), closely followed by exclusively PET data (AUC 0.89; accuracy 83.3%). Lowest results were achieved by exclusive T2 imaging, yielding an AUC of 0.74 and accuracy of 75%.*Conclusions 18F-FDG PET/MRI enables comprehensive high-quality radiomics analysis for prediction of therapy response to neoadjuvant chemotherapy in patients with breast cancer, with strong radiomic signatures being provided by all dynamic MRI and PET data.*Clinical Relevance/Application Multiparametric 18F-FDG PET/MRI enables high-quality radiomics analysis for prediction of therapy response to neoadjuvant chemotherapy in patients with breast cancer.

RESULTS

Highest AUC and accuracy for differentiation between responders (partial or complete response) and non-responders (stable disease or progressive disease was achieved by all MR aand PET data (AUC 0.9; accuracy 84.3%), closely followed by exclusively PET data (AUC 0.89; accuracy 83.3%). Lowest results were achieved by exclusive T2 imaging, yielding an AUC of 0.74 and accuracy of 75%.

CLINICAL RELEVANCE/APPLICATION

Multiparametric 18F-FDG PET/MRI enables high-quality radiomics analysis for prediction of therapy response to neoadjuvant chemotherapy in patients with breast cancer.

NMMI03-B2 **Radiomic Analysis For Forfollicular Lymphoma And Diffuse Large B-cell Lymphoma Classification**

Participants
Yunchao Yin, MSc, Groningen, Netherlands (*Presenter*) Nothing to Disclose

PURPOSE

Follicular lymphoma (FL) is a B-cell non-Hodgkin lymphoma associated with a generally favorable prognosis. However, one of the challenges in the management of these patients is the identification of individuals at high risk of histological transformation, most commonly into diffuse large B-cell lymphoma (DLBCL). Yet, no single reliable predictor has been identified. [18F]FDG PET/CT is increasingly used at diagnosis in FL patients but visual interpretation cannot reliably distinguish between FL and DLBCL. Therefore, we evaluated whether radiomic analysis of clinical baseline [18F]FDG PET/CT may be used to discriminate between patients with FL and DLBCL, potentially identify patients with transformation of FL during the course of disease.*Methods and Materials A retrospective cohort of patients consecutively included at a tertiary care center between the years 2010 and 2020. Patients were selected based on confirmed histopathological diagnosis of primary FL or DLBCL as well as available [18F]FDG PET/CT with EARL reconstruction parameters within 6 months of diagnosis. Radiomic features were extracted from the region of interest on well-registered CT and PET images. A subset of features selected by univariate analysis were used for radiomic analysis based on multiple logistic regression and ensemble classifiers. The trained models were tested on 20% of patients. The performance of radiomic analysis was compared with SUVmax as a sole predictor.*Results The study cohort included 76 patients with DLBCL and 44 patients with FL.214 features were extracted from CT and PET images and 135 were remained after feature selection. The best performing radiomic analysis for FL and DLBCL classification reached an AUC of 0.86 and accuracy of 0.8. Th analysis with SUVmax as sole predictor achieved an AUC 0.79, accuracy of 0.7. Based on gradient boosting classifier, the AUC and accuracy of radiomic features was found to be significantly larger than that of SUVmax (P<0.01).*Conclusions Radiomic analysis was superior to SUVmax in differentiating FL from DLBCL. Our current approach represents a small but significant improvement compared to current semiquantitative methods using SUVmax and should be further investigated.*Clinical Relevance/Application Radiomic analysis is superior to lesion semiquantification with SUVmax at differentiating FL from DLBCL.

RESULTS

The study cohort included 76 patients with DLBCL and 44 patients with FL.214 features were extracted from CT and PET images and 135 were remained after feature selection. The best performing radiomic analysis for FL and DLBCL classification reached an AUC of 0.86 and accuracy of 0.8. Th analysis with SUVmax as sole predictor achieved an AUC 0.79, accuracy of 0.7. Based on

gradient boosting classifier, the AUC and accuracy of radiomic features was found to be significantly larger than that of SUVmax (P<0.01).

CLINICAL RELEVANCE/APPLICATION

Radiomic analysis is superior to lesion semiquantification with SUVmax at differentiating FL from DLBCL.

RI01-A2 **Reproductive Outcome Of Infertile Patients With Proximal Tubal Obstruction Treated With Selective Salpingography With Tubal Catheterization.**

Participants
Marcin Czeczelewski, Lublin, Poland (*Presenter*) Nothing to Disclose

PURPOSE

Evaluation of pregnancy rate of infertile patients with proximal tubal obstruction 12 months after selective salpingography (SSG) and tubal catheterization (TC).*Methods and Materials The prospective, single-center study between January 2012 and January 2019 included 248 women (age 34.4 ± 4.7 years) without any patent tube diagnosed. SSG was performed with the 5 F Kumpe catheter (Cook, Bloomington, IN) directed to the proximal tubal opening by tactile sensation. Its position was controlled under fluoroscopy and if correct, a contrast medium was injected to assess the patency and attempt to unblock the tube. In case of persistent obstruction, the radiologically guided tubal catheterization and guidewire recanalization was performed. Reproductive outcomes at minimum of 12 months following the treatment were collected by a telephone survey in patients with at least one patent tube.*Results Of a total of 399 tubes with confirmed proximal tubal occlusion, 383 successfully restored their patency resulting in a 96% technical success rate. Thirty-five percent of occluded oviducts were treated with SSG and 65% required additional TC. Out of 200 patients included in follow-up, 80 patients conceived which resulted in a 40% overall pregnancy rate. In this group 68 women conceived spontaneously (85 %) and 12 after controlled ovarian hyperstimulation (15 %).*Conclusions The SSG with TC is an effective method of restoring tubal patency with promising clinical outcomes. However, careful assessment of fallopian tubes and comprehensive evaluation of partners' reproductive situation before therapy required.*Clinical Relevance/Application Selective salpingography and tubal canalization offer minimally invasive and cost-effective alternatives to tubal microsurgery and IVF-ET in women with tubal occlusion.

RESULTS

Of a total of 399 tubes with confirmed proximal tubal occlusion, 383 successfully restored their patency resulting in a 96% technical success rate. Thirty-five percent of occluded oviducts were treated with SSG and 65% required additional TC. Out of 200 patients included in follow-up, 80 patients conceived which resulted in a 40% overall pregnancy rate. In this group 68 women conceived spontaneously (85 %) and 12 after controlled ovarian hyperstimulation (15 %).

CLINICAL RELEVANCE/APPLICATION

Selective salpingography and tubal canalization offer minimally invasive and cost-effective alternatives to tubal microsurgery and IVF-ET in women with tubal occlusion.

CA05-A2   **A Lasso-derived Risk Model For Subclinical Cac Progression In Asian Population With An Initial Score Of Zero**

Participants
Fu-Zong Wu, MD, Kaohsiung, Taiwan (*Presenter*) Nothing to Disclose

PURPOSE

This study is aimed at developing a prediction nomogram for subclinical coronary atherosclerosis in an Asian population with baseline zero score, and to compare its discriminatory ability with Framingham risk score (FRS) and atherosclerotic cardiovascular disease (ASCVD) models.*Methods and Materials Clinical characteristics, physical examination, and laboratory profiles of 830 subjects were retrospectively reviewed. Subclinical coronary atherosclerosis in term of Coronary artery calcification (CAC) progression was the primary endpoint. A nomogram was established based on a least absolute shrinkage and selection operator (LASSO)-derived logistic model. The discrimination and calibration ability of this nomogram was evaluated by Hosmer-Lemeshow test and calibration curves in the training and validation cohort.*Results Of the 830 subjects with baseline zero score with the average follow-up period of 4.55 ± 2.42 year in the study, these subjects were randomly placed into the training set or validation set at a ratio of 2.8:1. These study results showed in the 612 subjects with baseline zero score, 145 (23.69%) subjects developed CAC progression in the training cohort (N = 612), while in the validation cohort (N = 218), 51 (23.39%) subjects developed CAC progression. This LASSO-derived nomogram included the following 10 predictors: "sex," age," "hypertension," "smoking habit," "Gamma-Glutamyl Transferase (GGT)," "C-reactive protein (CRP)," "high-density lipoprotein cholesterol (HDL-C)," "cholesterol," "waist circumference," and "follow-up period." Compared with the FRS and ASCVD models, this LASSO-derived nomogram had higher diagnostic performance and lower Akaike information criterion (AIC) and Bayesian information criterion (BIC) value. The discriminative ability, as determined by the area under receiver operating characteristic curve was 0.780 (95% confidence interval: 0.731-0.829) in the training cohort and 0.836 (95% confidence interval: 0.761-0.911) in the validation cohort.*Conclusions This validated nomogram provided a useful predictive value for subclinical coronary atherosclerosis in subjects with baseline zero score, and could provide clinicians and patients with the primary preventive strategies timely in individual-based preventive cardiology.*Clinical Relevance/Application This nomogram could help clinicians to identify subclinical coronary atherosclerosis in subjects at low to intermediate risk for guidance for the primary preventive strategies in individual-based preventive cardiology.

RESULTS

Of the 830 subjects with baseline zero score with the average follow-up period of 4.55 ± 2.42 year in the study, these subjects were randomly placed into the training set or validation set at a ratio of 2.8:1. These study results showed in the 612 subjects with baseline zero score, 145 (23.69%) subjects developed CAC progression in the training cohort (N = 612), while in the validation cohort (N = 218), 51 (23.39%) subjects developed CAC progression. This LASSO-derived nomogram included the following 10 predictors: "sex," age," "hypertension," "smoking habit," "Gamma-Glutamyl Transferase (GGT)," "C-reactive protein (CRP)," "high-density lipoprotein cholesterol (HDL-C)," "cholesterol," "waist circumference," and "follow-up period." Compared with the FRS and ASCVD models, this LASSO-derived nomogram had higher diagnostic performance and lower Akaike information criterion (AIC) and Bayesian information criterion (BIC) value. The discriminative ability, as determined by the area under receiver operating characteristic curve was 0.780 (95% confidence interval: 0.731-0.829) in the training cohort and 0.836 (95% confidence interval: 0.761-0.911) in the validation cohort.

CLINICAL RELEVANCE/APPLICATION

This nomogram could help clinicians to identify subclinical coronary atherosclerosis in subjects at low to intermediate risk for guidance for the primary preventive strategies in individual-based preventive cardiology.

IR01-B3   **Evaluating Uterine Fibroids Pre And Post Uterine Artery Embolization Using Advanced Ultrasound Techniques**

Participants
Priscilla Machado, MD, Philadelphia, Pennsylvania (*Presenter*) Nothing to Disclose

PURPOSE

To assess fibroid microvascularity before and after uterine artery embolization (UAE) using contrast-enhanced ultrasound (CEUS) and superb microvascular imaging (SMI; Canon Medical Systems, Tustin, CA, USA); a new high-sensitive Doppler mode.*Methods and Materials To date 38 women scheduled for UAE to treat their uterine fibroids were enrolled in this ongoing IRB-approved study. Subjects underwent 3 examinations (day 0, 15 and 90 after UAE) using an Aplio i800 scanner (Canon Medical Systems) with a curvilinear array. Color Doppler (CDI), power Doppler (PDI), color and monochrome SMI (cSMI and mSMI) images of the uterine fibroids were acquired followed by CEUS. For the CEUS examination 2.0 mL of Lumason (Bracco, Milan, Italy) was administered IV. Digital clips were assessed by two radiologists classifying the fibroids as having internal, peripheral or no vascularity for CDI, PDI, cSMI and mSMI; the classification for CEUS was a binary yes/no for the presence of vascularity within the fibroid. The images were analyzed using ImageJ (NIH, Bethesda, MD, USA) to quantify the fractional vascularity of the fibroids (FV) and flow intensity. Results were analyzed using one-way ANOVA, t-test and kappa-values.*Results All 38 subjects underwent the pre-UAE ultrasound examination, 35 subjects underwent the 15 days post-UAE ultrasound examination and 28 subjects underwent the 90 days post-UAE ultrasound examination completing their enrollment in the study. There was an overall agreement between the 2 readers for all imaging modalities (CDI, PDI, cSMI, mSMI and CEUS) and examination times (p=0.25) with kappa=0.7. Fraction vascularity (FV) analysis across imaging modes (CDI, PDI, cSMI, mSMI and CEUS) and examination times showed statistically significant differences (p<0.0001). Flow intensity values across imaging modes (CDI, PDI, cSMI and mSMI) and examination times pre UAE and 15 days post UAE showed statistically significant differences (p<0.02), the flow intensity analysis for the 90 days post UAE showed no statistically significant difference (p>0.4).*Conclusions Results indicate that CEUS and SMI pre and post UAE can accurately evaluate fibroid microvascularity, and therefore, can be a noninvasive and accurate method for monitoring treatment results.*Clinical Relevance/Application UAE is a nonsurgical therapy to block blood flow to fibroids. CEUS and SMI can accurately evaluate fibroid microvascularity, and therefore can become noninvasive methods for monitoring UAE treatment results.

RESULTS

All 38 subjects underwent the pre-UAE ultrasound examination, 35 subjects underwent the 15 days post-UAE ultrasound examination and 28 subjects underwent the 90 days post-UAE ultrasound examination completing their enrollment in the study. There was an overall agreement between the 2 readers for all imaging modalities (CDI, PDI, cSMI, mSMI and CEUS) and examination times (p=0.25) with kappa=0.7. Fraction vascularity (FV) analysis across imaging modes (CDI, PDI, cSMI, mSMI and CEUS) and examination times showed statistically significant differences (p<0.0001). Flow intensity values across imaging modes (CDI, PDI, cSMI and mSMI) and examination times pre UAE and 15 days post UAE showed statistically significant differences (p<0.02), the flow intensity analysis for the 90 days post UAE showed no statistically significant difference (p>0.4).

CLINICAL RELEVANCE/APPLICATION

UAE is a nonsurgical therapy to block blood flow to fibroids. CEUS and SMI can accurately evaluate fibroid microvascularity, and therefore can become noninvasive methods for monitoring UAE treatment results.

IR01-B4   **Blood Derived Embolic Materials For Embolization**

Participants
Izzet Altun, Scottsdale, Arizona (*Presenter*) Nothing to Disclose

PURPOSE

Endovascular embolization has become the cornerstone of clinical interventions in the treatment of life-threatening vascular hemorrhages, aneurysms and vascular malformation. Here, we present novel blood-derived embolic material (BEM) with regenerative properties that can be prepared at point-of-care for urgent embolization and can be delivered using endovascular catheters to achieve instant and durable intra-arterial hemostasis regardless of coagulopathy.*Methods and Materials Adult Yorkshire pigs were anticoagulated with IV heparin (ACT 250-500). Following intra-arterial access into the carotid artery, a clinical catheter was advanced to the renal arteries or pelvic arteries and digital subtraction angiography (DSA) was performed. Arteries embolized with approximately 2 ml of BEM. BEM was produced by isolating the platelet rich fibrin from 10 ml of blood and mixed with nanosilicates to create the shear thinning hydrogel. Subset of the animals was allowed to survive 1 hour (n=4), 14 days (n=4) and another subset (n=4) received traumatic vascular injury to simulate point-of-care rapid synthesis and embolization. CT angiography (CTA) was conducted just prior to necropsy. Extensive cell culture and in vitro testing of BEM were also performed.*Results In a large animal model of vascular embolization, we show that BEM can be prepared at point-of-care within 26 minutes using fresh blood, it can be easily delivered using clinical catheters to embolize renal and iliac arteries, and we show that BEM is safe and biocompatible. We further demonstrated that in an anticoagulated state, delivery of 1-2 ml of point of care BEM into the coil mass was able to achieve complete occlusion of iliac and renal arteries and eventually rescuing failed coil embolization. Additionally, BEM could be successfully

retrieved in the event of temporary embolization or non-target delivery of BEM. Histology and micro-CT of embolized arteries demonstrated complete occlusion of the artery and gradual biodegradation of BEM over time with its replacement with fibroinflammatory tissue. Fluoroscopy images of all the animals and CTA studies of day 14 pigs consistently showed successful embolization with BEM without any recanalization, artifact, fragmentation, displacement, or migration.*Conclusions In the swine arteries, BEM achieved durable hemostasis without any complication, imaging artifact, recanalization, displacement and fragmentation. BEM has many advantages over currently used embolic materials, making it a promising new tool for embolization.*Clinical Relevance/Application BEM has significant advantages over the current embolic agents with the potential for rapid adoption in clinical practice.

RESULTS

In a large animal model of vascular embolization, we show that BEM can be prepared at point-of-care within 26 minutes using fresh blood, it can be easily delivered using clinical catheters to embolize renal and iliac arteries, and we show that BEM is safe and biocompatible. We further demonstrated that in an anticoagulated state, delivery of 1-2 ml of point of care BEM into the coil mass was able to achieve complete occlusion of iliac and renal arteries and eventually rescuing failed coil embolization. Additionally, BEM could be successfully retrieved in the event of temporary embolization or non-target delivery of BEM. Histology and micro-CT of embolized arteries demonstrated complete occlusion of the artery and gradual biodegradation of BEM over time with its replacement with fibroinflammatory tissue. Fluoroscopy images of all the animals and CTA studies of day 14 pigs consistently showed successful embolization with BEM without any recanalization, artifact, fragmentation, displacement, or migration.

CLINICAL RELEVANCE/APPLICATION

BEM has significant advantages over the current embolic agents with the potential for rapid adoption in clinical practice.

IR01-B5   **Deep Convolutional-Neural-Network-Based Metal Artifact Reduction For CT-Guided Interventional Oncology Procedures (MARIO)**

Participants
Liqiang Ren, PhD, Rochester, Minnesota (*Presenter*) Nothing to Disclose

PURPOSE

To train and evaluate a deep convolutional neural network (CNN) model to identify and remove metallic-probe-induced artifact on CT images acquired during interventional oncology procedures.*Methods and Materials A previously validated metal insertion framework was applied to create CNN training images from the planning scans of ten CT-guided kidney cryoablation procedures (SOMATOM Edge, Siemens Healthcare). For each case, up to 4 intersecting cryoablation probes (IceForce, Boston Scientific) were artificially inserted in multiple positions/orientations into projection (images with artifacts, input) and in image (artifact-free images, target) CT data, respectively, creating a total of ~200 CT volumes. Training images were reconstructed with clinical reconstruction parameters (kernel: Br40(3), thickness: 3 mm, field of view: 400 mm) using manufacturer reconstruction software. Approximately 23,000 training patches with at least 5% of the total pixels affected by probe-induced artifact were cropped from training images with and without artifacts for network inputs and targets, respectively; 3 adjacent slices comprised the input channel dimension. A CNN model (MARIO) was trained to identify and remove artifacts from input images, and then applied to 50 independent, previously unseen CT datasets from treatment monitoring scans during kidney cryoablations. One hundred CT datasets (50 original, 50 MARIO processed) were reviewed independently by three senior interventional radiologists in a randomized, blinded study. Each dataset was scored on an ordinal scale (1 unacceptable, 4 excellent) on aspects that included overall image quality, severity of metal artifact, visualization of needle tips, ice-ball conspicuity, and overall treatment confidence. Signed-rank tests were performed to compare the scores between original and MARIO images.*Results Average reader scores were significantly higher for MARIO images compared to the original images across all metrics (all p<0.0001), demonstrating the effectiveness of MARIO to reduce probe-induced artifacts. Notably, the number of image quality metrics with suboptimal (i.e. average score <2) scores decreased from 10/300 in the original images to 1/300 in the MARIO data.*Conclusions Reduction of metal artifacts by the CNN-based MARIO model significantly improved overall image quality, provided better visualization of the needle tips and ice-ball, and increased radiologists' overall treatment confidence.*Clinical Relevance/Application MARIO increased radiologists' confidence in the placement accuracy of the cryoablation probes and in the resulting treatment zone, which may improve safety and oncologic outcomes for patients undergoing CT-guided interventional oncology procedures.

RESULTS

Average reader scores were significantly higher for MARIO images compared to the original images across all metrics (all p<0.0001), demonstrating the effectiveness of MARIO to reduce probe-induced artifacts. Notably, the number of image quality metrics with suboptimal (i.e. average score <2) scores decreased from 10/300 in the original images to 1/300 in the MARIO data.

CLINICAL RELEVANCE/APPLICATION

MARIO increased radiologists' confidence in the placement accuracy of the cryoablation probes and in the resulting treatment zone, which may improve safety and oncologic outcomes for patients undergoing CT-guided interventional oncology procedures.

IR01-B6   **Hepatocellular Carcinoma Circulating Tumors Cells Using Interventional Treatment: Conventional Transarterial Chemoembolization Versus Microwave Ablation**

Participants
Thomas J. Vogl, MD, PhD, Frankfurt, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the short-term dynamics of circulating tumor cells (CTCs) in patients with hepatocellular carcinoma (HCC) under conventional transarterial chemoembolization (cTACE) or microwave ablation (MWA). The short-term dynamics were compared with the clinical course of the patients using a novel method for the isolation and detection of CTCs.*Methods and Materials Blood samples from 18 patients with HCC who underwent cTACE (n=8) or MWA (n=10) were analyzed. Intravenous blood was taken before and immediately after the radiological interventions to isolate CTCs and quantify them by flow cytometry. CTCs were considered to be those cells that were negative for the marker CD45 and positive for the markers ASGPR, CD146, and CD274 (PDL1). Follow-up studies of up to 2 years after the radiological intervention were evaluated.*Results The number of CTCs after radiological intervention (post=0.9 CTCs/ml of blood) was on average lower than that before therapy (pre=1.2 CTCs/ml of blood). The number of CTCs decreased more in patients treated with MWA (0.4 CTCs/ml of blood) than in those who received cTACE (0.2 CTCs/ml of blood). The 2-year survival rate in the group receiving cTACE (37.5% died) was lower than that in MWA patients (0% died).*Conclusions The therapeutic benefit of cTACE and MWA in patients with HCC is emphasized by decreasing CTCs and the

clinical course of the patients.*Clinical Relevance/Application Interventional treatment using cTACE or MWA results in improved survival rates in patients with HCC

RESULTS

The number of CTCs after radiological intervention (post=0.9 CTCs/ml of blood) was on average lower than that before therapy (pre=1.2 CTCs/ml of blood). The number of CTCs decreased more in patients treated with MWA (0.4 CTCs/ml of blood) than in those who received cTACE (0.2 CTCs/ml of blood). The 2-year survival rate in the group receiving cTACE (37.5% died) was lower than that in MWA patients (0% died).

CLINICAL RELEVANCE/APPLICATION

Interventional treatment using cTACE or MWA results in improved survival rates in patients with HCC

SDP-CH-1   A Hybrid Loss-based Network Architecture For End-to-end Lung Nodule Segmentation

Participants
Jiangdian Song, PhD, Shenyang, China (*Presenter*) Nothing to Disclose

PURPOSE

Machine learning-based lung nodule segmentation methods are limited by the requirement for additional human interaction and the challenge of accurately segmenting adhesive nodules, whereas current deep learning models may be strict towards image pre-processing and pre-selected nodule patches. We aim to propose a hybrid loss-based network by integrating the Faster R-CNN with generalized intersection over union (GIoU) and the Wasserstein generative adversarial network with a gradient penalty (WGAN-GP) for end-to-end lung nodules segmentation on CT images.*Methods and Materials The proposed model consisted of a Faster-RCNN module for bounding box detection of nodule candidates, and subsequently a refined WGAN-GP module for lung nodule segmentation. GIoU loss was used to improve nodule detection of Faster-RCNN, and mean square error loss and VGG loss were used in WGAN-GP to improve nodule generation, respectively. In addition, short connection was introduced to accumulate the output of each 2D Conv with the corresponding 2D DeConv results in the generator of WGAN-GP to stimulate the network for nodule segmentation. The LIDC-IDRI dataset were used in this study, and U-net was used for comparison. Dice coefficient was used to evaluate the segmentation accuracy, and the measurements of precision and recall were used to evaluate nodule detection performance.*Results A total of 2,635 lung nodules collected from the LIDC-IDRI dataset were used in this study, and was randomly divided into training, validation, and test dataset (8:1:1). For the proposed network, DC of 85.33%, 77.43%, and 76.09% was acquired on the three datasets for segmentation, with precision of 85.00% and recall of 91.73% on the test dataset for detection, respectively. For the U-net, DC of 94.58%, 81.09%, and 80.55% was acquired on the three datasets, with precision of 60.11% and recall of 88.71% on the test dataset, respectively. Compared with U-net, overfitting and false positive nodule production could be significantly mitigated using the proposed model (P < 0.001).*Conclusions Our study provided a new solution for mitigating the inevitable human interaction and pre-processing procedures which are necessary for the existing lung nodule segmentation methods. Compared with the current mainstream segmentation network, the proposed approach alleviated false positive production and overfitting challenges and achieved competitive segmentation result.*Clinical Relevance/Application Our findings offer a new paradigm to effectively utilize state-of-the-art networks for accurate detection and end-to-end segmentation of lung nodules on CT images. The mitigation on manual interaction and network overfitting will promote lung nodule segmentation algorithms to clinical practice.

RESULTS

A total of 2,635 lung nodules collected from the LIDC-IDRI dataset were used in this study, and was randomly divided into training, validation, and test dataset (8:1:1). For the proposed network, DC of 85.33%, 77.43%, and 76.09% was acquired on the three datasets for segmentation, with precision of 85.00% and recall of 91.73% on the test dataset for detection, respectively. For the U-net, DC of 94.58%, 81.09%, and 80.55% was acquired on the three datasets, with precision of 60.11% and recall of 88.71% on the test dataset, respectively. Compared with U-net, overfitting and false positive nodule production could be significantly mitigated using the proposed model (P < 0.001).

CLINICAL RELEVANCE/APPLICATION

Our findings offer a new paradigm to effectively utilize state-of-the-art networks for accurate detection and end-to-end segmentation of lung nodules on CT images. The mitigation on manual interaction and network overfitting will promote lung nodule segmentation algorithms to clinical practice.

SDP-CH-11   Progression Of Architectural Distortion In Usual Interstitial Pneumonia: Evaluation Based On Deformable Registration Of Sequential Computed Tomography Images

Participants
NAOFUMI YASUDA, Yokohama, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Idiopathic pulmonary fibrosis (IPF) presents a usual interstitial pneumonia (UIP) pattern on computed tomography (CT). Subpleural fibrosis with architectural distortion is a characteristic histological finding of UIP. We assessed the architectural distortion accompanying disease progression by measuring deformities in the peripheral lung structures on sequential CT.*Methods and Materials This single-institution retrospective study was approved by our institutional review board. Written informed patient consent was waived. We included IPF patients who initially visited our hospital in 2015 and underwent three annual CT scans and pulmonary function tests. The total CT lung volume (CTLVtotal) and lesion volume were measured using Quantification software (QZIP, Ziosoft, Inc.). The lesion extent was defined as the lesion volume divided by CTLVtotal. The initial and follow-up CT images were deformably registered and the three-dimensional average displacement (3D-AD) of the pulmonary vessels and peripheral bronchi were calculated using Ziostation2 software (Ziosoft, Inc.). We defined the subpleural lung region as within 1 cm below the pleura, and compared various parameters in the whole, subpleural region, and inner region of lungs using Wilcoxon's signed-rank test.*Results Forty-one IPF patients (median age, 69 y; 36 men, 5 women; median %forced vital capacity, 84.8%) were included.

The median normal lung volume decreased from 3362 cc on the initial CT to 3331, and 3098 cc on the 2nd, and 3rd CT, respectively. The median lesion volume increased from 531 cc to 600, and 714 cc, respectively. On initial CT, the median lesion extent was larger in the outer than in the inner lungs (22.0% vs. 5.7%, p<0.001). The peripheral bronchi and vessels approached the pleura. The 3D-AD color map revealed peripheral structure deviation. The median 3D-AD was larger in the subpleural region than in the inner region of lungs: 4.1 vs. 3.4 mm (p<0.001) between the initial and 1st follow-up CT, 5.3 vs. 4.9 mm (p<0.001) between the initial and 2nd follow-up CT.*Conclusions The 3D-AD-based architectural distortion was larger in the outer lungs in IPF patients.*Clinical Relevance/Application The 3D-AD color map by deformable registration of sequential CT images can help visualize the progression of pulmonary architectural distortion in patients with idiopathic pulmonary fibrosis.

RESULTS

Forty-one IPF patients (median age, 69 y; 36 men, 5 women; median %forced vital capacity, 84.8%) were included. The median normal lung volume decreased from 3362 cc on the initial CT to 3331, and 3098 cc on the 2nd, and 3rd CT, respectively. The median lesion volume increased from 531 cc to 600, and 714 cc, respectively. On initial CT, the median lesion extent was larger in the outer than in the inner lungs (22.0% vs. 5.7%, p<0.001). The peripheral bronchi and vessels approached the pleura. The 3D-AD color map revealed peripheral structure deviation. The median 3D-AD was larger in the subpleural region than in the inner region of lungs: 4.1 vs. 3.4 mm (p<0.001) between the initial and 1st follow-up CT, 5.3 vs. 4.9 mm (p<0.001) between the initial and 2nd follow-up CT.

CLINICAL RELEVANCE/APPLICATION

The 3D-AD color map by deformable registration of sequential CT images can help visualize the progression of pulmonary architectural distortion in patients with idiopathic pulmonary fibrosis.

SDP-CH-12 Association Of Total Lung Field Volume Change In Peri-peak Inspiration Period Measured On Dynamic-ventilation Computed Tomography With Percent Forced Vital Capacity: Comparison Between Idiopathic Pulmonary Fibrosis And Connective-tissue Disease Interstitial Lung Disease

Participants
Yukihiro Nagatani, MD, Otsu, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To compare the association of global lung volume change in peri-peak inspiration period with percent forced vital capacity (%FVC) and relative time duration of inspiration to expiration on dynamic-ventilation computed tomography (DVCT) between idiopathic pulmonary fibrosis/usual interstitial pneumonia (IPF/UIP) and connective-tissue disease interstitial lung disease (CTD-IP)*Methods and Materials Thirty-four patients including 12 IPF/UIP and 16 CTD-IP patients underwent DVCT by using 320-row scanner (Aquilion ONE, Canon Medical Systems, Otawara, Tochigi, Japan) with 16cm-coverage during 5.5m-sec single respiration for upper and lower lung fields in a single examination (4.8 mSv). Bilateral lung field volumes (LFVs) were automatically measured by dedicated software in each phase during a single respiration. Average volume decrease ratio (aVDR) in peri-peak inspiration period for 3 and 5 time frames: 1.05 and 1.75 sec (PPIP-3 and PPIP-5) and maximal volume decrease ratio in respiration (mVDR) were calculated for total LFVs by using measured values at peak-inspiration as standard of reference. Correlation between %FVC and quantified values such as aVDR in PPIP-3 and PPIP-5, mVDR, LFVs for total, right and left LF at peak-inspiration (PI) were assessed by using Spearman's rank coefficient, in total as well as IPF/UIP and CTD-ILD. Ratio in time duration of inspiration to expiration (IER-TD) and ratio in maximal volume change velocity of inspiration to expiration (IER-MVCV) were compared between IPF/UIP and CTD-ILD by using Mann-Whitney U test.*Results In IPF/UIP as well as total study population, %FVC correlated positively with aVDR in PPIP-3 and PPIP-5 and LFVs for total, right and left LFs at PI (r= 0.717, 0.749, 0.809, 0.837 and 0.830, p<0.05), and did not correlate with mVDR (r=0.500, p=0.10). Whereas in CTD-ILD, %FVC correlated positively only with aVDR in PPIP-5, LFs for total and left LFs at PI (r=0.537, 0.507 and 0.690, p<0.05). IER in IPF/UIP (0.83 ± 0.35) was smaller than that in CTD-ILD (0.98 ± 0.23) (p=0.02), although IER-MVCV in IPF/UIP (1.36 ± 0.60) was comparable to that in CTD-ILD (1.16 ± 0.37) (p=0.54).*Conclusions Global lung volume analysis on DVCT demonstrated relative shorter inspiratory duration with positive relation between change in peri-peak inspiration period and %FVC, reflecting subpleural fibrosis and its advance parallel to %FVC reduction in IPF/UIP.*Clinical Relevance/Application Pathological change such as subpleural fibrosis could be reflected in respiratory change in global lung volume on dynamic-ventilation CT.

RESULTS

In IPF/UIP as well as total study population, %FVC correlated positively with aVDR in PPIP-3 and PPIP-5 and LFVs for total, right and left LFs at PI (r= 0.717, 0.749, 0.809, 0.837 and 0.830, p<0.05), and did not correlate with mVDR (r=0.500, p=0.10). Whereas in CTD-ILD, %FVC correlated positively only with aVDR in PPIP-5, LFs for total and left LFs at PI (r=0.537, 0.507 and 0.690, p<0.05). IER in IPF/UIP (0.83 ± 0.35) was smaller than that in CTD-ILD (0.98 ± 0.23) (p=0.02), although IER-MVCV in IPF/UIP (1.36 ± 0.60) was comparable to that in CTD-ILD (1.16 ± 0.37) (p=0.54).

CLINICAL RELEVANCE/APPLICATION

Pathological change such as subpleural fibrosis could be reflected in respiratory change in global lung volume on dynamic-ventilation CT.

SDP-CH-13 To Explore The Correlation Of Ge Revolution Wide-body Detector Energy Spectrum CT Multi-mode Iterative Reconstruction Algorithm To Chest Vascular Image Quality In Energy Spectrum CT Scanning

Participants
Xin Fang, Shizuishan, China (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the influence of adaptive statistical iterative restructure-VEO (ASIR-V) algorithm on the image quality of chest CT enhanced with energy spectrum at low radiation dose, and to provide reference for optimizing the use of iterative reconstruction on chest CT enhanced with energy spectrum.*Methods and Materials 30 patients were scanned using fast kVp switch (80/140 kVp) spectral CT, automatic mA (200mA-485mA), pitch 0.992:1, noise index 11 for the enhanced CT chest enhancement examination. All patients received total 0.8*weight bolus of iodixanol 320 at an infusion rate of 4ml/s. Theparenchymal phase image was acquired after 50 seconds after trigger threshold (130HU). The CT scan was reconstructed using 4 levels of iterative reconstruction 20%, 40%, 60% and 80%at 70kev monochromatic energy level. The CT value, standard deviation, image noise (SD) and other energy

spectrum information of thoracic aorta in each 70keV single-energy reconstructed image were recorded in FILE format, and the SNR and CNR of thoracic aorta were calculated, and then the data were analyzed by statistical analysis. Subjective image evaluation was performed by 2 physicians.*Results There was no significant difference in CT values of thoracic aorta under different posterior weights. There were statistically significant differences in the SD, SNR and CNR of thoracic aorta in different image reconstruction groups in the four groups (P < 0.05). The SD of thoracic aorta in each group were 20% (29.35±3.65) HU, 40% (23.29±2.57) HU, 60% (17.53±1.61) HU, and 80% (12.44±1.10) HU, respectively.he subjective score of 60% and 80% ASiR-V were 4.48±0.74 and 4.03±0.59, respectively. The subjective scores of all other iterative recontruction level were all below 4.0.*Conclusions Energy spectrum CT scanning using full model real-time iterative reconstruction technique can provide image quality of thoracic aorta at low radiation dose.*Clinical Relevance/Application For thoracic aortic vascular diseases, energy spectrum CT single energy scan combined with 60% iterative reconstruction weight can be used to significantly improve the image quality of vascular lumen and provide more effective information for clinical use.

RESULTS

There was no significant difference in CT values of thoracic aorta under different posterior weights. There were statistically significant differences in the SD, SNR and CNR of thoracic aorta in different image reconstruction groups in the four groups (P < 0.05). The SD of thoracic aorta in each group were 20% (29.35±3.65) HU, 40% (23.29±2.57) HU, 60% (17.53±1.61) HU, and 80% (12.44±1.10) HU, respectively.he subjective score of 60% and 80% ASiR-V were 4.48±0.74 and 4.03±0.59, respectively. The subjective scores of all other iterative recontruction level were all below 4.0.

CLINICAL RELEVANCE/APPLICATION

For thoracic aortic vascular diseases, energy spectrum CT single energy scan combined with 60% iterative reconstruction weight can be used to significantly improve the image quality of vascular lumen and provide more effective information for clinical use.

SDP-CH-14 Computed Tomography Quantitative Analysis Of Diaphragmatic Crus In Patients With Chronic Obstructive Pulmonary Disease

Participants
Shinji Wada, MD, Kawasaki, Japan (*Presenter*) Nothing to Disclose

PURPOSE

This study aimed to investigate the relationship between the results of the pulmonary function tests (PFTs) of patients with chronic obstructive pulmonary disease (COPD) and the size of their diaphragmatic crus as evaluated with inspiratory and expiratory computed tomography (CT).*Methods and Materials Inspiratory and expiratory CT was performed between July and December 2019 in 33 patients who underwent PFTs within one week. The short axis, long axis, and cross-sectional area (CSA) at the superior mesenteric artery orifice level of the right and left crus were measured, and the rate of change in the size of the diaphragmatic crus due to respiration (ROCC) was determined. The correlation between the results of the PFTs (forced expiratory volume in one second [FEV1], FEV1/forced vital capacity [FVC], percent predicted FEV1 [%FEV1]) and the size and the ROCC were statistically analyzed.*Results In the right crus, the short axis was extended by 32%; the long axis was contracted by 6%; and the CSA was 21% larger in inspiration than in expiration. In the left crus, the short axis was hardly extended, the long axis was contracted by 5%, and the CSA was 20% larger in inspiration than in expiration. The short axis of the diaphragmatic crus contracted more as age increased. There was a positive correlation between the short axis of the right and left diaphragmatic crus at expiration and PFTs (FEV1, r = -0.35, -0.48; FEV1/FVC, r = -0.52, -0.65; %FEV1, r = -0.56, -0.60), between the CSA of the right crus at expiration and PFTs (FEV1/FVC, r = -0.42; %FEV1, r = -0.41), and between the ROCC of the short axis of the left crus and the CSA of the right and left crus and PFTs (FEV1, r = 0.64, 0.39, 0.56; FEV1/FVC, r = 0.48, 0.46, 0.44; %FEV1, r = 0.52, 0.44, 0.51), each of which was statistically significant. The smaller the short axis of the crus and the CSA and the larger the ROCC, the better the PFT results.*Conclusions There was a positive correlation between the following: (1) the short axis of the bilateral diaphragmatic crus at expiration and the PFT results and (2) the ROCC of the CSA at expiration and the PFT results. These results suggested that measurements of the diaphragmatic crus by means of CT may be used as biomarkers for COPD.*Clinical Relevance/Application When checking for bronchial and lung lesions in COPD patients with chest CT, measurements of the diaphragmatic crus should also be conducted to estimate respiratory function since these may be used as biomarkers for COPD.

RESULTS

In the right crus, the short axis was extended by 32%; the long axis was contracted by 6%; and the CSA was 21% larger in inspiration than in expiration. In the left crus, the short axis was hardly extended, the long axis was contracted by 5%, and the CSA was 20% larger in inspiration than in expiration. The short axis of the diaphragmatic crus contracted more as age increased. There was a positive correlation between the short axis of the right and left diaphragmatic crus at expiration and PFTs (FEV1, r = -0.35, -0.48; FEV1/FVC, r = -0.52, -0.65; %FEV1, r = -0.56, -0.60), between the CSA of the right crus at expiration and PFTs (FEV1/FVC, r = -0.42; %FEV1, r = -0.41), and between the ROCC of the short axis of the left crus and the CSA of the right and left crus and PFTs (FEV1, r = 0.64, 0.39, 0.56; FEV1/FVC, r = 0.48, 0.46, 0.44; %FEV1, r = 0.52, 0.44, 0.51), each of which was statistically significant. The smaller the short axis of the crus and the CSA and the larger the ROCC, the better the PFT results.

CLINICAL RELEVANCE/APPLICATION

When checking for bronchial and lung lesions in COPD patients with chest CT, measurements of the diaphragmatic crus should also be conducted to estimate respiratory function since these may be used as biomarkers for COPD.

SDP-CH-15 The Incidence Rate Of Which Radiologists Miss Breast Lesions On Contrast Chest CT

Participants
Jiyeon Park, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the incidence rate of which radiologists miss breast lesions on contrast chest CT*Methods and Materials In this study, medical records of 344 patients who registered with the diagnosis code 'breast cancer' in between February 2016 to September 2020 and had undergone contrast chest CT exams 3 to 18 months before the code registration were reviewed. 250 patients with known breast lesions or histories of breast cancers were excluded. Chest CT exams of the remaining 94 patients were reviewed retrospectively. The incidence rates of which the radiologists had missed or incidentally detected breast lesions were calculated. A breast lesion was classified as either 'missed' or 'detected' if its location and shape matched those at the time of cancer diagnosis. The characteristics of the lesions, including sizes, shapes, margins, and enhancements, were evaluated and compared.*Results 81 patients had breast lesions on chest CT, while 13 patients had no breast lesion on CT. Only on CT of 9

patients (11.0%; 9/81), the radiologists had detected the lesions and further exams for cancer evaluation were carried out. On CT of other 73 patients (90.0%; 73/81), radiologists had missed the breast lesions. In the group of the missed breast lesions, the mean time interval between the CT examination and the initiation of the breast lesion work up was 8.3 ± 5.9 months. Mean size of the missed breast lesions (8.6 ± 4.0mm) was smaller than the mean size of the detected breast lesions (12.8 ± 3.8mm) (p = 0.002). There was no significant difference in the enhancement ratio between the two groups (p = 0.46). There was no predominance in the breast lesion location and breast density in either group. Missed breast lesions showed no significant tendency in their shapes, margins and enhancement patterns. All detected breast lesions showed homogeneous enhancement patterns and had regular shapes, and most of them had well circumscribed margins (7/8).*Conclusions In this study, 90% of the incidental breast lesions, especially the lesions with sub-centimeter sizes, irregular shapes and margins, or heterogeneous enhancement patterns, were missed on contrast chest CT and later confirmed as breast cancers through other examinations. More careful imaging review of a chest CT will enable early detection and treatment of breast cancer.*Clinical Relevance/Application As more patients undergo chest CT for various clinical purposes, careful imaging review for small enhancing breast lesions on contrast chest CT will increase the number of incidental detection of breast cancers.

RESULTS

81 patients had breast lesions on chest CT, while 13 patients had no breast lesion on CT. Only on CT of 9 patients (11.0%; 9/81), the radiologists had detected the lesions and further exams for cancer evaluation were carried out. On CT of other 73 patients (90.0%; 73/81), radiologists had missed the breast lesions. In the group of the missed breast lesions, the mean time interval between the CT examination and the initiation of the breast lesion work up was 8.3 ± 5.9 months. Mean size of the missed breast lesions (8.6 ± 4.0mm) was smaller than the mean size of the detected breast lesions (12.8 ± 3.8mm) (p = 0.002). There was no significant difference in the enhancement ratio between the two groups (p = 0.46). There was no predominance in the breast lesion location and breast density in either group. Missed breast lesions showed no significant tendency in their shapes, margins and enhancement patterns. All detected breast lesions showed homogeneous enhancement patterns and had regular shapes, and most of them had well circumscribed margins (7/8).

CLINICAL RELEVANCE/APPLICATION

As more patients undergo chest CT for various clinical purposes, careful imaging review for small enhancing breast lesions on contrast chest CT will increase the number of incidental detection of breast cancers.

SDP-CH-16 Motion Tracking Analysis Of Cine MRI For Diagnosing Thymic Epithelial Tumors: A Feasibility Study

Participants
Koji Takumi, MD,PhD, Kagoshima, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Cine MRI is widely used for evaluating cardiovascular diseases or chest wall invasion of a thoracic mass, and also has the potential to provide the information of the morphological deformation of the mass due to pulsation of adjacent vascular structure. Thymic epithelial tumors (TETs) are pathologically diagnosed based on the morphologic manifestations of the epithelial cells and the ratio of lymphocytes to epithelial cells, which could result in differences in tumor stiffness among the TET subtypes. We hypothesize that the evaluation of morphological deformation using cine MRI motion tracking analysis can help diagnose histopathological subtypes of TETs.*Methods and Materials Our study population consisted of 42 consecutive patients with pathologically proven TETs including 9 low-grade thymomas (WHO classification type A, AB, B1), 23 high-grade thymomas (B2, B3), and 10 thymic carcinomas. Cine MR images were acquired using balanced steady state free precession (bSSFP) sequence with short periods of breath-holding in axial planes on the slice with the largest lesion cross sectional area. The tumor margin was manually delineated on diastolic phase and automatically tracked for all the other cardiac phases. The change rates of long-to-short diameter ratio (?LSratio) and tumor area (?Area) associated with pulsation were compared among the three groups using Kruskal-Wallis H test and the Mann-Whitney U test. Receiver-operating characteristic (ROC) curve analysis was performed to assess the ability of each parameter to differentiate thymic carcinomas from thymomas.*Results The ?LSratio and ?Area were significantly different among the three groups (p=0.027 and 0.011, respectively). The ?LSratio and ?Area of thymic carcinomas were significantly smaller than those of thymomas (p=0.014 and 0.024, respectively). Area under the ROC curves for ?LSratio and ?Area to diagnose thymic carcinomas were 0.756 and 0.738, respectively.*Conclusions The evaluation of morphological deformation using cine MR motion tracking analysis can help diagnose histopathological subtypes of TETs and identify thymic carcinomas preoperatively.*Clinical Relevance/Application The evaluation of morphological deformation using cine MR motion tracking analysis may be useful in diagnosing histological subtype of TETs.

RESULTS

The ?LSratio and ?Area were significantly different among the three groups (p=0.027 and 0.011, respectively). The ?LSratio and ?Area of thymic carcinomas were significantly smaller than those of thymomas (p=0.014 and 0.024, respectively). Area under the ROC curves for ?LSratio and ?Area to diagnose thymic carcinomas were 0.756 and 0.738, respectively.

CLINICAL RELEVANCE/APPLICATION

The evaluation of morphological deformation using cine MR motion tracking analysis may be useful in diagnosing histological subtype of TETs.

SDP-CH-17 3D Airway Reconstruction Enabled By A Novel Bronchiole-sensitive Deep-learning Model For Planning Of Navigation Bronchoscopy

Participants
Andong Wang, BEng, Hong Kong, Hong Kong (*Presenter*) Nothing to Disclose

PURPOSE

Navigation bronchoscopy is a promising approach to safer sampling of pulmonary nodules than transthoracic needle biopsy. A 3D tracheobronchial airway roadmap reconstructed from CT images is the prerequisite for the bronchoscopy procedure. We hereby hypothesize that Deep Learning (DL) can better delineate complex tree-like structures of airways than existing automated algorithms during reconstruction.*Methods and Materials Our proposed DL model is based on 3D U-Net with 1) a new loss function together with an enhanced training strategy which can recognize more bronchioles of higher generations by penalizing the airway segments with low confidence and focusing on bronchiole training and 2) dilated convolutions with self-attention mechanism which extract morphological features in a larger area to distinguish between real airways and other shapes, like the esophagus. 80 cases annotated with ITK-SNAP and clinicians' correction (regarded as benchmark (BM) annotation because ideal ground truth annotation can only be obtained by bronchoscopy) from two open-source chest CT datasets — EXACT09 and LIDC-IDRI — were used for

model training and testing with a split of 70/10. Cross-validation was conducted. Lung CT images from 9 anonymized patients scanned at the Queen Mary Hospital in Hong Kong were annotated with LungPoint and clinicians' correction for external testing of our bronchiole-sensitive DL model performance on unseen data.*Results The model outputs a probability map (p) of airways. As BM annotations may miss some bronchioles, p=0.7 denotes airway segments with high confidence, while 0.5=p=0.7 indicates inferred airway segments by the learned features from BM. For internal testing, precision/sensitivity were 96.1±1.4%/92±1.5% (threshold of p = 0.7) and 85.6±1.9%/98.0±0.9% (threshold of p = 0.5), respectively. When threshold of p = 0.5, the tree detection rate (ratio of model-outputted airway length to BM airway length) was 114.0±14.7%. This suggested that the model detected almost all the BM airways and many unlabeled bronchioles, which were visually validated by an expert. For external testing, precision, sensitivity, and tree detection rate were 81.4±4.7%, 89.3±5.4%, and 82%±13.7%, respectively (threshold of p = 0.5), showing that the model performed well on unseen data.*Conclusions Results validated our hypothesis that our DL model could detect finer bronchioles (up to 12th generation with mean and median generations being 7.9 and 7.5, respectively) while maintaining high overall accuracy for 3D airway reconstruction.*Clinical Relevance/Application Our DL model reconstructs a 3D airway roadmap with finer bronchioles detected, showing clearer paths with possibility values for pulmonary nodule sampling in navigation bronchoscopy.

RESULTS

The model outputs a probability map (p) of airways. As BM annotations may miss some bronchioles, p=0.7 denotes airway segments with high confidence, while 0.5=p=0.7 indicates inferred airway segments by the learned features from BM. For internal testing, precision/sensitivity were 96.1±1.4%/92±1.5% (threshold of p = 0.7) and 85.6±1.9%/98.0±0.9% (threshold of p = 0.5), respectively. When threshold of p = 0.5, the tree detection rate (ratio of model-outputted airway length to BM airway length) was 114.0±14.7%. This suggested that the model detected almost all the BM airways and many unlabeled bronchioles, which were visually validated by an expert. For external testing, precision, sensitivity, and tree detection rate were 81.4±4.7%, 89.3±5.4%, and 82%±13.7%, respectively (threshold of p = 0.5), showing that the model performed well on unseen data.

CLINICAL RELEVANCE/APPLICATION

Our DL model reconstructs a 3D airway roadmap with finer bronchioles detected, showing clearer paths with possibility values for pulmonary nodule sampling in navigation bronchoscopy.

SDP-CH-19 AI For High-performance "Data Capture" Automated CXR Annotation Of Three Large Public Datasets Based On "Similarity" To A Validated Model

Participants
Doyun Kim, PhD, Boston, Massachusetts (*Presenter*) Nothing to Disclose

PURPOSE

CheXpert, MIMIC, and NIH are large open access CXR datasets for widespread AI development. Unfortunately, the accuracy of their provided labels is unknown and may vary between datasets. We built and tested an explainable model for automated CXR annotation which leverages atlas creation/prediction-basis retrieval modules for high-quality labeling at a user selected performance level.*Methods and Materials We developed our model from 241,723 frontal CXR images (2015-2020) trained on 20 features, with 3-6 expert readers as ground truth. The model outputs a probability estimate of input-image similarity for each of 5 pooled-feature categories: cardiomegaly, atelectasis, edema, pneumonia, and pleural effusion. The system, which consists of an explainable AI model (Fig A) and an auto-annotation algorithm (Fig B), mimics human thinking, in that it associates degree of similarity between novel input-images and its "memory" of stored images (i.e., atlas of typical, representative features from the training sets). We tested model performance for a random subset of images from the public datasets at two different probability thresholds, "TH=0" (nominal similarity but maximal image capture count) and "TH=best" (maximal similarity but lower image capture count), applied to posteroanterior (PA) images in CheXpert (n=224,316), MIMIC (n=377,110), and NIH (n=108,948); majority vote of 7 expert readers was ground truth.*Results The positive/negative image count captured by our model per category per dataset at the TH=0 and TH=best thresholds is in Fig C (UL=unlabeled public data), with examples in Fig E; overall percent images captured at the TH=best threshold were 86% for cardiomegaly, 62% atelectasis, 59% edema, 37% pneumonia, and 82% for pleural effusion. For the image subsets with 7-reader ground truth, model labeling performance equaled or exceeded that of the public label accuracy for all categories (Fig D). Labels are available at: https://github.com/MGH-LMIC/AutoLabels-PublicData-CXR-PA.git.*Conclusions Our model for automated labeling of public CXR datasets, based on similarity to a validated model, is highly accurate and efficient. This approach may be generalizable and has the potential to help inform future automated re-training strategies.*Clinical Relevance/Application Commonly shared, defined labels among different datasets can allow for generalized AI model development.

RESULTS

The positive/negative image count captured by our model per category per dataset at the TH=0 and TH=best thresholds is in Fig C (UL=unlabeled public data), with examples in Fig E; overall percent images captured at the TH=best threshold were 86% for cardiomegaly, 62% atelectasis, 59% edema, 37% pneumonia, and 82% for pleural effusion. For the image subsets with 7-reader ground truth, model labeling performance equaled or exceeded that of the public label accuracy for all categories (Fig D). Labels are available at: https://github.com/MGH-LMIC/AutoLabels-PublicData-CXR-PA.git.

CLINICAL RELEVANCE/APPLICATION

Commonly shared, defined labels among different datasets can allow for generalized AI model development.

SDP-CH-2 Machine Learning Model For Chest X-rays In Emergency Radiology: Using Local Data To Enhance Performance

Participants
Sarah Mohn, BEng, Vancouver, British Columbia (*Presenter*) Nothing to Disclose

PURPOSE

Our purpose was to develop and assess the diagnostic performance of a machine learning (ML) model which screens chest radiographs for multiple pathologies simultaneously. The model was developed for integration into the emergency radiology workflow at our local institution to prioritize the order in which chest x-rays are reported. Many ML algorithms in radiology have been developed, but they are not always generalizable for use at various institutions. We hypothesize that a model trained on an open-source dataset will have improved performance at our local institution after being fine-tuned on local data.*Methods and Materials An ensemble of neural networks was trained on the Stanford ML CheXpert open-source dataset consisting of 224,316 x-rays for 14 pathologies. The model was then tested on chest radiographs from our local institution and subsequently fine-tuned using 4510 local studies. Radiologists' reports were used as the gold standard when evaluating model performance. Finally, the model's

accuracy was tested on a new set of 802 local radiographs.*Results The model was trained to identify 14 chest x-ray pathologies. Of these, it identified 12 pathologies with areas under the receiver operating curve (AUC) greater than 0.75. For example, the fine-tuned model detected pleural effusions with AUC of 0.86 (95% CI(0.836, 0.887)), pneumothorax with AUC of 0.87 (95% CI (0.834, 0.904)), and negative x-rays with AUC of 0.90 (95% CI (0.843, 0.951)). After fine-tuning with local data, the model performed significantly better in detecting six pathologies (p<0.05). For example, the AUC for detecting pneumothorax improved from 0.82 to 0.87. Overall, the AUC increased from 0.79 to 0.82 (p=0.002) after fine-tuning with local data*Conclusions A ML model with the ability to accurately detect 14 different chest pathologies was successfully developed using open-source data and its performance was improved after fine-tuning on local data. This multi-pathology detection model can be easily integrated into the radiology workflow and used to prioritize the order in which chest radiographs are interpreted by radiologists, knowing that it has been adapted to the local reporting practices.*Clinical Relevance/Application We have shown that fine-tuning a model with a local dataset can improve its performance locally. Our model can now be integrated into the local emergency radiology workflow and used to prioritize the most critical cases, which may lead to improved patient outcomes.

RESULTS

The model was trained to identify 14 chest x-ray pathologies. Of these, it identified 12 pathologies with areas under the receiver operating curve (AUC) greater than 0.75. For example, the fine-tuned model detected pleural effusions with AUC of 0.86 (95% CI(0.836, 0.887)), pneumothorax with AUC of 0.87 (95% CI (0.834, 0.904)), and negative x-rays with AUC of 0.90 (95% CI (0.843, 0.951)). After fine-tuning with local data, the model performed significantly better in detecting six pathologies (p<0.05). For example, the AUC for detecting pneumothorax improved from 0.82 to 0.87. Overall, the AUC increased from 0.79 to 0.82 (p=0.002) after fine-tuning with local data

CLINICAL RELEVANCE/APPLICATION

We have shown that fine-tuning a model with a local dataset can improve its performance locally. Our model can now be integrated into the local emergency radiology workflow and used to prioritize the most critical cases, which may lead to improved patient outcomes.

SDP-CH-20 Iodine And Water Concentrations In COVID-19 Pneumonia Assessed By Contrast Enhanced Dual-energy Computed Tomography

Participants
Lien van Liedekerke, MD, Ghent, Belgium (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate iodine and water concentrations in normal lung tissue, ground-glass opacities and consolidations in COVID-19 patients without pulmonary embolisms, obtained by contrast enhanced DECT.*Methods and Materials In this IRB approved study, pulmonary DECT angiography scans were analyzed of patients with clinical signs of COVID-19 pneumonia who presented themselves at the emergency department of our tertiary center, between September 1st 2020 and December 31th 2020. We selected all patients that tested positive for COVID-19 by RT-PCR. Patients with pulmonary embolisms and lung pathologies other than COVID-19 pneumonia were excluded. Iodine and water concentrations were measured in normal lung tissue, ground-glass opacity and consolidation by manually drawing 1 cm3 regions of interest (ROI). Normalized iodine concentrations were calculated by dividing the iodine concentration value of the tissue by the concentration inside the pulmonary artery trunk. A CT-severity score was determined for each scan. Obtained values were compared by paired samples T-test. Spearman's Rho correlation tests were performed to investigate correlations between relative iodine concentrations, water concentrations and CT- severity scores. Descriptive statistics and the Shapiro-Wilk test were performed on all data to check the normality.*Results A total of 65 patients (49 male and 19 female with mean age 63, range 19 - 92 yr) were included in this study. All data was normally distributed (p-values ranging from 0,002 to 0,046). The mean CT-severity score was 11,8/25 ± 5,2. Compared to normal lung tissue (0,076 +/- 0,036 mgI/mL), normalized iodine concentration was significantly higher in ground-glass opacity (0,125 +/- 0,043 mgI/mL, p = 0,001) and consolidation (0,167 +/- 0,055 mgI/mL, p = 0,001). Water concentration was significantly higher in ground-glass opacity (284,7 mgH2O/mL, p = 0,001) and consolidation (832,6 +/- 146 mgH2O/mL, p = 0,001) compared to normal tissue (147,1 +/- 33,8 mgH2O/mL). A significant positive correlation was found between the normalized iodine concentrations and CT-severity scores in ground-glass opacity (p < 0,002) and consolidation (p < 0,001).*Conclusions Different iodine and water concentrations are seen in normal lung tissue, ground-glass opacities and consolidations in COVID-19 pneumonia. Iodine concentrations in ground-glass opacities and consolidations are positively correlated with the CT-severity scores.*Clinical Relevance/Application In contrast to low-dose pulmonary CT scans, contrast enhanced dual-energy CT scans give additional information about iodine and water content in COVID-19 lesions. In the literature, iodine and water concentrations have been described as parameters for inflammation and lung perfusion.

RESULTS

A total of 65 patients (49 male and 19 female with mean age 63, range 19 - 92 yr) were included in this study. All data was normally distributed (p-values ranging from 0,002 to 0,046). The mean CT-severity score was 11,8/25 ± 5,2. Compared to normal lung tissue (0,076 +/- 0,036 mgI/mL), normalized iodine concentration was significantly higher in ground-glass opacity (0,125 +/- 0,043 mgI/mL, p = 0,001) and consolidation (0,167 +/- 0,055 mgI/mL, p = 0,001). Water concentration was significantly higher in ground-glass opacity (284,7 mgH2O/mL, p = 0,001) and consolidation (832,6 +/- 146 mgH2O/mL, p = 0,001) compared to normal tissue (147,1 +/- 33,8 mgH2O/mL). A significant positive correlation was found between the normalized iodine concentrations and CT-severity scores in ground-glass opacity (p < 0,002) and consolidation (p < 0,001).

CLINICAL RELEVANCE/APPLICATION

In contrast to low-dose pulmonary CT scans, contrast enhanced dual-energy CT scans give additional information about iodine and water content in COVID-19 lesions. In the literature, iodine and water concentrations have been described as parameters for inflammation and lung perfusion.

SDP-CH-21 Anterior Mediastinal Cystic Lesions Assessed With Chest MRI: Follow-up Outcome And Clinical Implications

Participants
Jooae Choe, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

The use of chest MR has been increased for the evaluation of anterior mediastinal cystic lesion as suggested by International

Thymic Malignancy Interest Group (ITMIG) but the outcome in those patients is not well known. This study aimed to evaluate the follow-up outcome in patients with chest MR findings of probable cysts in the anterior mediastinum and assess whether MR findings can rule out malignancy.*Methods and Materials In this multicenter retrospective study, patients who underwent contrast enhanced chest MR from two tertiary center for the evaluation of anterior mediastinal lesion and suspected for cystic lesions were evaluated. Chest MR was evaluated by thoracic radiologist, and patients were classified into two categories: probable cystic lesion or indeterminate lesion based on MR findings. Baseline and follow-up imaging was evaluated in terms of the largest dimension and imaging characteristics. Events of surgery and incidence of confirmed tumor were recorded.*Results A total of 205 patients (mean age 59±11 years; M:F = 111:94) were studied. 186 (90.7%) were classified as probable cystic lesion on MR and 19 (9.3%) were classified indeterminate on MR. The median follow-up duration in patients with probable cystic lesions was 2.9 years (range, 0-15) and follow-up interval was variable among physicians after MR (median 12 months; range 3-50 months). Patients with probable cystic lesion with more than 6 months follow-up showed variable change in size (28.0% increase, 60.6% stable, and 11.3% decrease), but no new enhancing nodular portion was observed during follow-up. Among such patients with an increase in probable cystic lesions, six patients underwent surgery, and all confirmed thymic cyst. In patients with an indeterminate lesion on MR, 21.1% were confirmed tumors (3 thymomas and 1 teratoma).*Conclusions Diagnosing anterior mediastinal cystic lesions is accurate, which can rule out malignancy. Those cystic lesions can show a variable change in size on follow-up, but none of the probable cystic lesions on MR turned out to be malignant.*Clinical Relevance/Application Diagnosing anterior mediastinal cystic lesions using MR is accurate, which can rule out malignancy. Understanding long-term follow-up changes of anterior mediastinal cystic lesion and recognizing indeterminate features on chest MR can reduce the number of unnecessary follow-up and surgery.

RESULTS

A total of 205 patients (mean age 59±11 years; M:F = 111:94) were studied. 186 (90.7%) were classified as probable cystic lesion on MR and 19 (9.3%) were classified indeterminate on MR. The median follow-up duration in patients with probable cystic lesions was 2.9 years (range, 0-15) and follow-up interval was variable among physicians after MR (median 12 months; range 3-50 months). Patients with probable cystic lesion with more than 6 months follow-up showed variable change in size (28.0% increase, 60.6% stable, and 11.3% decrease), but no new enhancing nodular portion was observed during follow-up. Among such patients with an increase in probable cystic lesions, six patients underwent surgery, and all confirmed thymic cyst. In patients with an indeterminate lesion on MR, 21.1% were confirmed tumors (3 thymomas and 1 teratoma).

CLINICAL RELEVANCE/APPLICATION

Diagnosing anterior mediastinal cystic lesions using MR is accurate, which can rule out malignancy. Understanding long-term follow-up changes of anterior mediastinal cystic lesion and recognizing indeterminate features on chest MR can reduce the number of unnecessary follow-up and surgery.

SDP-CH-22   Diagnosis Of Pneumothorax After Percutaneous Transthoracic Needle Biopsy On Chest Radiographs: Impact Of Clinical Implementation Of A Deep Learning System

Participants
Wonju Hong, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To investigate whether a deep learning based computer-aided detection (CAD) system can improve pneumothorax diagnosis on chest radiographs (CXRs) after percutaneous transthoracic needle biopsies (PTNBs) in actual clinical practice.*Methods and Materials Our institution implemented a deep learning based CXR CAD system for pneumothorax detection after PTNBs on February, 2020. In this retrospective cohort study, CXRs interpreted with CAD assistance (CAD-applied group, obtained from February 4, 2020 to November 2020) after the implementation and those interpreted before the implementation (conventional group, obtained from January 2018 to February 3, 2020) were consecutively included. The diagnostic accuracy of CXR interpretation for pneumothorax were compared between the two groups using generalized estimating equations. Matching was made according to whether the reader of CXRs and the operator of PTNB were the same by using Greedy method.*Results A total of 676 CXRs from 655 patients (M:F=390:286, mean age 66.6 years) in the CAD-applied group and 676 CXRs from 664 patients (M:F=400:276, mean age 65.5 years) in the conventional group were included in this study. One hundred twenty-three CXRs (18.2%) in the CAD-applied group and 152 CXRs (22.5%) in the conventional group (P=0.052) had pneumothorax. The sensitivity, specificity, PPV, NPV, and accuracy in the conventional group were 67.1%, 99.6%, 98.1%, 91.3%, and 92.3%, respectively. Those in the CAD-applied group were 85.4%, 99.3%, 96.3%, 96.8%, and 96.8%, respectively. The CAD-applied group showed significantly higher sensitivity (P<0.001), NPV (P<0.001), and accuracy (P<0.001) for pneumothorax diagnosis than the conventional group. Among patients with pneumothorax, 50 cases (3.7%) required subsequent drainage catheter insertion (34 cases [5.0%] from the conventional group and 16 cases [2.4%] from the CAD-applied group) (P=0.009). The time interval from follow-up CXRs to drainage catheter insertion (25.2±19.5 hours vs. 26.5±27.4 hours; P=0.869) and the catheter dwell time (75.9±32.5 hours vs. 91.7±85.6 hours, P=0.479) were shortened in the CAD-applied group, however the difference did not reach statistical significance.*Conclusions A deep learning based computer-aided detection system improved the sensitivity, negative predictive value, and accuracy of pneumothorax diagnosis on CXRs after PTNBs.*Clinical Relevance/Application A deep learning based CAD system can improve the accuracy of radiologists' CXR interpretation and might be expected to shorten management time in patients with pneumothorax.

RESULTS

A total of 676 CXRs from 655 patients (M:F=390:286, mean age 66.6 years) in the CAD-applied group and 676 CXRs from 664 patients (M:F=400:276, mean age 65.5 years) in the conventional group were included in this study. One hundred twenty-three CXRs (18.2%) in the CAD-applied group and 152 CXRs (22.5%) in the conventional group (P=0.052) had pneumothorax. The sensitivity, specificity, PPV, NPV, and accuracy in the conventional group were 67.1%, 99.6%, 98.1%, 91.3%, and 92.3%, respectively. Those in the CAD-applied group were 85.4%, 99.3%, 96.3%, 96.8%, and 96.8%, respectively. The CAD-applied group showed significantly higher sensitivity (P<0.001), NPV (P<0.001), and accuracy (P<0.001) for pneumothorax diagnosis than the conventional group. Among patients with pneumothorax, 50 cases (3.7%) required subsequent drainage catheter insertion (34 cases [5.0%] from the conventional group and 16 cases [2.4%] from the CAD-applied group) (P=0.009). The time interval from follow-up CXRs to drainage catheter insertion (25.2±19.5 hours vs. 26.5±27.4 hours; P=0.869) and the catheter dwell time (75.9±32.5 hours vs. 91.7±85.6 hours, P=0.479) were shortened in the CAD-applied group, however the difference did not reach statistical significance.

CLINICAL RELEVANCE/APPLICATION

A deep learning based CAD system can improve the accuracy of radiologists' CXR interpretation and might be expected to shorten management time in patients with pneumothorax.

SDP-CH-23 **Attention-guided Analysis To Predict Presence Of Pulmonary Embolism And Related Features On CTPA Using A Multi-stage Deep Learning Framework**

Participants
Gagandeep Singh, MD, Newark, New Jersey (*Presenter*) Nothing to Disclose

PURPOSE

Pulmonary embolism (PE) is the most common preventable cause of hospital death. Detection of PE on Computed Tomography Pulmonary Angiography (CTPA) is the diagnostic gold standard. Timely diagnosis is crucial to halt subsequent decompensation into heart failure. Current machine learning algorithms for detecting PE focus on blood clot regions. Analysis of other abnormal regions suggestive of clots remains unexplored. We propose a two-stage attention-based network comprising a Convolutional Neural Network (CNN) and a Sequence model (LSTM+Dense) to predict PE and its associated attributes like laterality, chronicity, and Right Ventricular to Left Ventricular ratio on CTPA. The learnt features capture spatial and global relationships between successive slices to mimic the human cognitive process while examining cross-sectional images.*Methods and Materials We used the RSNA PE CT dataset. 5824 studies were randomly assigned to the training dataset D1, and 1455 to the validation cohort D2. For the test set, D3, 106 CTPA studies were collected from InstituteX. We trained the network in two stages. Stage 1 includes using CNN Efficient-Net to extract features from each slice, followed by average pooling. In Stage 2, we use a sequence model to capture long-range image dependencies. The sequence model consists of bidirectional long short-term memory (BiLSTM) and a dense layer. It has two heads; one is used to detect PE (?image), another is used to predict different characteristics of PE (?study). Features generated from the Sequence Model are passed through the attention module to facilitate the identification of informative slices in the study and assign them higher value for final study level prediction. This yielded bag-level features are passed through ?study for global prediction. We provided features from LTSM directly to ?image to detect the presence of PE on each slice. A custom loss function was used to train the network and the model with lowest loss on D2 was used to evaluate performance on D3.*Results We compared our model with a CNN classifier (Baseline 1) and a CNN-LTSM network without attention module (Baseline 2). Test set area under receiver operating curve (AUC) of Baseline 1, Baseline 2, and our method were 0.5, 0.94, and 0.95, respectively. The accuracies were 0.74, 0.65, and 0.88, respectively.*Conclusions Our attention based two stage CNN-LSTM network was able to learn and predict the presence of PE and associated attributes with a high AUC. This can potentially increase the speed of PE detection without a decrease in accuracy.*Clinical Relevance/Application Incorporating deep learning models into clinical workflows can decrease diagnostic delays and errors, thereby lowering morbidity and mortality associated with PE.

RESULTS

We compared our model with a CNN classifier (Baseline 1) and a CNN-LTSM network without attention module (Baseline 2). Test set area under receiver operating curve (AUC) of Baseline 1, Baseline 2, and our method were 0.5, 0.94, and 0.95, respectively. The accuracies were 0.74, 0.65, and 0.88, respectively.

CLINICAL RELEVANCE/APPLICATION

Incorporating deep learning models into clinical workflows can decrease diagnostic delays and errors, thereby lowering morbidity and mortality associated with PE.

SDP-CH-25 **Deep Learning-based Computer-aided Detection System For Pulmonary Metastasis On Chest Ct: Performance In Consecutive Patients Undergoing Pulmonary Metastasectomy**

Participants
Eui Jin Hwang, MD, Seoul, Korea, Republic Of (*Presenter*) Research Grant, Lunit Inc;Research Grant, Coreline Soft, Co Ltd;Research Grant, Monitor Corporation Inc

PURPOSE

To develop a deep learning-based computer-aided detection (CAD) system for pulmonary metastasis in chest CTs of patients with cancers and to evaluate its performance in patients undergoing pulmonary metastasectomy.*Methods and Materials A deep learning-based CAD system for identifying pulmonary metastasis was developed with 5000 chest CTs (19064 annotated potential metastasis) from patients with cancers. For evaluation of the CAD, patients who underwent therapeutic pulmonary metastasectomy were consecutively included from a single institution. Thoracic radiologists marked any pulmonary nodules suspicious of metastasis on chest CTs before surgery as a part of clinical practice (original reading). The CAD system was retrospectively applied to preoperative CTs to identify pulmonary metastasis. After CAD analysis, a thoracic radiologist reviewed CAD results to check additional nodules overlooked in the radiologists' annotation (Second reading with CAD). Whether individual nodules were metastatic or not was determined by pathologic results of resected nodule or presence of growth on follow-up CT examinations. Nodules that were stable for more than two years were regarded as benign nodules.*Results Among 71 patients (47 men, median age 56 years), 232 pulmonary metastases were identified (median 2 per patient). In the original reading, radiologists identified 590 nodules (median 6 per patient) and exhibited sensitivity and positive predictive value (PPV) of 92% and 38%, respectively. The CAD detected 767 lesions (median 10 per patient), and its sensitivity (82% vs. 92%; P<.001) and PPV (25% vs. 38%; P<.001) for detecting pulmonary metastasis were significantly lower than radiologists. Interestingly, in the second reading with CAD assistance, radiologists detected 64 additional nodules, and 7 (11%) of them were true metastasis. With CAD assistance, the sensitivity of detecting metastasis (95%) was significantly improved (P=.01), while PPV was declined (38% to 35%; P<.001).*Conclusions In consecutive patients undergoing pulmonary metastasectomy, a deep learning-based CAD could detect pulmonary metastases that radiologists overlooked in daily practice.*Clinical Relevance/Application Deep learning-based CAD for pulmonary metastasis may help manage patients undergoing pulmonary metastasis since complete resection of every metastasis is essential in pulmonary metastasectomy.

RESULTS

Among 71 patients (47 men, median age 56 years), 232 pulmonary metastases were identified (median 2 per patient). In the original reading, radiologists identified 590 nodules (median 6 per patient) and exhibited sensitivity and positive predictive value (PPV) of 92% and 38%, respectively. The CAD detected 767 lesions (median 10 per patient), and its sensitivity (82% vs. 92%; P<.001) and PPV (25% vs. 38%; P<.001) for detecting pulmonary metastasis were significantly lower than radiologists. Interestingly, in the second reading with CAD assistance, radiologists detected 64 additional nodules, and 7 (11%) of them were true metastasis. With CAD assistance, the sensitivity of detecting metastasis (95%) was significantly improved (P=.01), while PPV was declined (38% to 35%; P<.001).

CLINICAL RELEVANCE/APPLICATION

Deep learning-based CAD for pulmonary metastasis may help manage patients undergoing pulmonary metastasis since complete

resection of every metastasis is essential in pulmonary metastasectomy.

SDP-CH-26 Performance Assessment Of Artificial Intelligence (ai) Assisted Incomplete Rib Fracture Diagnostic For Residents In Radiology Department For Emergency Trauma

Participants
Yanhong Zhao, MMed,MMed, Yinchuan, China (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the effect of artificial intelligence (AI)-assisted diagnostic system on detection of incomplete rib fracture for residents.*Methods and Materials Seventy-six patients with emergency chest trauma underwent chest CT examination were enrolled. The image reconstruction slice thickness was set to 1-1.25mm and reconstructed under lung algorithms. Reading time and detection sensitivity was used to compare the observer's performance in detecting incomplete rib fracture with and without use of AI-assisted system (InferRead CT Bone Research,Infervision, Beijing), with the interval of more than 4 weeks. Gold standard of incomplete rib fracture was established by two board-certified radiologists with more than 15 years of experience on the review of the results by AI-assisted system. Chi-square test was used to compare the sensitivity and false positive rate of incomplete rib fracture detection between two reading modes while reading time was compared using independent-sample t test.*Results 1822 ribs (two of which were hypoplastic) including 108 incomplete rib fractures were found in 76 patients. For resident without using AI, a total of 113 rib fractures including 82 true positive and 31 false positive were identified, with a sensitivity of 75.93% and a false positive rate of 1.81%. For radiologist resident with using AI, a total of 136 rib fractures including 94 true positive and 42 false positive were detected, with a sensitivity of 87.04% and the false positive rate of 2.45%. There was significant difference in the sensitivity of incomplete rib fracture detection with or without AI (p=0.036), while no significant difference was found in the false positive rate of rib fracture detection (p=0.193). The reading time using AI (105.26±57.20 s) was found to be significantly reduced as compared with that without using AI (240.79±63.20 s) (p<0.001).*Conclusions AI-assisted fracture system improved the accuracy of incomplete rib fracture detection and significantly shortened the diagnosis time for residents.*Clinical Relevance/Application Although incomplete rib fracture is easily missed by residents which might be life-threatening, the use of AI-assisted fracture detection system could improve incomplete rib fracture detection sensitivity.

RESULTS

1822 ribs (two of which were hypoplastic) including 108 incomplete rib fractures were found in 76 patients. For resident without using AI, a total of 113 rib fractures including 82 true positive and 31 false positive were identified, with a sensitivity of 75.93% and a false positive rate of 1.81%. For radiologist resident with using AI, a total of 136 rib fractures including 94 true positive and 42 false positive were detected, with a sensitivity of 87.04% and the false positive rate of 2.45%. There was significant difference in the sensitivity of incomplete rib fracture detection with or without AI (p=0.036), while no significant difference was found in the false positive rate of rib fracture detection (p=0.193). The reading time using AI (105.26±57.20 s) was found to be significantly reduced as compared with that without using AI (240.79±63.20 s) (p<0.001).

CLINICAL RELEVANCE/APPLICATION

Although incomplete rib fracture is easily missed by residents which might be life-threatening, the use of AI-assisted fracture detection system could improve incomplete rib fracture detection sensitivity.

SDP-CH-27 Identification Of Active Pulmonary Tuberculosis Among Patients With Latent Tuberculosis Infection: Application Of Deep Learning-based Computer-aided Detection System

Participants
Jongsoo Park, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Identification of active tuberculosis (TB) patients before treatment of latent tuberculosis infection (LTBI) is one of the vital roles of chest X-ray (CXR) in managing patients with TB. We aimed to evaluate the diagnostic performance of a deep learning-based computer-aided detection (CAD) system in identifying patients with active TB among consecutive patients with LTBI.*Methods and Materials We consecutively collected CXRs of patients with LTBI confirmed by immunoglobulin release assay. Reference standard for active pulmonary TB was defined by culture or nucleic acid amplification test of respiratory specimens. A previously developed deep learning-based CAD (TB-CAD, hereafter), trained with 54221 normal CXRs and 6768 CXRs with active TB, was applied to all CXRs to provide probability scores for active pulmonary TB. The performance of CAD was compared to a commercialized deep learning-based CAD, trained for various abnormalities in addition to findings of TB (Commercial CAD, hereafter). For comparison of radiologists' performance, a reader test was conducted with 5 radiologists, using subgroup CXRs with enriched prevalence. At first, each reader interpreted CXRs to identify active pulmonary TB at their discretion. Afterward, each reader re-interpreted CXRs after reviewing TB-CAD results (CAD-assisted reading).*Results Among 1780 patients (53.8% male; median age 56 years) with LTBI, 44 (2.5%) were confirmed as active pulmonary TB. The TB-CAD exhibited higher performance than commercial CAD (area under curves, 0.85 vs. 0.70; P<.001). At pre-defined thresholds, the TB-CAD exhibited 89% sensitivity at 61% specificity and 61% sensitivity at 90% specificity. In the reader test (219 CXRs, 44 active TB), the TB-CAD exhibited higher sensitivity than radiologists (73% vs. 60%; P=.01), at the same specificity (88%). In the CAD-assisted reading, radiologists' sensitivity was improved (60% to 72%; P<.001) with a modest decline of specificity (88% to 83%; P<.001).*Conclusions Deep learning-based CAD for active TB could accurately identify CXRs with active pulmonary TB among patients with LTBI. The CAD showed higher sensitivity than radiologists and enhanced radiologists' sensitivity.*Clinical Relevance/Application The deep learning-based CAD system can help to screen active pulmonary TB on CXR before treatment of LTBI, with higher sensitivity than radiologists' interpretation.

RESULTS

Among 1780 patients (53.8% male; median age 56 years) with LTBI, 44 (2.5%) were confirmed as active pulmonary TB. The TB-CAD exhibited higher performance than commercial CAD (area under curves, 0.85 vs. 0.70; P<.001). At pre-defined thresholds, the TB-CAD exhibited 89% sensitivity at 61% specificity and 61% sensitivity at 90% specificity. In the reader test (219 CXRs, 44 active TB), the TB-CAD exhibited higher sensitivity than radiologists (73% vs. 60%; P=.01), at the same specificity (88%). In the CAD-assisted reading, radiologists' sensitivity was improved (60% to 72%; P<.001) with a modest decline of specificity (88% to 83%; P<.001).

CLINICAL RELEVANCE/APPLICATION

The deep learning-based CAD system can help to screen active pulmonary TB on CXR before treatment of LTBI, with higher sensitivity than radiologists' interpretation.

SDP-CH-28 Clinical Dual Source Photon Counting CT For Non-contrast Enhanced Chest CT: Initial Results

Participants
Ronald Booij, PhD, Rotterdam, Netherlands (*Presenter*) Research Collaboration, Siemens AG

PURPOSE

To assess improvements in image quality (IQ) and lung structure visualization of a clinical dual source photon counting detector (PCD) CT in comparison with energy integrating detector (EID) CT.*Methods and Materials Twenty adult patients (12 males [age range 39 - 71 years and 8 females [age range 33 - 78 years]) referred for a follow-up non-contrast enhanced chest CT were scanned on a dual source PCD CT (Siemens NAEOTOM Alpha). Virtual monoenergetic plus images at 70 keV were reconstructed with a Bl64 kernel and an automatically selected matrix size (either 768 or 1024 elements). Images were compared with the most recent prior non-contrast enhanced chest CT of the same patient obtained with an EID CT scanner (Siemens SOMATOM Force) with a median time difference of nine months. EID CT data was reconstructed with routine lung reconstruction kernels (Bl57/I70f) and a 512 matrix. Both scans were reconstructed with a slice thickness / increment of 1.0 / 0.8 mm. Two experienced radiologists qualitatively compared PCD CT and EID CT images using 5-point Likert scales. We compared the mean score of the answers regarding IQ for 8 items regarding specific anatomical parts of the lung (1=very poor, poor, fair, good or 5=excellent) between EID CT and PCD CT. Specific attention was given to bronchial division visibility. Additionally, for ten items the observers' preference for either the PCD CT or the EID CT was determined using a 5-point Likert scale (1=EID better, EID slightly better, EID and PCD equal, PCD slightly better, 5=PCD better).*Results In comparison with EID CT, both observers rated the mean overall IQ for the specific anatomical parts of the lung 0.3 points higher for PCD CT at 4.8. IQ per lung lobe was scored similarly, but the agreement between observers was higher for PCD CT (range 70% - 90%) compared to EID CT (range 30% - 55%). The smallest bronchial division visibility was scored 'slightly better' or 'better' on PCD CT by both observers for all scans. Overall, the observers had a preference for the PCD CT over EID CT (mean score 4.0 and 4.2 for observer A and B, respectively). In 17/20 patients, PCD CT was scored as better than the EID CT.*Conclusions PCD CT provides superior overall IQ and was scored as the preference for clinical non-contrast enhanced chest CT exams compared to EID CT.*Clinical Relevance/Application The image quality of chest CT scans obtained with PCD CT is scored as superior including more detailed evaluation of the lung parenchyma which may lead to more consistent evaluation of especially small airway disease.

RESULTS

In comparison with EID CT, both observers rated the mean overall IQ for the specific anatomical parts of the lung 0.3 points higher for PCD CT at 4.8. IQ per lung lobe was scored similarly, but the agreement between observers was higher for PCD CT (range 70% - 90%) compared to EID CT (range 30% - 55%). The smallest bronchial division visibility was scored 'slightly better' or 'better' on PCD CT by both observers for all scans. Overall, the observers had a preference for the PCD CT over EID CT (mean score 4.0 and 4.2 for observer A and B, respectively). In 17/20 patients, PCD CT was scored as better than the EID CT.

CLINICAL RELEVANCE/APPLICATION

The image quality of chest CT scans obtained with PCD CT is scored as superior including more detailed evaluation of the lung parenchyma which may lead to more consistent evaluation of especially small airway disease.

SDP-CH-29 Deep Learning-based Lung Nodule Detection And Classification System In Lung Cancer Screening Population: Improved Radiologists' Nodule Detection Sensitivity And Inter-reader Agreement

Participants
Jongsoo Park, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the performance of a deep learning-based lung nodule detection and classification system for interpretation of low dose chest CTs (LDCTs) in comparison with radiologists' interpretations.*Methods and Materials Screening LDCTs of 50 high-risk participants were retrospectively collected from a nationwide lung cancer screening program, with enriched lung cancer prevalence (30%). A commercialized, regulatory-approved deep learning-based software analyzed LDCTs to detect and classify lung nodules based on the Lung-RADS (ver. 1.1). For comparison, 3 thoracic radiologists and 3 radiology residents independently interpreted LDCTs using the Lung-RADS (reader-alone interpretation). After the interpretation, each reader reviewed software results and modified their initial interpretation as needed (software-assisted interpretation). The majority of three thoracic radiologists decided reference standards for the presence and classification of lung nodules based on the Lung-RADS. Diagnostic accuracy was calculated for lung cancer and Lung-RADS positive nodules.*Results Among 50 participants (male 100%; median age 63 years; median smoking burden of 40 pack-year), 15 participants were diagnosed as lung cancer. For the identification of participants with lung cancer, the software exhibited similar sensitivity (87%) with readers (81%; P=.57) with lower specificity (60% vs. 75%; P=.04). The software and readers exhibited similar sensitivities for detection of any lung nodules (67% vs. 60%; P=.08), and Lung-RADS positive (category =3) nodules (73% vs. 71%; P=.72). In the software-assisted interpretation, sensitivities of readers in the detection of any lung nodules (60% to 73%; P<.001) and Lung-RADS positive nodules (71% to 76%; P=.02) were improved compared to the reader-alone interpretation. Inter-reader agreement of Lung-RADS categorization was improved in the software-assisted interpretation (Fleiss' kappa, 0.51 to 0.57).*Conclusions To interpret screening LDCTs, a deep learning-based lung nodule detection and classification system exhibited radiologist-level sensitivity and improved radiologists' lung nodule detection performance and inter-reader agreement of interpretation.*Clinical Relevance/Application To interpret screening LDCTs, a deep learning-based lung nodule detection and classification system can help radiologists detect lung nodules and reduce inter-reader variability.

RESULTS

Among 50 participants (male 100%; median age 63 years; median smoking burden of 40 pack-year), 15 participants were diagnosed as lung cancer. For the identification of participants with lung cancer, the software exhibited similar sensitivity (87%) with readers (81%; P=.57) with lower specificity (60% vs. 75%; P=.04). The software and readers exhibited similar sensitivities for detection of any lung nodules (67% vs. 60%; P=.08), and Lung-RADS positive (category =3) nodules (73% vs. 71%; P=.72). In the software-assisted interpretation, sensitivities of readers in the detection of any lung nodules (60% to 73%; P<.001) and Lung-RADS positive nodules (71% to 76%; P=.02) were improved compared to the reader-alone interpretation. Inter-reader agreement of Lung-RADS categorization was improved in the software-assisted interpretation (Fleiss' kappa, 0.51 to 0.57).

CLINICAL RELEVANCE/APPLICATION

To interpret screening LDCTs, a deep learning-based lung nodule detection and classification system can help radiologists detect

lung nodules and reduce inter-reader variability.

SDP-CH-30 A Comparative Study To Evaluate CtBased Semantic And Radiomic Features In Preoperative Diagnosis Of Invasive Pulmonary Adenocarcinomas Manifesting As Subsolid Nodules

Participants
Fu-Zong Wu, MD, Kaohsiung, Taiwan (*Presenter*) Nothing to Disclose

PURPOSE

This study aims to predict the histological invasiveness of pulmonary adenocarcinoma spectrum manifesting with subsolid nodules ?3 cm using the preoperative CT-based radiomic approach.*Methods and Materials A total of 186 patients with 203 SSNs confrmed with surgically pathologic proof were retrospectively reviewed from February 2016 to March 2020 for training cohort modeling. The validation cohort included 50 subjects with 57 SSNs confrmed with surgically pathologic proof from April 2020 to August 2020. CT-based radiomic features were extracted using an open-source software with 3D nodular volume segmentation manually. The association between CT-based conventional features/ selected radiomic features and histological invasiveness of pulmonary adenocarcinoma status were analyzed. Diagnostic models were built using conventional CT features, selected radiomic CT features and experienced radiologists.*Results In the training cohort of 203 SSNs, there were 106 invasive lesions and 97 pre-invasive lesions. Logistic analysis identifed that a selected radiomic feature named GLCM_Entropy_log10 was the predictor for histological invasiveness of pulmonary adenocarcinoma spectrum (OR: 38.081, 95% CI 2.735-530.309, p = 0.007). The sensitivity and specifcity for predicting histological invasiveness of pulmonary adenocarcinoma spectrum using the cutof value of CT-based radiomic parameter (GLCM_Entropy_log10) were 84.8% and 79.2% respectively (area under curve, 0.878). The diagnostic model of CT-based radiomic feature was compared to those of conventional CT feature (morphologic and quantitative) and three experienced radiologists. The diagnostic performance of radiomic feature was similar to those of the quantitative CT feature (nodular size and solid component, both lung and mediastinal window) in prediction invasive pulmonary adenocarcinoma (IPA). The AUC value of CT radiomic feature was higher than those of conventional CT morphologic feature and three experienced radiologists. The c-statistic of the training cohort model was 0.878 (95% CI 0.831-0.925) and 0.923 (0.854-0.991) in the validation cohort. Calibration was good in both cohorts.*Conclusions The diagnostic performance of CT-based radiomic feature is not inferior to solid component (lung and mediastinal window) and nodular size for predicting invasiveness. CT-based radiomic feature and nomogram could help to diferentiate*Clinical Relevance/Application Radiomic feature may provide superior diagnostic performance compared with those of morphologic CT features and radiologists. Te nomogram may help clinicians with decision making in the management of subsolid nodules.

RESULTS

In the training cohort of 203 SSNs, there were 106 invasive lesions and 97 pre-invasive lesions. Logistic analysis identifed that a selected radiomic feature named GLCM_Entropy_log10 was the predictor for histological invasiveness of pulmonary adenocarcinoma spectrum (OR: 38.081, 95% CI 2.735-530.309, p = 0.007). The sensitivity and specifcity for predicting histological invasiveness of pulmonary adenocarcinoma spectrum using the cutof value of CT-based radiomic parameter (GLCM_Entropy_log10) were 84.8% and 79.2% respectively (area under curve, 0.878). The diagnostic model of CT-based radiomic feature was compared to those of conventional CT feature (morphologic and quantitative) and three experienced radiologists. The diagnostic performance of radiomic feature was similar to those of the quantitative CT feature (nodular size and solid component, both lung and mediastinal window) in prediction invasive pulmonary adenocarcinoma (IPA). The AUC value of CT radiomic feature was higher than those of conventional CT morphologic feature and three experienced radiologists. The c-statistic of the training cohort model was 0.878 (95% CI 0.831-0.925) and 0.923 (0.854-0.991) in the validation cohort. Calibration was good in both cohorts.

CLINICAL RELEVANCE/APPLICATION

Radiomic feature may provide superior diagnostic performance compared with those of morphologic CT features and radiologists. Te nomogram may help clinicians with decision making in the management of subsolid nodules.

SDP-CH-31 Comparison Of Capability For Lymph Node Metastasis Prediction Among Lung MRIs With Ultra-Short TE (UTE-MRIs) By Single And Dual Echo Techniques, Thin-section CT, DWI, FDG-PET/CT And Combined MR Predictors In Non-small Cell Lung Cancer

Participants
Yoshiharu Ohno, MD,PhD, Toyoake, Japan (*Presenter*) Research Grant, Canon Medical Systems Corporation;Research Grant, DAIICHI SANKYO Group

PURPOSE

Evaluation of solid component within tumor as ratio between consolidation and total tumor (C/T ratio) on thin-section CT had been suggested as useful for prediction of patients' survival in non-small cell lung cancer (NSCLC). Recently, lung MRI with ultra-short TE (UTE) has been suggested as useful for tumor morphological evaluation since 2016. Moreover, lung MRI with multiple UTEs is tested for adding morphological information with T2* relaxation time in various diseases. The purpose of this study was to compare capability for lymph node metastasis prediction in NSCLC among UTE-MRIs with single- and dual-echo techniques (UTE-MRISingle and UTE-MRIDual), CT, DWI, FDG-PET/CT and combined MR predictors.*Methods and Materials 56 NSCLC patients underwent CT, UTE-MRIs with both techniques, DWI, FDG-PET/CT, surgical resection and pathological and follow-up examinations. Then, C/T ratios from CT and both UTE-MRIs, ADC and SUVmax at each primary lesion were assessed. All indexes were compared between N0 and equal to or more than N1 (N1=) cases by Student's t test. Multiple regression analysis was performed to determine predictors for differentiation of N1= from N0 cases among all MR indexes. Moreover, ROC analysis was also performed among all indexes and combined MR predictors. Finally, sensitivity (SE), specificity (SP) and accuracy (AC) were compared among all indexes.*Results There was significant difference of each index between N0 and N1= cases (p<0.05). C/T ratio from UTE-MRIDual (p=0.04) and ADC (p=0.0002) were determined significant predictors in this setting. Area under the curves (AUCs) of ADC (AUC=0.84), SUVmax (AUC=0.82) or combined MR predictors (AUC=0.90) were significantly larger than that of each C/T ratio (0.69=AUC=0.73, p<0.05). SP or AC of combined MR predictors were significantly higher than those of others (p<0.05). Moreover, SP and AC of ADC and SUVmax were significantly higher than those of each C/T ratio (p<0.05).*Conclusions UTE-MRIDual is considered as having the capability to play as significant predictor for lymph node metastasis similar to DWI, and combined MR predictors shows significant higher capability than each C/T ratio, DWI and PET/CT in this setting.*Clinical Relevance/Application UTE-MRIDual is considered as having the capability to play as significant predictor for lymph node metastasis similar to DWI, and combined MR predictors shows significant higher capability than each C/T ratio, DWI and PET/CT in this setting.

RESULTS

There was significant difference of each index between N0 and N1= cases (p<0.05). C/T ratio from UTE-MRIDual (p=0.04) and ADC

There was significant difference of each index between N0 and N1= cases (p<0.05). C/T ratio from UTE-MRIDual (p=0.04) and ADC (p=0.0002) were determined significant predictors in this setting. Area under the curves (AUCs) of ADC (AUC=0.84), SUVmax (AUC=0.82) or combined MR predictors (AUC=0.90) were significantly larger than that of each C/T ratio (0.69=AUC=0.73, p<0.05). SP or AC of combined MR predictors were significantly higher than those of others (p<0.05). Moreover, SP and AC of ADC and SUVmax were significantly higher than those of each C/T ratio (p<0.05).

CLINICAL RELEVANCE/APPLICATION

UTE-MRIDual is considered as having the capability to play as significant predictor for lymph node metastasis similar to DWI, and combined MR predictors shows significant higher capability than each C/T ratio, DWI and PET/CT in this setting.

SDP-CH-32   Clinical Research On Patients With Surgically Resected Primary Lung Adenocarcinoma: Are Heterogeneous Ggns Different From Part Solid Nodules?

Participants
Hirofumi Koike, Nagasaki, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the natural course of patients with surgically resected lung adenocarcinoma (Ad) with heterogenous GGN, and to clarify the difference between heterogeneous GGNs and part solid nodules.*Methods and Materials Between 2006 and 2015, 507 patients with proven lung Ad were retrospectively reviewed. Preoperative lung Ad lesions were investigated, and were classified into solid nodule, part solid nodule, heterogeneous GGN, and pure GGN group on thin-section CT. After surgery, they were examined pathologically. Disease-free survival (DFS) and overall survival (OS) of the patients were also investigated.*Results All of the 61 heterogeneous GGNs were found only in patients with postoperative stage IA. The numbers of the other types including solid nodule, part solid nodule, and pure GGN in stage IA were 70, 181, and 9, respectively. In part solid nodule group, recurrence of lung Ad and death from the primary disease were observed in 12(6.6%) and 6(3.3%) of 181 patients, respectively. There were no recurrences or deaths from the primary disease of lung Ad in heterogeneous GGN group. Heterogeneous GGNs were significantly associated with longer DFS than part solid nodules (p=0.042). On the other hand, there was no significant difference between heterogeneous GGNs and part solid nodules (p=0.139) in OS. Pathological diagnoses based on IASLC/ATS/ERS new classification of lung Ad advocated in 2011 have been obtained in 176 patients. 100 part solid nodules were classified into 71 invasive adenocarcinomas (71%), 24 minimally invasive adenocarcinomas (MIAs) (24%), and 5 adenocarcinomas in situ (AIS) (5%), and 32 heterogeneous GGNs were classified into 9 invasive adenocarcinomas (28.1%), 15 MIAs (46.9%), and 8 AIS (25%).*Conclusions Heterogeneous GGNs were associated with longer DFS than part solid nodules. Pathologically, the heterogeneous GGN group had a lower proportion of invasive adenocarcinoma, a higher proportion of MIA and AIS than part solid nodule group.*Clinical Relevance/Application • Heterogeneous GGNs were found only in patients with postoperative stage IA. • There were no recurrences or deaths from the primary disease of lung Ad in heterogeneous GGN group after surgery. • There were differenced in proportions of pathological subclassification of lung Ad between part solid nodule and heterogeneous GGN.

RESULTS

All of the 61 heterogeneous GGNs were found only in patients with postoperative stage IA. The numbers of the other types including solid nodule, part solid nodule, and pure GGN in stage IA were 70, 181, and 9, respectively. In part solid nodule group, recurrence of lung Ad and death from the primary disease were observed in 12(6.6%) and 6(3.3%) of 181 patients, respectively. There were no recurrences or deaths from the primary disease of lung Ad in heterogeneous GGN group. Heterogeneous GGNs were significantly associated with longer DFS than part solid nodules (p=0.042). On the other hand, there was no significant difference between heterogeneous GGNs and part solid nodules (p=0.139) in OS. Pathological diagnoses based on IASLC/ATS/ERS new classification of lung Ad advocated in 2011 have been obtained in 176 patients. 100 part solid nodules were classified into 71 invasive adenocarcinomas (71%), 24 minimally invasive adenocarcinomas (MIAs) (24%), and 5 adenocarcinomas in situ (AIS) (5%), and 32 heterogeneous GGNs were classified into 9 invasive adenocarcinomas (28.1%), 15 MIAs (46.9%), and 8 AIS (25%).

CLINICAL RELEVANCE/APPLICATION

• Heterogeneous GGNs were found only in patients with postoperative stage IA. • There were no recurrences or deaths from the primary disease of lung Ad in heterogeneous GGN group after surgery. • There were differenced in proportions of pathological subclassification of lung Ad between part solid nodule and heterogeneous GGN.

SDP-CH-33   Improvement Diagnostic Performance On Fibrotic Hypersensitivity Pneumonitis Using Ultra-high Resolution Computed Tomography

Participants
Tae Iwasawa, MD,PhD, Yokohama, Japan (*Presenter*) Support, Canon Medical Systems CorporationSupport, Ziosoft Inc.Speaker, FUJIFILM Holdings CorporationSpeaker, Boehringer Ingelheim GmbH

PURPOSE

To evaluate whether ultra-high-resolution computed tomography (U-HRCT) can increase diagnostic performance of fibrotic hypersensitivity pneumonitis (fHP) compared to conventional CT.*Methods and Materials This single-institution retrospective study was approved by our institutional review board. Fifty-five patients (38 men, 17 women; median age: 63 years) who underwent surgical lung biopsy and were diagnosed with chronic fibrotic interstitial lung diseases by multi-disciplinary discussion as idiopathic pulmonary fibrosis (n=22), fHP (n=14), and others (n=19) were included in this study. All CT scans were performed by a 160-row U-HRCT scanner (Aquilion Precision, Canon Medical Systems, Otawara,Tochigi, Japan). CT scans were performed at 120 kVp, 0.25 × 160 collimation, and 0.828 beam pitch using automatic exposure control. Two kinds of images were constructed and compared: U-HRCT image (1024 × 1024 matrix size, 0.25-mm slice thickness, and deep learning reconstruction algorithm for the lung) and normal-resolution simulation (NR-sim) image (512 × 512 matrix size, 0.5-mm slice thickness, and iterative reconstruction method). Three board-certificated chest radiologists independently and randomly evaluated these images and judged the probability of usual interstitial pneumonia (UIP) or fHP patterns based on each guideline. We compared the probability of UIP or fHP patterns using the average area under the curve (AUC) of the receiver operating characteristics. The radiologists counted lung segments with bronchiectasis and bronchioloectasis and evaluated overall image qualities. These data were compared using the Wilcoxon's signed-rank test.*Results The overall U-HRCT image qualities were better than the NR-sim image qualities (p<0.001). The median number of lung segments with bronchiectasis was significantly more in U-HRCT (15) than in NR-sim images (12) (p<0.001). The AUC for UIP in U-HRCT and NR-sim images was 0.745 and 0.746, respectively. The AUC for fHP diagnosis significantly increased from 0.692 in NR-sim images to 0.794 in U-HRCT images.*Conclusions U-HRCT can increase diagnostic performance of fHP.*Clinical Relevance/Application U-HRCT can clearly visualize peripheral bronchiectasis and increase the diagnostic performance of fibrotic

hypersensitivity pneumonitis, which is difficult to diagnose with conventional CT.

RESULTS

The overall U-HRCT image qualities were better than the NR-sim image qualities (p<0.001). The median number of lung segments with bronchiectasis was significantly more in U-HRCT (15) than in NR-sim images (12) (p<0.001). The AUC for UIP in U-HRCT and NR-sim images was 0.745 and 0.746, respectively. The AUC for fHP diagnosis significantly increased from 0.692 in NR-sim images to 0.794 in U-HRCT images.

CLINICAL RELEVANCE/APPLICATION

U-HRCT can clearly visualize peripheral bronchiectasis and increase the diagnostic performance of fibrotic hypersensitivity pneumonitis, which is difficult to diagnose with conventional CT.

SDP-CH-34　Idiopathic Dendriform Pulmonary Ossification; Detailed CT Pathologic Correlation In 22 Patients

Participants
Midori Ueno, MD, Kitakyushu, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Idiopathic dendriform pulmonary ossification (DPO) is a rare condition which characterized the mature bone formation in the lung parenchyma. The aim of this study is to clarify the histological background of HRCT findings in DPO.*Methods and Materials 22 DPO patients (18 men and 4 women, mean age, 37.9 years; range, 22-56 years), histologically confirmed by surgical lung biopsy, were identified in a nationwide epidemiological survey. HRCT findings of the high-attenuated structures on bone window (WW 2500HU, WL 500HU), and other associated parenchymal findings including iso-attenuated nodule, band-like opacity, reticulation, ground-glass opacity (GGO) and cysts were compared to the corresponding histological ones side by side.*Results High-attenuated structures, showing either linear, branching, or round forms, on CT (n=22) were seen in centrilobular and perilobular area and histologically corresponded to dendriform ossification itself both in alveolar space and interstitium. Band like opacities (n=22) corresponded to fibrous scar or partial collapsing lung, iso-attenuated nodules (n=22) corresponded to small ossification with cicatricialorganizing pneumonia (OP) or ossification with bone marrow, GGOs (n=22) to hemorrhage, alveolar edema and/or accumulation of macrophages, cysts (n=7) to emphysematous change and reticulation (n=4) corresponded to small foci of ossification and fibrosis.*Conclusions In idiopathic DPO, HRCT findings histologically corresponded to dendriform ossification itself and associated cicatricial OP, fibrosis, or hemorrhage. Small ossifications and ossification with bone marrow can be seen as iso-attenuated nodules or reticulation on HRCT.*Clinical Relevance/Application The HRCT findings seen in DPO reflected not only ossification, but also accompanying cicatricial OP, fibrosis, and hemorrhage. This result may help to understand the pathogenesis of this disease.

RESULTS

High-attenuated structures, showing either linear, branching, or round forms, on CT (n=22) were seen in centrilobular and perilobular area and histologically corresponded to dendriform ossification itself both in alveolar space and interstitium. Band like opacities (n=22) corresponded to fibrous scar or partial collapsing lung, iso-attenuated nodules (n=22) corresponded to small ossification with cicatricialorganizing pneumonia (OP) or ossification with bone marrow, GGOs (n=22) to hemorrhage, alveolar edema and/or accumulation of macrophages, cysts (n=7) to emphysematous change and reticulation (n=4) corresponded to small foci of ossification and fibrosis.

CLINICAL RELEVANCE/APPLICATION

The HRCT findings seen in DPO reflected not only ossification, but also accompanying cicatricial OP, fibrosis, and hemorrhage. This result may help to understand the pathogenesis of this disease.

SDP-CH-35　Validation Of A Deep Learning-based Automatic Detection Algorithm For Reticular Opacity On Chest Radiograph

Participants
Wooil Kim, MD, Charlottesville, Virginia (*Presenter*) Nothing to Disclose

PURPOSE

To validate a deep learning-based algorithm (DLA) in diagnosing reticular opacity on chest radiograph in patients with surgically confirmed interstitial lung disease.*Methods and Materials Two test sets (abnormal : normal = 1:1) were separately included from two institutions (validation set A: 396; validation set B: 102). The performance of the DLA was assessed using the validation set A and B. Six reader without and with DLA interpreted chest radiographs in the validation set A. The area under the receiver operating characteristic curve (AUC) and diagnostic indices of the DLA and readers were measured and compared. Inter-reader agreement was measured with Fleiss' Kappa. Subgroup analysis according to CT-based severity classification of reticular opacity was also performed.*Results The AUCs of DLA in detecting reticular opacity in validation set A and B were 0.987 and 1, respectively. The AUCs of pooled readers without and with DLA were 0.879 and 0.966, respectively (P=0.15). The sensitivity, specificity, and accuracy of pooled readers without DLA were 77.3%, 92.3%, and 84.8%, respectively. With DLA assistance, the sensitivity, specificity, and accuracy of pooled readers increased to 93.8%, 97.3%, and 95.6%, respectively (all, P<0.0001). The sensitivity of pooled readers in diagnosing reticular opacity in mild and moderate category improved with assistance of DLA (mild, 66.7% and 86.8%; moderate, 84.2% and 98.8%; all, P<0.0001). The DLA also improved inter-reader agreement from moderate (kappa=0.517) to excellent (kappa=0.870) degree.*Conclusions The DLA presented excellent performance in diagnosing reticular opacity on chest radiograph. DLA assistance improved diagnostic performance, especially sensitivity and interobserver agreement.*Clinical Relevance/Application The DLA presented excellent performance in diagnosing reticular opacity on chest radiograph and with its assistance the interobserver agreement and sensitivity improved in diagnosing relatively subtle reticular opacity.

RESULTS

The AUCs of DLA in detecting reticular opacity in validation set A and B were 0.987 and 1, respectively. The AUCs of pooled readers without and with DLA were 0.879 and 0.966, respectively (P=0.15). The sensitivity, specificity, and accuracy of pooled readers without DLA were 77.3%, 92.3%, and 84.8%, respectively. With DLA assistance, the sensitivity, specificity, and accuracy of pooled readers increased to 93.8%, 97.3%, and 95.6%, respectively (all, P<0.0001). The sensitivity of pooled readers in diagnosing reticular opacity in mild and moderate category improved with assistance of DLA (mild, 66.7% and 86.8%; moderate, 84.2% and 98.8%; all, P<0.0001). The DLA also improved inter-reader agreement from moderate (kappa=0.517) to excellent (kappa=0.870)

degree.

CLINICAL RELEVANCE/APPLICATION

The DLA presented excellent performance in diagnosing reticular opacity on chest radiograph and with its assistance the interobserver agreement and sensitivity improved in diagnosing relatively subtle reticular opacity.

SDP-CH-36 Can Deep Learning Reconstruction Keep Balance Between Lower Dose And High Image Quality In Interstitial Lung Disease

Participants
Ruijie Zhao, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the feasibility of deep learning reconstruction in improving the image quality and reducing radiation dose in ILD, in comparison with HRCT.*Methods and Materials 50 cases of ILD patients (were prospectively enrolled in this study, including 14 male and 36 female, mean age (59.7±9.9) years old, BMI (24.68±3.00) kg/m2. 22 patents were CTD-related ILD, 1 sarcoidosis-related, 1 IgG4-related and the other 24 unclear. All patients underwent HRCT(120kVp, automatic tube current) followed by (LDCT (120kVp, 30mAs). HRCT images were reconstructed with Adaptive Iterative Dose Reduction 3-Dimensional, AIDR3D, standard setting, and LDCT images were reconstructed with Advanced Intelligence Clear-IQ Engine[AiCE], lung/bone, mild/standard/strong setting. Two radiologists independently evaluated the image noise, streak artifact, image quality, visualization of normal and abdominal features of ILD, and comparison between all reconstructed HRCT and LDCT images were conducted.*Results The mean radiation dose of LDCT was reduced to 1/3 of HRCT. The image noise of all reconstructed images in low dose scan was about 33.4% to 91.5% of HRCT, and signal-to-noise ratio (SNR) was improved to 1.1 to 3 times of the latter (p<0.0001). No significant difference was found in overall image quality, streak artifact, and visualization of normal features(fissures, proximal bronchi and vessels, peripheral bronchi and vessels, subpleural vessels) between all reconstructed LDCT images and HRCT images, and in some cases, LDCT scores were even higher(p < 0.05). LDCT (AiCE, lung) was superior to HRCT (AIDR3D) in visualizing ground-glass opacity (GGO) and architectural distortion (p < 0.05). LDCT(AiCE, lung-strong setting, bone-mild/strong setting) had better scores in honeycombing than HRCT (p < 0.05), while no significant difference was found in other abnormal features (reticulation, bronchiectasis and bronchiolectasis) between reconstructed LDCT and HRCT images(p > 0.05).*Conclusions Deep learning reconstruction could effectively reduce the radiation dose and keep the image quality compared with HRCT in ILD patients, and AiCE (lung, strong setting) was promising to become the preferred reconstruction scheme for LDCT scans for ILD patients in the future.*Clinical Relevance/Application Deep learning reconstruction could be applied to improve the image quality of low dose chest CT in ILD patients.

RESULTS

The mean radiation dose of LDCT was reduced to 1/3 of HRCT. The image noise of all reconstructed images in low dose scan was about 33.4% to 91.5% of HRCT, and signal-to-noise ratio (SNR) was improved to 1.1 to 3 times of the latter (p<0.0001). No significant difference was found in overall image quality, streak artifact, and visualization of normal features(fissures, proximal bronchi and vessels, peripheral bronchi and vessels, subpleural vessels) between all reconstructed LDCT images and HRCT images, and in some cases, LDCT scores were even higher(p < 0.05). LDCT (AiCE, lung) was superior to HRCT (AIDR3D) in visualizing ground-glass opacity (GGO) and architectural distortion (p < 0.05). LDCT(AiCE, lung-strong setting, bone-mild/strong setting) had better scores in honeycombing than HRCT (p < 0.05), while no significant difference was found in other abnormal features (reticulation, bronchiectasis and bronchiolectasis) between reconstructed LDCT and HRCT images(p > 0.05).

CLINICAL RELEVANCE/APPLICATION

Deep learning reconstruction could be applied to improve the image quality of low dose chest CT in ILD patients.

SDP-CH-37 Utility Of Visual Coronary Artery Calcification In Prognosticating Patients With COVID-19

Participants
Anirudh Nair, MBBS, Doha, Qatar (*Presenter*) Nothing to Disclose

PURPOSE

To ascertain the role of semi-quantitative scoring in visual-coronary artery calcification score (V-CACS) for predicting the clinical severity and outcome in patients with COVID-19.*Methods and Materials The study included 67 COVID-19 confirmed adult patients who underwent non-cardiac gated CT chest in an inpatient setting. Two blinded radiologists (Radiologist-1 &2) assessed the V-CACS, CT Chest severity score (CT-SS). The inter-rater agreement was assessed using Cohens k. The clinical data including the requirement for oxygen, ventilation, ICU admission, and the outcome was assessed. The patients were clinically subdivided depending on severity into mild and severe. Multivariate logistic regression analyses were performed to identify independent predictors. ROC curves analysis is performed for the assessment of performance. Pearson correlation was performed to looks for the associations.*Results V-CACS cut-off value of 3 (82.67% sensitivity and 54.55% specificity; AUC 0.75) and CT-SS with a cut-off value of 21.5 and above (95.7% sensitivity and 63.6% specificity; AUC 0.87) are independent predictors of clinical disease severity and also the need for ICU admission or assisted ventilation. The pooling of both CT-SS and V-CACS (82.67% sensitivity and 86.4% specificity) is associated with a primary outcome. V-CACS and CT-SS are individual independent predictors of clinical severity in COVID-19 (Odds ratio, 1.72; 95% CI, 0.99-2.98; p = 0.05 and Odds ratio, 1.22; 95% CI, 1.08-1.39; p = 0.001 respectively). The area under the curve (AUC) for pooled V-CACS and CT-SS was 0.96 (95% CI 0.84-0.98).*Conclusions Logistic regression model using pooled Visual-Coronary artery calcification score and CT Chest severity score in non-cardiac gated CT can predict clinical severity and outcome in patients with COVID-19.*Clinical Relevance/Application This study evaluated the ability of V-CACS in predicting clinical severity and outcome in COVID-19, using semi-quantitative scoring of coronary artery calcifications. Our results indicate patients with a known COVID-19, in whom there is an inpatient CT scan the V-CACS and CT-SS above the threshold will help to identify potential clinically severe disease.

RESULTS

V-CACS cut-off value of 3 (82.67% sensitivity and 54.55% specificity; AUC 0.75) and CT-SS with a cut-off value of 21.5 and above (95.7% sensitivity and 63.6% specificity; AUC 0.87) are independent predictors of clinical disease severity and also the need for ICU admission or assisted ventilation. The pooling of both CT-SS and V-CACS (82.67% sensitivity and 86.4% specificity) is associated with a primary outcome. V-CACS and CT-SS are individual independent predictors of clinical severity in COVID-19 (Odds ratio, 1.72; 95% CI, 0.99-2.98; p = 0.05 and Odds ratio, 1.22; 95% CI, 1.08-1.39; p = 0.001 respectively). The area under the curve (AUC) for pooled V-CACS and CT-SS was 0.96 (95% CI 0.84-0.98).

This study evaluated the ability of V-CACS in predicting clinical severity and outcome in COVID-19, using semi-quantitative scoring of coronary artery calcifications. Our results indicate patients with a known COVID-19, in whom there is an inpatient CT scan the V-CACS and CT-SS above the threshold will help to identify potential clinically severe disease.

SDP-CH-38 Extracting And Quantifying Shape Pattern Of Ascending Aorta By Statistical Shape Analysis In Patients With Marfan Syndrome.

Participants
Yu-cheng Huang, MD, Taipei, Taiwan (*Presenter*) Nothing to Disclose

PURPOSE

Aortic dissection is one of the major causes of mortality in patients with Marfan syndrome. However, morphology and speed of progression is variable between patients. In this study, we aimed to develop a computational way to quantify the shape pattern changes in ascending aorta of patients with Marfan syndrome with statistical shape analysis.*Methods and Materials Patients with marfan syndrome who received cross sectional imaging during 2017 to 2020 for evaluation of aorta diameter were retrospectively reviewed and included in this study. Patients with no preoperative image, with bicuspid aortic valve or poor image quality were excluded. Aortic valves, sinus valsalva, sinotubular junction and ascending aorta were segmented and transformed into shape meshes. These meshes were then landmarked and subdivision fit to standardize comparison between different patients. Statistical shape analysis with Procrustes transformation and Principal component analysis was applied to register different standardized meshes, gain independant major shape change patterns and quantify shape changes in each subject.*Results A total of 43 patients were found to have cross sectional imaging. After excluding patients with no preoperative image, with bicuspid aortic valve and poor image quality, there are 32 eligible studies for analysis. All ascending aorta in remaining patients are segmented and subdivision-fit successfully. Principal component yielded independent 5 major shape change patterns (modes) that correspond to the shape pattern observed in clinical practice. Major change modes are observed in subgroups of patients.*Conclusions Statistical shape analysis is a feasible way of performing major shape pattern capture and quantification in pathological aorta with marfan syndrome. It might allow further grouping and analysis.*Clinical Relevance/Application Statistical shape analysis might be a feasible quantification tool that captures information in addition to conventional morphometry. Our method potentially adapts to different body sizes and habitus. It might allow further statistical analysis with correlation with genetic study, prognosis and automatic grouping in a wider range of age groups in congenital disease.

RESULTS

A total of 43 patients were found to have cross sectional imaging. After excluding patients with no preoperative image, with bicuspid aortic valve and poor image quality, there are 32 eligible studies for analysis. All ascending aorta in remaining patients are segmented and subdivision-fit successfully. Principal component yielded independent 5 major shape change patterns (modes) that correspond to the shape pattern observed in clinical practice. Major change modes are observed in subgroups of patients.

CLINICAL RELEVANCE/APPLICATION

Statistical shape analysis might be a feasible quantification tool that captures information in addition to conventional morphometry. Our method potentially adapts to different body sizes and habitus. It might allow further statistical analysis with correlation with genetic study, prognosis and automatic grouping in a wider range of age groups in congenital disease.

SDP-CH-39 Development Of Medication Prediction Model For COPD Patients With Using Chest CT Image And Pulmonary Function Test: Pilot Study

Participants
Zepa Yang, PhD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Treatment of most COPD patients is usually done with prescription medications. However, due to the ambiguous relationship between COPD subtyping and prescription medications, prescriptions for the treatment of patients are based on changes in the patient's current symptoms, patient status based on previous prescription results, and experience of the respiratory physicians.This study purposes to develop deep learning based classification and prediction models using medical records and CT image of patients who have been prescribed drugs due to lung diseases such as COPD, that can classify which groups of COPD that patient is currently included and which drugs should be administered in current status.*Methods and Materials The list of prescriptible medication in our hospital were categorized as LAMA / LABA / ICS group with overlapped. From 2000 patient who is being treated at a medical center for COPD disease, prescript drug information, the pulmonary function test result and chest CT data of 2000 patient was acquired, and were pre-processed and converted to a time-series data. The data with the same medication prescribed for six consecutive months were assumed as gold standard, and used for training and the validation of the estimation model. Machine learning based prediction model was developed with using CNN-LSTM based estimation model.Among the various patient information, the specific features used in prediction process were PFT measurements which are commonly referred to by respiratory physicians in the diagnosis process, such as DLCO, FEV1, TV, TLC, etc., as well as image biomarkers acquired from chest CT, such as emphysema index (LAA%), airway thickness (AWT-Pi10), long airway vessel, volume, pectoralis muscle volume, etc. From the gold standard data, 200 CT data and PFT data were used for validation set, and the estimation results were compared with groups of drugs. Binary cross entropy was used to assess the estimation performance for gold standard and the result of the proposed model.*Results In training and validation process, average accuracy and loss value of the estimation model was 0.8523 and 0.1536, respectively.In manual evaluation, the accuracy of the estimated result was 83.5%. In detail, 112 cases were estimated exactly same drug as gold standard, and 52 cases were estimated the drugs in same group.*Conclusions The medication estimation model showed promising result, even with relatively sparse time series data. The performance of the estimation may show better result with larger, dense data is provided in further study.*Clinical Relevance/Application Based on the information on the current patient's condition and the process of the medication, deep learning model could determine what medication should be taken for current status.

RESULTS

In training and validation process, average accuracy and loss value of the estimation model was 0.8523 and 0.1536, respectively.In manual evaluation, the accuracy of the estimated result was 83.5%. In detail, 112 cases were estimated exactly same drug as gold standard, and 52 cases were estimated the drugs in same group.

CLINICAL RELEVANCE/APPLICATION

Based on the information on the current patient's condition and the process of the medication, deep learning model could determine what medication should be taken for current status.

SDP-CH-4   The Evolution Of The Lung Damages After COVID-19 Infection In The Early And Late Term According To CT Data

Participants
Katsiaryna Rudas, Minsk, Belarus (*Presenter*) Nothing to Disclose

PURPOSE

Using LDCT to assess the consequences of Covid19-associated lung damage, depending on the volume of lung tissue damage in patients of different age groups.*Methods and Materials The study involved 130 patients aged 35 to 80 years with laboratory-confirmed Covid19, changes in the lungs and comorbidity. The primary and repeated studies were performed on a GE Revolution CT using a low-dose protocol for scanning in pulmonary mode with a step of 0.625mm and soft tissue reformats. DLP coefficient was 1mSv.*Results We assessed the characteristics of changes in the lungs during the primary study, the repeated studies performed from 14 days to 3, 6, 9 months.First group includes 95 patients 35-60 years old with non-severe comorbidity who had mild to moderate disease with the lesions in the lungs up to 50% of lung volume. During the second study 73 patients (77%) showed a complete restoration of the pulmonary pattern and pneumatization of the interstitium within 3 months. Within 6 months 9 patients (9%) of this group demonstrated total recovering of the lung tissue. Second group includes 28 patients 55-80 years old with comorbidity (diabetes 2nd type, IHD, thrombosis etc.) with lung damages up to 50-75% of lung volume. Within 3 months 25 patients (90%) showed lung lesions: disatelectasis in the peripheral parts of the lungs, local emphysema of the intact parenchyma, fibrosis-like changes in the lungs. These changes persisted longer in patients with high volume of consolidation of the lung tissue. 16 patients (64%) passed the examination within 6 and 9 months, the lung tissue was almost recovered at 12 patients (75%), with minimal residual changes at the 4 patients (25%) mostly with large volume of the consolidation during the acute phase of the disease. Third group includes 7 patients over 55 years old with comorbidity who underwent severe disease with a lesion up to 75-100% of lung volume. After 3 months intensity of damage to lung tissue decreased in 5 examined patients (71%), intact parenchyma became emphysematous. Within 6 months all of them showed a further reduction of lesions: emphysema of the intact parenchyma, a gradual decrease of the length and the volume of subsegmental disatelectasis in the peripheral parts of the lungs.*Conclusions Complete reparation of lung tissue is possible after suffering COVID19 in mild to moderate form within 3-6 months. Comorbidity plays a greater role than age in the timing of the resolution of residual changes in the lungs and more often accompanies moderate and severe forms of COVID19.*Clinical Relevance/Application Patients with large residual changes should be monitored by a pulmonologist and undergo rehabilitation. Patients with mild to moderate course of COVID19 do not show significant residual lung changes within 3 months.

RESULTS

We assessed the characteristics of changes in the lungs during the primary study, the repeated studies performed from 14 days to 3, 6, 9 months.First group includes 95 patients 35-60 years old with non-severe comorbidity who had mild to moderate disease with the lesions in the lungs up to 50% of lung volume. During the second study 73 patients (77%) showed a complete restoration of the pulmonary pattern and pneumatization of the interstitium within 3 months. Within 6 months 9 patients (9%) of this group demonstrated total recovering of the lung tissue. Second group includes 28 patients 55-80 years old with comorbidity (diabetes 2nd type, IHD, thrombosis etc.) with lung damages up to 50-75% of lung volume. Within 3 months 25 patients (90%) showed lung lesions: disatelectasis in the peripheral parts of the lungs, local emphysema of the intact parenchyma, fibrosis-like changes in the lungs. These changes persisted longer in patients with high volume of consolidation of the lung tissue. 16 patients (64%) passed the examination within 6 and 9 months, the lung tissue was almost recovered at 12 patients (75%), with minimal residual changes at the 4 patients (25%) mostly with large volume of the consolidation during the acute phase of the disease. Third group includes 7 patients over 55 years old with comorbidity who underwent severe disease with a lesion up to 75-100% of lung volume. After 3 months intensity of damage to lung tissue decreased in 5 examined patients (71%), intact parenchyma became emphysematous. Within 6 months all of them showed a further reduction of lesions: emphysema of the intact parenchyma, a gradual decrease of the length and the volume of subsegmental disatelectasis in the peripheral parts of the lungs.

CLINICAL RELEVANCE/APPLICATION

Patients with large residual changes should be monitored by a pulmonologist and undergo rehabilitation. Patients with mild to moderate course of COVID19 do not show significant residual lung changes within 3 months.

SDP-CH-40   E-cigarette Use Among Self-described Former Smokers Undergoing Lung Cancer Screening

Participants
Karim Oueidat, MD,BEng, Providence, Rhode Island (*Presenter*) Nothing to Disclose

PURPOSE

Examine the extent to which lung cancer screening patients use e-cigarettes to achieve and maintain smoking cessation.*Methods and Materials An assessment of smoking behaviors and attitudes was conducted among (self-described) former smokers who attended an annual lung cancer screening from 12 imaging practices between 04/2019-05/2020. Patients eligible for lung cancer screens were at least 30 pack year smokers and 55-77 years old. Because data were anonymous, IRB determined no IRB approval was needed.*Results Of 1085 self-described former smokers, 13% (139) reported having vaped one or more times within the last 12 months. Of these, 84% (117/139) reported they had quit smoking 12 months ago or more. Of the 378 patients who provided an open-ended response to how they achieved smoking cessation, 27% (102/378) reported using an over-the-counter (OTC) nicotine replacement product; of these, 34.3% (34/102) vaped e-cigarettes, making it the second most common OTC product next to patches, 47.1% (47/102). Note, 31.4% (32/102) of participants reported using e-cigarettes exclusively with no other products. Likewise, of the 354 participants who provided an open-ended response to how they avoid smoking during a craving or urge, 36 (10.2%) indicated that they use OTC nicotine replacement products. Among these 36 patients, 12 (33.0%) vaped e-cigarettes, making it the second most common product; 52.8% (19/36) used gum.*Conclusions Many current e-cigarette users consider themselves former smokers, which suggests that some patients do not view vaping e-cigarettes as using tobacco. A sizeable number of former smokers indicated that they use e-cigarettes to maintain and achieve smoking cessation: e-cigarettes were listed only somewhat less often than gum. The prevalence of e-cigarette use for smoking cessation suggested by the current study is likely an under-estimation, as these data are only based off people who volunteered such information in response to generic, open-ended questions.*Clinical Relevance/Application This study suggests that e-cigarettes may be a common method of achieving and maintaining smoking abstinence among former smokers receiving a lung screen with a history of very heavy smoking. More research is needed concerning the efficacy and safety of e-cigarettes as a cessation tool given that many patients are naturalistically using them in this capacity.

Of 1085 self-described former smokers, 13% (139) reported having vaped one or more times within the last 12 months. Of these, 84% (117/139) reported they had quit smoking 12 months ago or more. Of the 378 patients who provided an open-ended response to how they achieved smoking cessation, 27% (102/378) reported using an over-the-counter (OTC) nicotine replacement product; of these, 34.3% (34/102) vaped e-cigarettes, making it the second most common OTC product next to patches, 47.1% (47/102). CLINICAL RELEVANCE/APPLICATION

This study suggests that e-cigarettes may be a common method of achieving and maintaining smoking abstinence among former smokers receiving a lung screen with a history of very heavy smoking. More research is needed concerning the efficacy and safety of e-cigarettes as a cessation tool given that many patients are naturalistically using them in this capacity.

SDP-CH-41 Automatic Labeling Of Airway Tree With Stream Order Robust To Anatomical Variations

Participants
Jihye Yun, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

The labeling of airway trees from thoracic CT scans is crucial to accurately quantify airway morphology which could be used to measure progression and response to treatment. To develop an automated airway tree labeling system robust to anatomical variations using stream order and expertise for anatomical characteristics of the airway tree.*Methods and Materials Airway segmentation was employed as a first step to obtaining personalized tree structures, and then the skeletonization method extracted the centerlines of airways. Using centerlines of airways, the airway branches were labeled in stream order in terms of generations. We assigned a stream number to all nodes of the airway tree in bottom-up order; 1) If two branches of the same order merge, the resulting branch is given a stream number that is one higher.; 2) If two branches with different orders merge, the resulting branch is given the higher stream number. And then we revisited and relabeled them in top-down order. The robustness of our method was improved by fixing the branch levels for branches with little anatomical variations. We maximized the usability of our system by developing efficient manual correction modules.*Results Our method outperformed the conventional airway labeling method for all 50 thoracic CT scans which were collected retrospectively, overcoming mislabeling due to trifurcation and problems that segmental bronchus of the same level was labeled to different levels in the lower lobe.*Conclusions For accurate airway tree labeling, we labeled the airway trees in stream order combined the expertise for anatomical characteristics of airways, resulting in robust anatomical variations.*Clinical Relevance/Application To enable more accurate and automated measurement of each airway level below the subsegmental bronchus for assessment of small airway disease.

RESULTS

Our method outperformed the conventional airway labeling method for all 50 thoracic CT scans which were collected retrospectively, overcoming mislabeling due to trifurcation and problems that segmental bronchus of the same level was labeled to different levels in the lower lobe.

CLINICAL RELEVANCE/APPLICATION

To enable more accurate and automated measurement of each airway level below the subsegmental bronchus for assessment of small airway disease.

SDP-CH-42 Chest CT Findings And Pulmonary Function Tests In The Post recovery Phase Of Mild To Severe Cases Of COVID-19

Participants
Eduardo Kaiser Ururahy Nunes Fonseca, MD, Sao Paulo, Brazil (*Presenter*) Nothing to Disclose

PURPOSE

To correlate follow-up chest computed tomography (CT) and pulmonary function test (PFT) findings of mild to severe COVID-19 survivors.*Methods and Materials This retrospective study was performed in two medical centers in Sao Paulo, Brazil. Data were collected from consecutive patients who underwent PFT and chest CT (within a maximum interval of 14 days) after recovery from COVID-19 between May and October 2021. Clinical data, spirometric parameters, diffusing capacity for carbon monoxide (DLCO), lung CT abnormalities, distribution and CT extent score were recorded. Clinical and tomographic differences between the patients with normal or abnormal PFTs were assessed by Chi-Square, Mann-Whitney or Fisher tests.*Results 101 COVID-19 survivors were included (mild disease 48, moderade 40, severe 13), at a median 95 days from initial symptom onset. 33% (33/101) had persistent symptoms. Reduction of DLCO% predicted was the most common abnormality in lung function (19% of the patients). Persistence of symptoms was not associated with abnormal lung function. The presence of reticular opacities (p=0.003), bronchial dilatation (p=0.005) and architectural distortion (p<0.001) in chest CT and a CT extent score > 5 (p=0.006) were significantly more prevalent in patients with impairment of DLCO.The optimal CT score for identifyng patients with reduced DLCO% predicted was 5.5 (area under curve = 0.7), with 78.9% sensitivity and 56.1% specificity.*Conclusions The presence of reticular opacities, bronchial dilatation and architectural distortion in chest CT and the extent of lung abnormalities was associated with lung function impairment in the postrecovery phase of mild to severe cases of COVID-19.*Clinical Relevance/Application The anatomical and functional pulmonary sequelae of SARS-CoV-2 infection are not yet fully understood. The evaluation of late chest CT findings associated with lung function impairment can help to estabilish the role of imaging in the postrecovery phase of COVID-19 patients.

RESULTS

101 COVID-19 survivors were included (mild disease 48, moderade 40, severe 13), at a median 95 days from initial symptom onset. 33% (33/101) had persistent symptoms. Reduction of DLCO% predicted was the most common abnormality in lung function (19% of the patients). Persistence of symptoms was not associated with abnormal lung function. The presence of reticular opacities (p=0.003), bronchial dilatation (p=0.005) and architectural distortion (p<0.001) in chest CT and a CT extent score > 5 (p=0.006) were significantly more prevalent in patients with impairment of DLCO.The optimal CT score for identifyng patients with reduced DLCO% predicted was 5.5 (area under curve = 0.7), with 78.9% sensitivity and 56.1% specificity.

The anatomical and functional pulmonary sequelae of SARS-CoV-2 infection are not yet fully understood. The evaluation of late chest CT findings associated with lung function impairment can help to establish the role of imaging in the postrecovery phase of COVID-19 patients.

SDP-CH-43 Integrated Application Of Noise Reduction And Emphysema Quantification Based On Deep Learning Training In Low-dose Chest CT For Lung Cancer Screening: A Feasibility Study

Participants
Suho Kim, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate integrated applicability of noise reduction and emphysema quantification based on deep learning training in low-dose chest CT for lung cancer screening.*Methods and Materials Using 281 lung cancer screening low-dose chest CT data, mean lung attenuation (MLA), total lung volume (TLV), RA950 (ml) and RA950 (%) were calculated by applying a newly developed, integrated denoising technique (ClariCT.AI, ClariPi) and emphysema quantification (ClariPulmo, ClariPi) trained with a deep learning model, which were compared with values obtained from a conventional emphysema quantification tool with anti-noise function, according to denoising settings (on or off) for AI-powered tool and anti-noise level (0 or 1) for conventional tool.*Results There was no statistically significant difference between MLA and TLV in both AI-powered and conventional tools regardless of denoising setting or anti-noise level. Between AI-powered, denoising off setting and conventional, anti-noise level 0, there was no statistically significant difference in RA950 (ml) and RA950(%). However, there was a statistically significant difference in RA950 (ml) and RA950(%) between AI-powered and conventional tools according to the denoising setting or anti-noise level. Between AI-powered, denoising on setting and conventional, anti-noise level 1, there was a statistically significant difference in RA950 (ml) and RA950(%).*Conclusions Even in the integrated application of the newly developed deep learning-based denoise and emphysema tools, MLA and TLV are considered reliable reference values. Although noise reduction is essential in the emphysema quantification of low-dose CT, there are still sensitive differences depending on the noise reduction method and level. In the future, it is expected that the integrated applicability of denosing and emphysema quantification will be better due to the algorithm improvement of deep learning models.*Clinical Relevance/Application Integrated application of deep learning-based noise reduction and emphysema quantification are expected to help early detection of chronic obstructive pulmonary disease by improving the accuracy of emphysema quantification through effective noise reduction of low-dose CT for lung cancer screening.

RESULTS

There was no statistically significant difference between MLA and TLV in both AI-powered and conventional tools regardless of denoising setting or anti-noise level. Between AI-powered, denoising off setting and conventional, anti-noise level 0, there was no statistically significant difference in RA950 (ml) and RA950(%). However, there was a statistically significant difference in RA950 (ml) and RA950(%) between AI-powered and conventional tools according to the denoising setting or anti-noise level. Between AI-powered, denoising on setting and conventional, anti-noise level 1, there was a statistically significant difference in RA950 (ml) and RA950(%).

CLINICAL RELEVANCE/APPLICATION

Integrated application of deep learning-based noise reduction and emphysema quantification are expected to help early detection of chronic obstructive pulmonary disease by improving the accuracy of emphysema quantification through effective noise reduction of low-dose CT for lung cancer screening.

SDP-CH-44 Clinical Potential For AI Enabled Dynamic Worklist Prioritization In Tele-radiology Settings

Participants
Xin Wang, PhD, Cambridge, Massachusetts (*Presenter*) Employee, Koninklijke Philips NV

PURPOSE

The aim is to use quantitative methodologies in the evaluation of clinical potential of using artificial intelligence to prioritize radiology exams with positive critical findings, so that radiology practices can appropriately apply AI technologies in their specific clinical settings.*Methods and Materials We used the discrete event simulation (DES) method to quantitatively evaluate how AI-enabled worklist prioritization can accelerate the Turnaround time (TAT) for pneumothorax (PTX) cases in chest radiograph (CXR), for both STAT and routine exams, and how much it affects the other CXR cases, in a realistic teleradiology setting. We simulated the CXR workflow of our collaborating teleradiology practice for 200 days, based on historic operational data, including discrete distributions of how often CXRs are received and how fast the reports are finalized, the prevalence of PTX cases, and order priority (STAT or routine). In total, about 60k STAT and 10k routine simulated events were generated. Detection of PTX was simulated based on the performance of our AI model, a DenseNet-based model trained on NIH ChestX-ray14 and MIMIC CXR with an AUC of 0.96. If a case was predicted to be PTX positive, it was moved to the top of the worklist.*Results We compared our simulation with AI prioritization to a simulation with the standard worklist processing "first-in, first-out" (FIFO). With the AI model, PTX was predicted and prioritized in about 5 STAT cases per day - the median TAT being reduced from 8.0 to 5.0 min (P < .0001), and in about 1 routine case per day - the median TAT being reduced from 51.0 to 5.0 min (P < .0001). For other STAT exams, the median TAT was still 8.0 min. Given findings of the study, the radiology practice can make informed decision on whether to apply AI on all CXR studies or only to routine CXR.*Conclusions Our study demonstrated a robust way to assess quality improvement of patient care with help of AI models, as well as associated operational impact. AI based worklist prioritization can significantly accelerate the TAT for pneumothorax cases in CXR, and its adverse impact on the TAT of other STAT exams should be evaluated before its adoption.*Clinical Relevance/Application AI-enabled techniques can look at hundreds of images in parallel, identify critical conditions, and prioritize these cases in the worklist to accelerate report turnaround time and patient care.

RESULTS

We compared our simulation with AI prioritization to a simulation with the standard worklist processing "first-in, first-out" (FIFO). With the AI model, PTX was predicted and prioritized in about 5 STAT cases per day - the median TAT being reduced from 8.0 to 5.0 min (P < .0001), and in about 1 routine case per day - the median TAT being reduced from 51.0 to 5.0 min (P < .0001). For other STAT exams, the median TAT was still 8.0 min. Given findings of the study, the radiology practice can make informed decision on whether to apply AI on all CXR studies or only to routine CXR.

CLINICAL RELEVANCE/APPLICATION

AI-enabled techniques can look at hundreds of images in parallel, identify critical conditions, and prioritize these cases in the worklist to accelerate report turnaround time and patient care.

SDP-CH-45 The CT Features Of Different Types Of The Pulmonary Lymphedema Caused By Congenital Lymphatic Refluxdisorders

Participants
Yan Zhang, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this study was to identify CT features of different types of the pulmonary lymphedema (PLE) caused by congenital lymphatic reflux disorders (CLRD).*Methods and Materials We collected 3440 patients with clinical and operative proven CLRD in the study, of which 580 cases presented with different types of pulmonary lymphedema on HRCT and MSCT lymphography. The imaging features of PLE were retrospectively reviewed by two chest radiologists who reached decisions by consensus.*Results PLE was seen in 580 (17%) of 3440 patients with CLRD, which consisted of various imaging manifestations of pulmonary interstitial thickening caused by pulmonary lymphatic disorders. According to the imaging patterns and distribution, it is divided into five types: (1) diffuse inhomogeneous ground-glass opacity (GGO) dominated by peripheral distribution (265/580, 46%); (2) diffuse patchy or butterfly's winged GGO or irregular consolidation dominated by intrapleural or central distribution (45/580, 8%); (3) diffuse reticular and linear patterns with extensive distribution (114/580, 20%); (4) diffuse frogspawn sign, which consisted of diffuse inhomogeneous GGO with superimposed multiple discontinuous small nodules (86/580, 15%); (5) diffuse crazy-paving appearance, which consisted of diffuse GGO with superimposed interlobular and intralobular interstitial thickening (71/580, 12%). The other accompanying findings includes stenosis or obstruction of thoracic duct (542/580, 94%) and right lymphatic duct (155/580, 27%),chylothorax (188/580, 32%), chylopericardium (45/580, 8%) and mediastinal thickening or lymphedema (322/580, 56%).*Conclusions Our data suggest that PLE is mostly a part of the systemic lymphedema, indecating the dilatation of the lymphatic vessels and lymphatic reflux in pulmonary interstitium. The different types of PLE are related to the degree and location of lymphedema and chylous fistula, also to the degree of lymphedema and the clinical stage.*Clinical Relevance/Application PLE is the main pathological change of pulmonary lymphatic dysplasia, which has various imaging morphological features that has not been reported in the literature by our knowledge.It is most important for clinical diagnosis and differential diagnosis and selection of reasonable treatment with understand with these imaging types and pathogenesis.

RESULTS

PLE was seen in 580 (17%) of 3440 patients with CLRD, which consisted of various imaging manifestations of pulmonary interstitial thickening caused by pulmonary lymphatic disorders. According to the imaging patterns and distribution, it is divided into five types: (1) diffuse inhomogeneous ground-glass opacity (GGO) dominated by peripheral distribution (265/580, 46%); (2) diffuse patchy or butterfly's winged GGO or irregular consolidation dominated by intrapleural or central distribution (45/580, 8%); (3) diffuse reticular and linear patterns with extensive distribution (114/580, 20%); (4) diffuse frogspawn sign, which consisted of diffuse inhomogeneous GGO with superimposed multiple discontinuous small nodules (86/580, 15%); (5) diffuse crazy-paving appearance, which consisted of diffuse GGO with superimposed interlobular and intralobular interstitial thickening (71/580, 12%). The other accompanying findings includes stenosis or obstruction of thoracic duct (542/580, 94%) and right lymphatic duct (155/580, 27%),chylothorax (188/580, 32%), chylopericardium (45/580, 8%) and mediastinal thickening or lymphedema (322/580, 56%).

CLINICAL RELEVANCE/APPLICATION

PLE is the main pathological change of pulmonary lymphatic dysplasia, which has various imaging morphological features that has not been reported in the literature by our knowledge.It is most important for clinical diagnosis and differential diagnosis and selection of reasonable treatment with understand with these imaging types and pathogenesis.

SDP-CH-46 Performance Of A Commercial Software Package For Lung Nodule Detection On Chest Radiographs Compared With 8 Expert Readers

Participants
Kicky van Leeuwen, MSc, Nijmegen, Netherlands (*Presenter*) Technical Expert, Scarlet NB

PURPOSE

Multi-center evaluation of the stand-alone performance of commercially available lung nodule detection software (Lunit INSIGHT CXR3).*Methods and Materials A set of 300 posteroanterior (PA) and lateral chest radiographs from four medical centers in the Netherlands was collected. Solitary lung nodules ranging from 5 to 35 mm in size were present in 111 of the cases. All nodules were confirmed by CT within three months of the radiograph acquisition. Control radiographs were determined based on a negative CT within six months. Five radiologists and three radiology residents scored the set to provide context to the algorithm performance. All PA radiographs were processed by Lunit INSIGHT CXR3, a commercial software product that detects ten common abnormalities in chest radiographs. Area under the receiver operating characteristics curve (AUC) and sensitivity at 90% specificity were used to measure performance. Multi-reader multi-case ROC analysis based on U-statistics (iMRMC-v4 software) was applied to compare CXR3 with the readers. Subanalysis was performed regarding nodule size (small<15mm, large>15mm) and conspicuity levels (well visible, moderately visible, subtle, very subtle).*Results Out of the 300 radiographs, 7 could not be processed by CXR3, resulting in a set of 104 nodule cases and 189 normal cases for evaluation. The CXR3 AUC was 0.93 and significantly higher than the mean reader AUC of 0.82 (p<0.001). CXR3 was also significantly better than the best reader with an AUC of 0.88 (p=0.028). At a specificity level of 90%, sensitivity was 83.2% for CXR3 and 63.3% (std±7.5%) for the reader average. Regarding conspicuity of the nodules, CXR3 AUCs were 0.99 for well visible, 0.94 for moderately visible, 0.94 for subtle, and 0.78 for very subtle nodules. No significant difference in CXR3 performance was observed between the detection of small (AUC 0.91) and large nodules (AUC 0.93).*Conclusions Lunit INSIGHT CXR3 significantly outperforms the comparison group of eight readers in nodule detection on chest radiographs.*Clinical Relevance/Application Generalizability of artificial intelligence algorithms is not trivial. Performance studies increase confidence in algorithms to the users, especially to those with similar patient populations.

RESULTS

Out of the 300 radiographs, 7 could not be processed by CXR3, resulting in a set of 104 nodule cases and 189 normal cases for evaluation. The CXR3 AUC was 0.93 and significantly higher than the mean reader AUC of 0.82 (p<0.001). CXR3 was also significantly better than the best reader with an AUC of 0.88 (p=0.028). At a specificity level of 90%, sensitivity was 83.2% for CXR3 and 63.3% (std±7.5%) for the reader average. Regarding conspicuity of the nodules, CXR3 AUCs were 0.99 for well visible, 0.94 for moderately visible, 0.94 for subtle, and 0.78 for very subtle nodules. No significant difference in CXR3 performance was observed between the detection of small (AUC 0.91) and large nodules (AUC 0.93).

SDP-CH-47   Utilizing A Generative Adversarial Network To Produce Realistic Novel Chest Radiographs

Participants
Christian Park, DO, Hershey, Pennsylvania (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the possibility of utilizing generative adversarial networks to synthesize chest radiographs that are functionally equivalent to real chest radiographs.*Methods and Materials The source dataset (CheXpert) included 224,316 chest x-rays of 65,240 patients. These included PA, AP and lateral projections as well as pathologies such as effusion, pneumonia and pneumothorax. 191,027 frontal (PA, AP) projection images were selected for the final dataset. The images were resized to 3x64x64 and input into an open source Generative Adversarial Network with a Pytorch machine learning framework. After training the discriminator and generator, the two competing neural networks, loss metrics for both networks, D(x) and D(G(z)) were recorded. Additionally, three radiology residents and one attending radiologist were provided a sample of both ground truth and synthesized images for scoring via five point Likert Scale (1=Completely Fake, 5 = Completely Real).*Results After five epochs, our GAN model achieved a Loss D: 0.4465, Loss G: 2.7268, D(x): 0.8291 (Discriminator was able to discern images were fake 83% of the time), and D(G(z)): 0.1878 / 0.0885. There was no significant difference in Likert scale scores between the real and generated images (t-test, p=0.35).*Conclusions These findings show that a GAN model is able to synthesize chest radiographs that are realistic enough to be found comparable to real radiographs. More investigation is required to improve generative performance (increasing resolution and reducing error) as well as developing tools for better detection of generated images.*Clinical Relevance/Application The potential applications include generation of an imaging database that can be used for educational purposes, particularly of rare pathologies such as hemangiopericytoma and pheochromocytoma in the abdomen.Utilization of "predictive" generation of stents and other procedures for pre-surgical/pre-procedural planningIt can also raise awareness about its potential for more nefarious use, such as removal or replacement of pathology within existing medical imaging datasets.Technologies such blockchain and non-fungible tokens could be utilized to ensure that study original and not altered. Additionally, non-fungible tokens may open up the possible for patients to have ownership of their health data, which is currently of great ethical debate.

RESULTS

After five epochs, our GAN model achieved a Loss D: 0.4465, Loss G: 2.7268, D(x): 0.8291 (Discriminator was able to discern images were fake 83% of the time), and D(G(z)): 0.1878 / 0.0885. There was no significant difference in Likert scale scores between the real and generated images (t-test, p=0.35).

CLINICAL RELEVANCE/APPLICATION

The potential applications include generation of an imaging database that can be used for educational purposes, particularly of rare pathologies such as hemangiopericytoma and pheochromocytoma in the abdomen.Utilization of "predictive" generation of stents and other procedures for pre-surgical/pre-procedural planningIt can also raise awareness about its potential for more nefarious use, such as removal or replacement of pathology within existing medical imaging datasets.Technologies such blockchain and non-fungible tokens could be utilized to ensure that study original and not altered. Additionally, non-fungible tokens may open up the possible for patients to have ownership of their health data, which is currently of great ethical debate.

SDP-CH-48   AI-based Severity Scoring Of Admission Chest CT Is Not Predictive For In-hospital Mortality In COVID-19 ICU Patients

Participants
Eva Gresser, BSC, Munich, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Severe COVID-19 disease is associated with a high in-hospital mortality due to respiratory failure and multi-organ dysfunction. We tested the diagnostic value of quantitative imaging features on admission chest CTs by using an artificial intelligence (AI)-based algorithm for mortality prediction and compared the performance to clinical scoring on ICU admission.*Methods and Materials 83 confirmed COVID-19 patients admitted to the participating ICUs were included for this single center retrospective study. Chest CT scans as well as the sequential organ failure assessment (SOFA) score on ICU admission were evaluated for the discriminative potential to predict in-hospital mortality. A CE-certified AI-based algorithm (CAD4COVID, Thirona) was used for chest CT assessment. Statistical analyses include multivariate regression analysis and receiver operating characteristic (ROC) curves.*Results In multivariate binary logistic regression, the CT severity score was not significantly associated with in-hospital mortality (odds ratio (OR) 1.02, 95%-CI 0.90-1.15, p=0.791), whereas the SOFA score showed a significant association (OR 1.48, 95%-CI 1.19-1.84). In ROC analysis SOFA score on admission resulted in an area under the curve (AUC) for in-hospital mortality of 0.79 (95%-CI 0.69-0.90), whereas CT severity score did not yield a sufficient AUC (0.55, 95%-CI 0.40-0.70). These results were consistent for the more critically ill subgroup of patients with moderate and severe ARDS (oxygenation index below 200, n=50) with an AUC for SOFA score of 0.78 (95%-CI 0.65-0.91) compared to an AUC for the CT severity score of 0.60 (95%-CI 0.43-0.78).*Conclusions Advanced COVID-19 disease is not restricted to lung damage but leads to a multi-organ involvement. Therefore, AI-based quantitative assessment of COVID-19 lung disease on chest CT on ICU admission is not sufficient in predicting in-hospital mortality, even for patients with moderate to severe ARDS.*Clinical Relevance/Application Risk stratification for severe COVID-19 ICU patients should not solely be based on lung involvement on chest CT but needs to include multi-organ failure assessment.

RESULTS

In multivariate binary logistic regression, the CT severity score was not significantly associated with in-hospital mortality (odds ratio (OR) 1.02, 95%-CI 0.90-1.15, p=0.791), whereas the SOFA score showed a significant association (OR 1.48, 95%-CI 1.19-1.84). In ROC analysis SOFA score on admission resulted in an area under the curve (AUC) for in-hospital mortality of 0.79 (95%-CI 0.69-0.90), whereas CT severity score did not yield a sufficient AUC (0.55, 95%-CI 0.40-0.70). These results were consistent for the more critically ill subgroup of patients with moderate and severe ARDS (oxygenation index below 200, n=50) with an AUC for SOFA score of 0.78 (95%-CI 0.65-0.91) compared to an AUC for the CT severity score of 0.60 (95%-CI 0.43-0.78).

CLINICAL RELEVANCE/APPLICATION

Risk stratification for severe COVID-19 ICU patients should not solely be based on lung involvement on chest CT but needs to

include multi-organ failure assessment.

SDP-CH-5   Quantitative CT Indexes At Discharge To Predict Pulmonary Diffusion Function 5 Months After COVID-19

Participants
Leqing Chen, Wuhan, China (*Presenter*) Nothing to Disclose

PURPOSE

To explore the predictive value of total lung and lobar quantitative CT indexes at discharge on the pulmonary diffusion function of coronavirus disease 2019 (COVID-19) patients at 5 months after symptoms onset.*Methods and Materials A total of 90 patients with moderate and severe COVID-19 were prospectively enrolled (35 male, 55 female, median age, 57 [49.75, 64.25] years), all of whom underwent CT scans at discharge, and quantitative analysis of the total lung and lobes were performed. Pulmonary function tests (PFTs) were performed at 5 months after symptoms onset (median duration, 146 [140, 164] days). The differences of quantitative CT and PFTs results between Group1 (abnormal diffusion function group) and Group2 (normal diffusion function group) were compared by Chi-square test, Fisher's exact test or Mann-Whitney U test. Univariate analysis, stepwise linear regression and logistic regression were used to determine the predictors of DLCO% of predicted and whether there was diffusion dysfunction, respectively.*Results A total of 58.9% (53/90) of moderate and severe patients presented pulmonary dysfunction at 5 months after symptoms onset, of whom 34 patients had diffusion dysfunction in Group1 (DLCO% of predicted, 74.55% [65.73%, 75.73%]), the remaining 56 patients in Group2 (DLCO% of predicted, 91.45% [85.28%, 98.95%]). The mean lung density (MLD) of the total lung in Group1 was higher than that in Group2 (P=0.023), and the percentage of well-aerated lung tissue volume (WAL%) of Group1 was lower than that of Group2 (P=0.019), but there were no differences in residual lesions (ground-glass opacity, consolidation) between the two groups evaluated from total lung level. Multiple stepwise linear regression only screened out WAL (Coefficient: 0.004; 95% CI: 0.001-0.007; P=0.002) from the total lung indexes and WAL% of left upper lobe (LUL) from the lobar indexes (Coefficient: 0.459; 95% CI: 0.152-0.766; P=0.004) that positively correlated with DLCO% of predicted. Multivariable analysis identified MLD (OR: 1.011; 95% CI: 1.001-1.02; P=0.035) and MLD of LUL (OR: 1.016; 95% CI: 1.004-1.027; P=0.008) as independent predictors for COVID-19 patients with diffusion dysfunction in the convalescence from the total lung and lobar CT indexes, respectively.*Conclusions At 5 months after symptoms onset, more than one-third of moderate and severe COVID-19 patients presented with diffusion dysfunction. The well-aerated lung and mean lung density quantified by CT at discharge could be predictors of diffusion function in convalesce.*Clinical Relevance/Application Providing suggestions for optimized management plans for COVID-19 patients in convalescent.

RESULTS

A total of 58.9% (53/90) of moderate and severe patients presented pulmonary dysfunction at 5 months after symptoms onset, of whom 34 patients had diffusion dysfunction in Group1 (DLCO% of predicted, 74.55% [65.73%, 75.73%]), the remaining 56 patients in Group2 (DLCO% of predicted, 91.45% [85.28%, 98.95%]). The mean lung density (MLD) of the total lung in Group1 was higher than that in Group2 (P=0.023), and the percentage of well-aerated lung tissue volume (WAL%) of Group1 was lower than that of Group2 (P=0.019), but there were no differences in residual lesions (ground-glass opacity, consolidation) between the two groups evaluated from total lung level. Multiple stepwise linear regression only screened out WAL (Coefficient: 0.004; 95% CI: 0.001-0.007; P=0.002) from the total lung indexes and WAL% of left upper lobe (LUL) from the lobar indexes (Coefficient: 0.459; 95% CI: 0.152-0.766; P=0.004) that positively correlated with DLCO% of predicted. Multivariable analysis identified MLD (OR: 1.011; 95% CI: 1.001-1.02; P=0.035) and MLD of LUL (OR: 1.016; 95% CI: 1.004-1.027; P=0.008) as independent predictors for COVID-19 patients with diffusion dysfunction in the convalescence from the total lung and lobar CT indexes, respectively.

CLINICAL RELEVANCE/APPLICATION

Providing suggestions for optimized management plans for COVID-19 patients in convalescent.

SDP-CH-6   Prospective Evaluation Of The Performance Of Deep Learning Image Reconstruction On Low-dose And Ultralow-dose Chest CT.

Participants
Seung-Jin Yoo, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To compare the image quality of low-dose and ultralow-dose chest CT scans reconstructed with deep learning image reconstruction (DLIR).*Methods and Materials This prospective study was approved by IRB, and informed consent was obtained from all the participants. From February to July 2020, 40 patients (mean age, 66±12; female 53%) underwent low-dose (CTDIvol, 0.96±0.15mGy) and ultralow-dose chest CT (CTDIvol, 0.12±0.01mGy) in a single CT vendor (Revolution CT, GE healthcare) and reconstructed with filtered back projection (FBP), adaptive statistical iterative reconstruction-V 50% (ASIR-V 50) and 100% (ASIR-V 100), and DLIR-high level (DLIR-H) technique. Objective image quality was calculated by the signal-to-noise ratio (SNR) in the whole lung area and pulmonary vessels using deep-learning-based chest CT segmentation tool (MEDIP, Medical IP). Two thoracic radiologists, blinded to the radiation dose and reconstruction algorithm, reviewed 20 patients' 160 CT and graded image noise, visibility of small structures, lesion conspicuity, overall image quality. Nodule detection sensitivity was evaluated with an automated lung nodule detection tool (VCAR, GE healthcare) in 28 patients' 43 pulmonary nodules larger than 4mm. Two thoracic radiologists reviewed 80 CT composed of 40 low-dose and 40 ultralow-dose CT with DLIR-H and detected nodules of Lung-RADS 1.1 category 3 or higher.*Results SNR was significantly higher in DLIR-H compared to ASIR-V 50 in low-dose chest CT (lung, -5.82±0.67 vs. -5.71±0.64, p<.001; vessel, -0.56±0.07 vs. -0.55±0.07, p<.001). SNR of lung was significantly higher in DLIR-H compared to ASIR-V 50 in ultralow-dose CT (-5.78±0.60 vs. -5.72±0.63, p<.001). DLIR-H yielded the best scores in small structures visibility, lesion conspicuity, overall image quality among the low-dose chest CT and ultralow-dose chest CT, respectively. Comparing the low-dose and ultralow-dose CT with DLIR-H, low-dose CT showed significantly better scores in every assessment category (all P<.001). Nodule detection sensitivity of VCAR was 70-74% for low-dose and 63-67% for ultralow-dose CT. Nodule detection sensitivity of observers in low-dose and ultralow-dose CT with DLIR-H was 75.6-88.2% and 64.7-82.4%, respectively.*Conclusions DLIR, compared to other conventional reconstruction techniques, showed better image quality in objective and subjective analyses in both low-dose and ultralow-dose chest CT. Comparing the low-dose and ultra-low dose CT with DLIR, low-dose CT yield a better image quality, however the CTDIvol was 8 times higher than that of ultralow-dose CT.*Clinical Relevance/Application Ultralow-dose CT with DLIR might have the potential of reducing radiation dose in certain patients who need frequent follow-up chest CT.

RESULTS

SNR was significantly higher in DLIR-H compared to ASIR-V 50 in low-dose chest CT (lung, -5.82±0.67 vs. -5.71±0.64, p<.001;

vessel, -0.56±0.07 vs. -0.55±0.07, p<.001). SNR of lung was significantly higher in DLIR-H compared to ASIR-V 50 in ultralow-dose CT (-5.78±0.60 vs. -5.72±0.63, p<.001). DLIR-H yielded the best scores in small structures visibility, lesion conspicuity, overall image quality among the low-dose chest CT and ultralow-dose chest CT, respectively. Comparing the low-dose and ultralow-dose CT with DLIR-H, low-dose CT showed significantly better scores in every assessment category (all P<.001). Nodule detection sensitivity of VCAR was 70-74% for low-dose and 63-67% for ultralow-dose CT. Nodule detection sensitivity of observers in low-dose and ultralow-dose CT with DLIR-H was 75.6-88.2% and 64.7-82.4%, respectively.

CLINICAL RELEVANCE/APPLICATION

Ultralow-dose CT with DLIR might have the potential of reducing radiation dose in certain patients who need frequent follow-up chest CT.

SDP-CH-7 Radiomic-based Prediction Of Hyperprogressive Disease To Immune Checkpoint Inhibitor: Special Considerations In Lesion-level Approach And Organ-specific Microenvironment.

Participants
Chorog Song, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Hyperprogressive disease (HPD) is a recognized pattern of tumor progression following immune checkpoint inhibitor (ICI) treatment. However, a biomarker to determine whether HPD will occur prior to treatment has not yet been established. The aim of this study is to evaluate radiomic features of HPD particularly in lesion-level and investigate its predictive potential.*Methods and Materials 196 advanced NSCLC patients treated with ICI monotherapy and underwent at least three CT scans from the pre-baseline, baseline, through the first follow-up were retrospectively enrolled, where a total of 621 lesions were determined for HPD using the TGK ratio. A multivariable logistic regression analysis of radiomics features from the baseline CT and clinicopathologic characteristics was used to develop a prediction model for HPD.*Results In a total of 621 lesions, there were 147 HPD lesions (23.7%) and 349 non-HPD lesions (56.2%). For each organ, 234 (47.2%) in lung, 65 (13.1%) in bone, 114 (23.0%) in LN, and 47 (9.5%) in livers. In addition, the number of HPD lesions was 80 (34.2%) in lung, with 15 (23.1%) in bone, 24 (21.1%) in LN and 21 (9.5%) in liver. There was no significant difference in clinicopathologic variables between HPD and non HPD lesions. The predictive model for HPD showed a discrimination performance of an area under the receiver operating characteristic curve (AUC) of 0.65 (p value< 0.002) with logUniformity_HIST1000 (p=0.001, OR=0.29) and log_Volume (p=0.002, OR=0.71) in the lung, AUC of 0.70 with LogUniformity_HIST1000 (p=0.017, OR=4.49) in bone, AUC of 0.60 with log_RMS (p=0.025, OR=3.88) in LN as well as AUC of 0.72 with cube_PH2_5 (p=0.006, OR=0.74) in liver.*Conclusions Our study shows different radiomic features per organ are concerned for HPD prediction, which would be observations reflecting the inter-tumor heterogeneity and organ-specific microenvironment.*Clinical Relevance/Application Our study shows that analysis using radiomic features has great potential for predicting HPD and understanding heterogenous tumor progression after ICI treatment.

RESULTS

In a total of 621 lesions, there were 147 HPD lesions (23.7%) and 349 non-HPD lesions (56.2%). For each organ, 234 (47.2%) in lung, 65 (13.1%) in bone, 114 (23.0%) in LN, and 47 (9.5%) in livers. In addition, the number of HPD lesions was 80 (34.2%) in lung, with 15 (23.1%) in bone, 24 (21.1%) in LN and 21 (9.5%) in liver. There was no significant difference in clinicopathologic variables between HPD and non HPD lesions. The predictive model for HPD showed a discrimination performance of an area under the receiver operating characteristic curve (AUC) of 0.65 (p value< 0.002) with logUniformity_HIST1000 (p=0.001, OR=0.29) and log_Volume (p=0.002, OR=0.71) in the lung, AUC of 0.70 with LogUniformity_HIST1000 (p=0.017, OR=4.49) in bone, AUC of 0.60 with log_RMS (p=0.025, OR=3.88) in LN as well as AUC of 0.72 with cube_PH2_5 (p=0.006, OR=0.74) in liver.

CLINICAL RELEVANCE/APPLICATION

Our study shows that analysis using radiomic features has great potential for predicting HPD and understanding heterogenous tumor progression after ICI treatment.

SDP-CH-8 A Wake-up Call For Non-predominant Pattern Within Invasive Lung Adenocarcinoma: Prognostic Dissection Focusing On A High-grade Pattern

Participants
Yeonu Choi, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Because most lung adenocarcinomas (ADCs) are mixed histologic patterns and the spectrum of actual prognosis varies widely among lung ADCs with the same most predominant pattern, prognostic considerations for non-predominant patterns are necessary. We aimed to identify prognostic stratification by second most predominant pattern of lung ADC. And to more accurately assess prognostic factor with CT imaging analysis, particularly enhancing non-predominant but high-grade pattern.*Methods and Materials In this prospective study, patients with early-stage lung ADC undergoing curative surgery underwent preoperative dual-energy CT (DECT) and positron emission tomography (PET)/CT. Histopathology of ADC, the most predominant and second most predominant histologic patterns, and preoperative imaging parameters were assessed and correlated with patient survival.*Results Among the 290 lung ADCs included in the study, 231 (79.7%) were mixed-pathologic pattern. When the most predominant histologic pattern was intermediate-grade, survival curves were significantly different among the three second most predominant subgroups (p=0.004; low, lepidic; intermediate, acinar and papillary; high, micropapillary and solid). When the second most predominant pattern was high-grade, recurrence risk increased by 4.2-fold compared with the low-grade group (p=0.005). To predict a non-predominant but high-grade pattern, the non-contrast CT value of tumor was meaningful with a lower HU value associated with the histologic combination of lower grade (low-grade as most predominant and intermediate-grade as second most predominant pattern, OR=6.15, p=0.005; intermediate-grade as most predominant and high-grade as second most predominant pattern, OR=0.10, p=0.033). SUVmax of the tumor was associated with the non-predominant but high-grade pattern, especially in the histologic combination of intermediate-high grade (OR=1.14, p=0.012).*Conclusions The second most predominant histologic pattern can stratify lung ADC patients according to prognosis. Also, imaging parameters of non-contrast CT value and SUVmax could be useful in predicting a non-predominant but high-grade histologic pattern.*Clinical Relevance/Application Predicting the malignant potential and establishing treatment policies should not rely only on the most predominant pattern. Non-contrast CT value and SUVmax may provide practical help in planning patient treatment in clinical practice.

RESULTS

Among the 290 lung ADCs included in the study, 231 (79.7%) were mixed-pathologic pattern. When the most predominant histologic

pattern was intermediate-grade, survival curves were significantly different among the three second most predominant subgroups (p=0.004; low, lepidic; intermediate, acinar and papillary; high, micropapillary and solid). When the second most predominant pattern was high-grade, recurrence risk increased by 4.2-fold compared with the low-grade group (p=0.005). To predict a non-predominant but high-grade pattern, the non-contrast CT value of tumor was meaningful with a lower HU value associated with the histologic combination of lower grade (low-grade as most predominant and intermediate-grade as second most predominant pattern, OR=6.15, p=0.005; intermediate-grade as most predominant and high-grade as second most predominant pattern, OR=0.10, p=0.033). SUVmax of the tumor was associated with the non-predominant but high-grade pattern, especially in the histologic combination of intermediate-high grade (OR=1.14, p=0.012).

CLINICAL RELEVANCE/APPLICATION

Predicting the malignant potential and establishing treatment policies should not rely only on the most predominant pattern. Non-contrast CT value and SUVmax may provide practical help in planning patient treatment in clinical practice.

SDP-CH-9   Primary Cystic And Cavitary Lung Cancer: Characteristic Features On CT And FDG-PET

Participants
Makiko Murota, MD, Kitagun, Japan (*Presenter*) Nothing to Disclose

PURPOSE

The aim of the present study was to investigate the CT and FDG-PET feature of primary cystic and cavitary lung cancer (CCLC).*Methods and Materials We examined 869 patients who underwent pulmonary resection for primary lung cancer from March 2013 through September 2019 and searched for the presence of cystic and cavitary lesion on CT. The study included 102 consecutive patients (79 men, 23 women; mean age, 69.7 years old) presenting as the CCLC on CT. We evaluated the diameters of tumor and airspace, the morphologic patterns of the cystic and cavitary lesion which were classified as into 4 types: type 1) nodule extruding from the wall of the cavitary lesion; type 2) nodule within the cavitary lesion; type 3) thickening of the wall and/or soft tissue density around the cavitary lesion; and type 4) soft tissue density intermixed within clusters of the cavitary lesion, the presence of ground-glass opacity (GGO), and the loculation pattern including the presence of septum.*Results Because each of the two patients had two lesions, a total of 104 lesions with CCLC were included. Histological analysis showed adenocarcinoma (AD) (n=85) and squamous cell carcinoma (SCC) (n=19). Average tumor and airspace size of CCLC was 3.1cm and 1.9cm, respectively. The morphologic patterns of the CCLC were seen type 1 in 29, type 2 in 1, type 3 in 36, and type 4 in 38 lesions, respectively. The presence of GGO were observed 60 lesions in AD. Regarding the loculation pattern, unilocular, multilocular, unilocular and septum, and multilocular and septum were seen in 10, in 7, in 28, and in 59 lesions, respectively. Type 4 and multilocular and septum pattern were significantly more common in ADs than in SCCs (P=0.002 and P=0.002, respectively). SUVmax of ADs on PET was significantly lower than SCCs (P=0.001), whereas it was different among solid lesions. Among solid lesions, only multilocular and septum pattern was significantly more common in ADs (P=0.028).*Conclusions The CT feature of CCLC was most common in AD, especially with GGO and with multilocular and septum. The presence of multilocular and septum was found to be similarly common among solid lesions. The uptake of FDG in lesions in AD was significantly lower than in SCC, although there was no significant difference among solid lesions.*Clinical Relevance/Application CCLC in AD often shows multilocular and septum in the airspace on CT, even if the lesion is solid. It may be helpful in differentiating histological findings.

RESULTS

Because each of the two patients had two lesions, a total of 104 lesions with CCLC were included. Histological analysis showed adenocarcinoma (AD) (n=85) and squamous cell carcinoma (SCC) (n=19). Average tumor and airspace size of CCLC was 3.1cm and 1.9cm, respectively. The morphologic patterns of the CCLC were seen type 1 in 29, type 2 in 1, type 3 in 36, and type 4 in 38 lesions, respectively. The presence of GGO were observed 60 lesions in AD. Regarding the loculation pattern, unilocular, multilocular, unilocular and septum, and multilocular and septum were seen in 10, in 7, in 28, and in 59 lesions, respectively. Type 4 and multilocular and septum pattern were significantly more common in ADs than in SCCs (P=0.002 and P=0.002, respectively). SUVmax of ADs on PET was significantly lower than SCCs (P=0.001), whereas it was different among solid lesions. Among solid lesions, only multilocular and septum pattern was significantly more common in ADs (P=0.028).

CLINICAL RELEVANCE/APPLICATION

CCLC in AD often shows multilocular and septum in the airspace on CT, even if the lesion is solid. It may be helpful in differentiating histological findings.

PH02-A10   Single-source Twin Beam Dual-energy CT: Radiation Dose And Image Quality

Participants
Srirajkumar Ranganathan, BS, Chicago, Illinois (*Presenter*) Nothing to Disclose

PURPOSE

To assess the radiation dose and image quality of abdominopelvic CT when using single-source twin beam dual-energy CT (tbDECT) scanner. This technique is the newest FDA-approved DECT technique which requires low pitch acquisition.*Methods and Materials In this IRB-approved retrospective study, imaging studies of adult patients who had abdominopelvic CT using tbDECT (SOMATOM X.Cite, Siemens) between October 2020 and February 2021 were investigated. Patients who had conventional CT examination (SOMATOM Drive, Force, Definition, Siemens) of the same region of body, using similar phase of contrast, within 6 months of tbDECT examination were selected for final analysis. Patient demographics, anthropomorphic parameters (weight, BMI, abdominal girth), CT dose descriptors (CTDIvol and dose-length product [DLP]), subjective image quality, and objective noise level (defined as standard deviation of the density in subcutaneous abdominal fat) were recorded. Dose metrics and noise levels were compared using paired t-test. Bland-Altman graphs were used to plot the intra-patient dose difference against the body size parameters. A p-value of <0.05 was set as a statistically significant difference.*Results 108 patients were included in the final analysis (53 female; mean age 57.8 ±15.6 years; mean BMI 27.9 ±8 kg/m²; mean abdominal girth 37.4±7.5 cm). Mean CTDIvol for tbDECT and conventional CTs were 10.29 ±7.26 mGy and 15.82±9.5 mGy, respectively, which were significantly different (p<0.001). All studies had acceptable subjective image quality, which was not different between the 2 groups. The objective noise level was higher for tbDECT with a mean difference of 1.2 HU (p<0.005). The intra-patient dose difference was not affected by weight, BMI, and abdominal girth (r=0.3, p<0.001).*Conclusions tbDECT offered diagnostic image quality and had lower radiation exposure compared to conventional CT across all different body sizes.*Clinical Relevance/Application Despite the low pitch acquisition, tbDECT has acceptable radiation exposure and can be safely used in all adult patients.

RESULTS

108 patients were included in the final analysis (53 female; mean age 57.8 ±15.6 years; mean BMI 27.9 ±8 kg/m²; mean abdominal girth 37.4±7.5 cm). Mean CTDIvol for tbDECT and conventional CTs were 10.29 ±7.26 mGy and 15.82±9.5 mGy, respectively, which were significantly different (p<0.001). All studies had acceptable subjective image quality, which was not different between the 2 groups. The objective noise level was higher for tbDECT with a mean difference of 1.2 HU (p<0.005). The intra-patient dose difference was not affected by weight, BMI, and abdominal girth (r=0.3, p<0.001).

CLINICAL RELEVANCE/APPLICATION

Despite the low pitch acquisition, tbDECT has acceptable radiation exposure and can be safely used in all adult patients.

PH02-A11   Preliminary Study Of CT Image Reconstruction From Limited-angular-range Data With Two-orthogonal-arc Configurations

Participants
Zheng Zhang, PhD, Chicago, Illinois (*Presenter*) Nothing to Disclose

PURPOSE

We in this work investigate computed tomography (CT) image reconstruction from data collected over two non-overlapping, orthogonal arcs of limited-angular-ranges (LARs), and demonstrate it may lead to more accurate reconstruction than a single arc of the same total angular range.*Methods and Materials We design a class of two non-overlapping, orthogonal arcs of LARs a1 and a2, which are separated by 90o between the centers of the two arcs. We generate simulation data from a numerical chest phantom using such two-orthogonal-arc configurations, with total angular ranges at= a1+a2=18o, 24o, 36o, 60o, 90o, 120o, 150o, and 180o. For given at, multiple configurations with different a1 and a2 can be formed, specified by a2/at=0, 1/6, 1/3, 1/2, 2/3, 5/6, and 1. We then carry out image reconstruction by using a directional-total-variation (DTV) algorithm, which is based on a primal-dual framework solving an optimization problem with a data-L2-minimization term and image DTV constraints. For comparison, we also reconstruct images from data collected over a single arc covering the same total angular range of a two-orthogonal-arc configuration.*Results We evaluate reconstruction performance by using visual inspection and quantitative analysis such as normalized root mean square error (nRMSE), Pearson correlation coefficient (PCC), and normalized mutual information (nMI). Results show that a two-orthogonal-arc configuration generally yields improved reconstruction accuracy than its single-arc counterpart, especially for at less than 90o. In particular, we notice that the reconstruction accuracy enhances as the total angular range at increases, as expected. Moreover, with fixed at, the two-orthogonal-arc configuration with a1=a2 leads to more accurate image reconstruction than those with a1?a2.*Conclusions Appropriately designed two-orthogonal-arc configurations can improve image-reconstruction accuracy in CT imaging, especially with a significantly reduced total angular coverage.*Clinical Relevance/Application This work may provide insights to design innovative configurations with LARs for CT imaging to yield reduced radiation dose and imaging time, and/or for non-diagnostic CT, such as C-arm CT, to avoid collision during scan.

RESULTS

We evaluate reconstruction performance by using visual inspection and quantitative analysis such as normalized root mean square error (nRMSE), Pearson correlation coefficient (PCC), and normalized mutual information (nMI). Results show that a two-orthogonal-arc configuration generally yields improved reconstruction accuracy than its single-arc counterpart, especially for at less than 90o. In particular, we notice that the reconstruction accuracy enhances as the total angular range at increases, as expected. Moreover, with fixed at, the two-orthogonal-arc configuration with a1=a2 leads to more accurate image reconstruction than those with a1?a2.

CLINICAL RELEVANCE/APPLICATION

This work may provide insights to design innovative configurations with LARs for CT imaging to yield reduced radiation dose and imaging time, and/or for non-diagnostic CT, such as C-arm CT, to avoid collision during scan.

PH02-A3   The Effect Of Automated Tube Voltage Selection And Organ-based Tube Current Modulation Systems On Organ Equivalent Dose And Image Quality In Thorax CT

Participants
Antonios Papadakis, MSc, PhD, Heraklion, Greece (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this study was to investigate the combined effect of automated tube voltage selection (ATVS) and organ-based tube current modulation (OTCM) systems on equivalent dose of primarily exposed radiosensitive organs and image quality in routine pediatric and adult thorax CT.*Methods and Materials Five physical anthropomorphic phantoms that simulate the average individual as a neonate, 1-, 5-, 10-years-old child and female adult were employed. Phantoms were scanned on a Revolution HD GE CT scanner with the ATVS+OTCM systems enabled. ATVS was operated in the non contrast soft tissue clinical diagnostic task. OTCM was activated within the region depicting breast. Whole body axial image series of the phantoms were used to generate age-specific voxelized phantoms, which were input to a Monte Carlo based simulation tool to generate three-dimensional radiation dose image maps. ATVS+OTCM disabled and ATVS+OTCM enabled acquisitions were simulated. The dose image maps were used to estimate breast, lung, esophagus, and thyroid equivalent doses. Percent reduction in organ equivalent dose achieved with ATVS+OTCM was determined. Image noise was measured as the standard deviation of the Hounsfield unit value at selected anatomical sites.*Results In ATVS+OTCM enabled acquisitions, breast equivalent dose ranged from 0.4 mGy in neonate to 3.0 mGy in adult. The corresponding organ equivalent doses for lung, esophagus and thyroid ranged from 0.5 mGy to 7.2 mGy, 0.6 mGy to 5.2 mGy, and 0.2 mGy to 1.9 mGy, respectively. ATVS+OTCM acquisitions resulted in a reduction of organ equivalent dose, which ranged from 44% for breast to 12% for thyroid. ATVS+OTCM increased noise by up to 18% in images located within the OTCM enabled region. Image noise increase was statistically significant (P<0.05) in all but neonate phantom. Noise was not significantly affected in images located outside the ODM enabled region (P>0.05).*Conclusions In non contrast enhanced CT where soft tissue anatomies are of primary diagnostic interest, ATVS+OTCM reduces organ equivalent dose to all major radiosensitive organs with the breast receiving the highest benefit. An increase in noise is however apparent in images located within the OTCM enabled imaged volume.This work has received funding from the Euratom research and training programme 2014-2018 under grant agreement No 755523 (MEDIRAD).*Clinical Relevance/Application The results presented in this study highlight the importance of employing the ATVS and OTCM tools offered by the new CT scanner models to optimize radiation dose and image quality in CT.

RESULTS

In ATVS+OTCM enabled acquisitions, breast equivalent dose ranged from 0.4 mGy in neonate to 3.0 mGy in adult. The corresponding organ equivalent doses for lung, esophagus and thyroid ranged from 0.5 mGy to 7.2 mGy, 0.6 mGy to 5.2 mGy, and 0.2 mGy to 1.9 mGy, respectively. ATVS+OTCM acquisitions resulted in a reduction of organ equivalent dose, which ranged from 44% for breast to 12% for thyroid. ATVS+OTCM increased noise by up to 18% in images located within the OTCM enabled region. Image noise increase was statistically significant (P<0.05) in all but neonate phantom. Noise was not significantly affected in images located outside the ODM enabled region (P>0.05).

CLINICAL RELEVANCE/APPLICATION

The results presented in this study highlight the importance of employing the ATVS and OTCM tools offered by the new CT scanner models to optimize radiation dose and image quality in CT.

PH02-A6   Impact Of Technology On Local Clinical Diagnostic Reference Levels In Mdct

Participants
Hugues G. Brat, MD, Sion, Switzerland (*Presenter*) Speaker, General Electric Company

PURPOSE

To assess the impact of a deep learning image reconstruction (DL) algorithm on local clinical indication-based diagnostic reference levels (LcDRLs).*Methods and Materials Clinical-indication and body mass index (BMI;< 25/= 25) based abdomen (378) and chest (2314) CT series from 7 CT scanners were reconstructed with a DL algorithm (TrueFidelity, GE Healthcare) in a multicenter setting (Group 1, G1). LcDRLs were calculated as the third quartile of the median dose values (CTDIvol, DLP) for each CT scanner and compared as percent reduction to previously calculated (2017) LcDRLs (Group 0, G0), based on iterative reconstruction algorithm (iDose, Philips). The new LcDRLs were also compared to the anatomy-based P50 (achievable) national DRLs (NDRLs).*Results G1 BMI<25 average CTDIcol/DLP reduction was -41%/-46% for chest and -27%/-29% for abdomen. G1 BMI=25 average CTDIcol/DLP reduction was -37%/-43% for chest and -17%/-30% for abdomen. Highest dose reduction for BMI < 25/= 25 classes was observed for emphysema (-71%/-78%) and kidney stones (-62%/-55%) clinical indications. For chest, LcDRLs compared to P50 NDRLS were lower in all indications and BMI classes for CTDIvol (range 1.6-5.6 vs. 6.0 mGy) and DLP (62-181 vs. 210 mGycm). For abdomen, LcDRLs were lower or comparable to P50 NDRLS for CTDIvol (2.5-10.2 vs 10 mGy) and DLP (96-418 vs. 470mGycm). For urolithiasis LcDRls were below P50 NDRL for CTDIvol (2.5/3.6 vs. 4.0 mGy) and DLP (96/120 vs. 180 mGycm) in both BMI classes. For Liver LcDRls were below P50 NDRL for CTDIvol (4.8 vs. 9.0 mGy) and DLP (243 vs. 300 mGycm) only for BMI<25.*Conclusions DL reconstruction algorithms allow further optimization of CT doses at a local level. Combined with protocol stratification according to clinical indication and BMI, LcDRLs remain lower than national P50 DRLs for chest and abdomen CT examinations.*Clinical Relevance/Application DRLs can only be used successfully with a continuous improvement program and experienced staff to perform clinical audits and carry the optimization process forward.

RESULTS

G1 BMI<25 average CTDIcol/DLP reduction was -41%/-46% for chest and -27%/-29% for abdomen. G1 BMI=25 average

CTDIcol/DLP reduction was -37%/-43% for chest and -17/-30% for abdomen. Highest dose reduction for BMI < 25/= 25 classes was observed for emphysema (-71%/-78%) and kidney stones (-62%/-55%) clinical indications. For chest, LcDRLs compared to P50 NDRLS were lower in all indications and BMI classes for CTDIvol (range 1.6-5.6 vs. 6.0 mGy) and DLP (62-181 vs. 210 mGycm). For abdomen, LcDRLs were lower or comparable to P50 NDRLS for CTDIvol (2.5-10.2 vs 10 mGy) and DLP (96-418 vs. 470mGycm). For urolithiasis LcDRls were below P50 NDRL for CTDIvol (2.5/3.6 vs. 4.0 mGy) and DLP (96/120 vs. 180 mGycm) in both BMI classes. For Liver LcDRls were below P50 NDRL for CTDIvol (4.8 vs. 9.0 mGy) and DLP (243 vs. 300 mGycm) only for BMI<25.

CLINICAL RELEVANCE/APPLICATION

DRLs can only be used successfully with a continuous improvement program and experienced staff to perform clinical audits and carry the optimization process forward.

PH02-A7   In Vivo Quantification Of Bone Mineral Density Of Lumbar Vertebrae Using Fast Kvp Switching Dual-energy CT: Correlation With Quantitative Computed Tomography

Participants
Kun Zhang, MD, Changsha, China (*Presenter*) Nothing to Disclose

PURPOSE

Osteoporosis is a common, progressive disease related to low bone mineral density (BMD). If it can be diagnosed at an early stage, osteoporosis is treatable. Quantitative computed tomography (QCT) is one of the current reference standards of BMD measurement, but dual-energy computed tomography (DECT) is considered to be a potential alternative. This study aimed to evaluate the feasibility and accuracy of phantomless in vivo DECT-based BMD quantification in comparison with QCT.*Methods and Materials A total of 128 consecutive participants who underwent DECT lumbar examinations between July 2019 and February 2021 were retrospectively analyzed. The density of calcium (water), hydroxyapatite (water), calcium (fat), and hydroxyapatite (fat) [DCa(Wa), DHAP(Wa), DCa(Fat) and DHAP(Fat), respectively] were measured along with BMD in the trabecular bone of lumbar level 1-2 by DECT and QCT. Linear regression analysis was performed to assess the relationship between DECT- and QCT-derived BMD at both the participant level and the vertebral level. Linear regression models were quantitatively evaluated with adjusted R-square, normalized mean squared error (NMSE) and relative error (RE). Bland-Altman analysis was conducted to assess agreement between measurements. P<0.05 was considered statistically significant.*Results Strong correlations were observed between DECT- and QCT-derived BMD at both the participant level and the vertebral level (adjusted R2 =0.983-0.987; NMSE = 1.6-2.1%; RElinear =0.6-0.9%). Bland-Altman plots indicated high agreement between both measurements. DCa(Fat) and DHAP(Fat) showed relatively similar and optimal predictive capability for QCT-derived BMD (both: adjusted R2 =0.987, NMSE =1.6%, RElinear =0.6%).*Conclusions Fast kVp switching DECT enabled accurate phantomless in vivo BMD quantification of the lumbar spine. DCa(Fat) and DHAP(Fat) had relatively similar and optimal predictive capability.*Clinical Relevance/Application Dual-energy computed tomography (DECT) is a potential alternative tool to evaluate bone mineral density .

RESULTS

Strong correlations were observed between DECT- and QCT-derived BMD at both the participant level and the vertebral level (adjusted R2 =0.983-0.987; NMSE = 1.6-2.1%; RElinear =0.6-0.9%). Bland-Altman plots indicated high agreement between both measurements. DCa(Fat) and DHAP(Fat) showed relatively similar and optimal predictive capability for QCT-derived BMD (both: adjusted R2 =0.987, NMSE =1.6%, RElinear =0.6%).

CLINICAL RELEVANCE/APPLICATION

Dual-energy computed tomography (DECT) is a potential alternative tool to evaluate bone mineral density .

PH02-A8   Accuracy Of Iodine Quantification Using Single-source Split-filter Dual-energy CT Compared To Dual-source Scanners: Phantom Study

Participants
Anzi Zhao, MS, Chicago, Illinois (*Presenter*) Nothing to Disclose

PURPOSE

To compare the in-vitro accuracy of iodine quantification algorithm of single-source split-filter dual-energy CT (DECT) with dual-source DECT platforms, using a multi-energy CT phantom.*Methods and Materials A multi-energy CT quality assurance phantom (with cylinder and oval setup to evaluate the effect of body habitus) with various nominal iodine concentration inserts (2 to 15 mg/ml, and 1, 2, 4 mg/ml mixed with blood mimicking materials) were scanned with three DECT scanners (SOMATOM X.Cite, Drive, and Force, Siemens Healthcare) employing two different dual-energy acquisition mechanisms. Clinical abdomen/pelvis dual-energy scanning protocols with different kilovolt peak and different energy spectral separation settings were used. Automatic tube current modulation was employed. Scans were repeated with iodine inserts switched between central and peripheral holes. Iodine concentration measurements were made on the images generated on Siemens Syngo.via. Linearity of measured iodine concentrations with nominal known insert concentrations were assessed. The degree of error between the calculated and actual iodine concentration were also analyzed.*Results Measured iodine concentrations from all three scanners showed excellent linear correlation with nominal values, with R2 values ranging between 0.9958 and 1 (p<0.05). Error between the measured and actual iodine concentrations ranged from -1.4 to 1.0 mg/ml. Degree of absolute error was higher with high-concentration (10 and 15 mg/ml) inserts, especially when these inserts were placed in the periphery of the oval-shaped phantom. There was degradation of iodine quantification with scanners Drive and X.Cite when iodine inserts were placed in the oval-shaped phantom. Scanner X.Cite showed notable degradation in accuracy of iodine quantification when admixture of blood-mimicking fluid and iodine was used, particularly when those inserts were placed in the periphery of the oval-shaped phantom.*Conclusions Although the correlation between calculated and actual iodine concentrations was excellent across all 3 scanners, some variations in accuracy of iodine quantification were noted between the scanners. Locations of the iodine inserts (peripheral versus central) and size of the phantom affected the accuracy of iodine quantification. In general, accuracy of split-filter DECT for iodine quantification was inferior to the dual-source scanners.*Clinical Relevance/Application Split-filter DECT, which is the newest FDA-approved DECT technology, offers excellent linearity for in-vitro iodine quantification. This scanner may offer reasonable accuracy for in-vivo iodine quantification although further clinical studies are required to prove this.

RESULTS

Measured iodine concentrations from all three scanners showed excellent linear correlation with nominal values, with R2 values ranging between 0.9958 and 1 (p<0.05). Error between the measured and actual iodine concentrations ranged from -1.4 to 1.0 mg/ml. Degree of absolute error was higher with high-concentration (10 and 15 mg/ml) inserts, especially when these inserts were

placed in the periphery of the oval-shaped phantom. There was degradation of iodine quantification with scanners Drive and X.Cite when iodine inserts were placed in the oval-shaped phantom. Scanner X.Cite showed notable degradation in accuracy of iodine quantification when admixture of blood-mimicking fluid and iodine was used, particularly when those inserts were placed in the periphery of the oval-shaped phantom.

CLINICAL RELEVANCE/APPLICATION

Split-filter DECT, which is the newest FDA-approved DECT technology, offers excellent linearity for in-vitro iodine quantification. This scanner may offer reasonable accuracy for in-vivo iodine quantification although further clinical studies are required to prove this.

PH02-A-HC1 High Resolution CT Using Photon Counting Detector (PCD) CT: Methods, Challenges And Clinical Benefits

Participants
Michael R. Bruesewitz, Rochester, Minnesota (*Presenter*) Nothing to Disclose

TEACHING POINTS

• To explain the method of achieving high resolution using an investigational PCD-CT scanner • To demonstrate the advantage of PCD-CT high-resolution imaging compared to existing technology• To describe the challenges and pitfalls of high-resolution imaging and strategy to overcome these challenges • To illustrate benefits of high-resolution imaging using PCD-CT in clinical applications

TABLE OF CONTENTS/OUTLINE

1. What is PCD and how is it different from the energy integrating detectors (EID) used on commercial CT scanners? a. PCD: Directly convert X-ray into electronic signals, count individual photon and record its energy b. EID: Indirect, 2 stage conversion of X-ray to light then to electronic signal. No information on individual photon 2. How high-resolution is achieved in PCD-CT? a. Smaller detector cell with almost 100% fill factor due to absence of septa b. More dose efficient compared to other high-resolution techniques based on comb filter and/or EID 3. Challenges of high-resolution imaging and solutions a. Need dedicated high-resolution kernel b. High image noise due to increased spatial resolution and sharp kernel c. Need advanced noise reduction techniques i. Iterative noise reduction techniques using prior knowledge ii. AI-based denoising techniques 4. Clinical applications a. Chest b. Temporal Bone c. Sinus d. Vascular e. MSK

RO01-A1   Low Dose Radiotherapy In The Management Of COVID-19 Pneumonia (LOWRAD-Cov19)

Participants
Sara Gomez Pena, Madrid, Spain (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the safety and efficacy of Low-Dose Radiation (LD-RT) to treat COVID-19 pneumonia.*Methods and Materials We conducted a prospective phase I-II trial enrolling patients = 50 years-old, COVID-19 positive, with lung involvement at imaging study and oxygen requirement. Patients received 100 cGy to total lungs in a single fraction. Dose planning goals were PTV95>80% with Dmax< 115%. Primary outcome was radiological response assessed as severity and extension scores at days 0, +3 and +7. Secondary outcomes were toxicity (CTCAE v5.0), days of hospitalization, changes in inflammatory blood parameters (ferritin, lymphocytes, C-reactive protein, d-dimer and LDH) and SatO2/ FiO2 index (SAFI), at day +3 and +7. Descriptive analyses were summarized as means with standard deviation (SD) and medians with interquartile ranges (IQR). A Wilcoxon sign rank test for paired data was used to assess the CT scores and Chi Square was used to assess for comparison of categorical variables.*Results Forty-one patients were included. Three patients died <72h after LD-RT and were excluded from the analysis. Median age was 71 (IQR 60-84). Eighteen patients (47%) received previously any antiCOVID treatment (tocilizumab, lopinavir/ritonavir, remdesivir) and thirty-two patients (84%) received esteroids (GC) during LD-RT. Extension score improved significantly (p=0.02) on day +7; severity score was stable or slightly decreased (p=0.1). Median SAFI on day 0 was 147 (IQR 118-264), 230 (IQR 120-343) on day +3 and 293 (IQR 121-353) on day +7 (p<0.01). SAFI improvement was associated with overall survival (p=0.01). Significant decrease was found in C-reactive protein on day +7 (p=0.02) and in lymphocytes counts on day +3 and +7 (p=0.02). Median time to receive RT from the date of admission was 19 days (ranging 2-87). Median number of days in hospital after RT was 11 (4-78) and overall was 37 days (range 11-155). With a median follow-up of 67 days after LD-RT, 24 (63%) patients were discharged, twelve (32%) died and two (5%) are still inpatients.*Conclusions Our preliminary results show that LD-RT was feasible and well-tolerated treatment, with potential clinical improvement. Randomized trials are needed to establish whether LD-RT improves severe pneumonia.*Clinical Relevance/Application LD-RT is a feasible (transfer, planning, 1-hour treatment) and well-tolerated treatment for the treatment of COVID-19 pneumonia. Our results suggested moderate radiological improvement and significant improvement in SAFI.

RESULTS

Forty-one patients were included. Three patients died <72h after LD-RT and were excluded from the analysis. Median age was 71 (IQR 60-84). Eighteen patients (47%) received previously any antiCOVID treatment (tocilizumab, lopinavir/ritonavir, remdesivir) and thirty-two patients (84%) received esteroids (GC) during LD-RT. Extension score improved significantly (p=0.02) on day +7; severity score was stable or slightly decreased (p=0.1). Median SAFI on day 0 was 147 (IQR 118-264), 230 (IQR 120-343) on day +3 and 293 (IQR 121-353) on day +7 (p<0.01). SAFI improvement was associated with overall survival (p=0.01). Significant decrease was found in C-reactive protein on day +7 (p=0.02) and in lymphocytes counts on day +3 and +7 (p=0.02). Median time to receive RT from the date of admission was 19 days (ranging 2-87). Median number of days in hospital after RT was 11 (4-78) and overall was 37 days (range 11-155). With a median follow-up of 67 days after LD-RT, 24 (63%) patients were discharged, twelve (32%) died and two (5%) are still inpatients.

CLINICAL RELEVANCE/APPLICATION

VA01-B1   Validation Of A Deep Learning Tool For Automatic Aortic Dissection Detection

Participants
Joel McLouth, MD, Orange, California (*Presenter*) Nothing to Disclose

PURPOSE

Aortic dissection (AD) is a rare and uncommon disease, but with high morbidity requiring time-sensitive treatments. Therefore, rapid detection of AD is critical. Artificial intelligence tools allow prompt diagnosis that can improve clinical outcomes. However, the generalizability of these tools across different clinical settings is not well described. This study aims to assess a commercially available deep learning-based tool, CINA® CHEST v1.0 device (Avicenna.ai, La Ciotat, France), in detecting AD across a variety of hospital settings throughout the US.*Methods and Materials This was a retrospective, multicenter, and blinded study that evaluated 298 Thoraco-abdominal CT angiography (CTA) images provided from a teleradiology organization. Data spanned 200 U.S. cities and included 4 CT vendors. The performance of CINA in AD detection was evaluated. Ground truth was determined by three board-certified radiologists.*Results There were 137 (46%) positive AD cases. CINA correctly identified 289/298 cases as positive or negative. The sensitivity was 96.4%, specificity was 97.5%, accuracy was 97.0%, area under the curve was 0.97, and Matthews correlation coefficient (MCC) was 0.94. Mean "time-to-notification" was estimated to be 36.5 seconds.*Conclusions This deep learning-based tool is generalizable and able to detect AD throughout a variety of hospital systems. Four false positives (FP), including two within aortic aneurysms, suggest that FPs can sometimes be triggered by findings already of interest to the radiologist. While there were five false negatives (FN), these all occurred in Type B dissections, which are often medically managed versus surgical management with Type A dissections. Additionally, these FNs primarily occurred in complicated cases that even prompted disagreement among the radiologists. Regardless, the robustness of this tool has implications for widespread clinical use which could help radiologists with AD triage for ultimately life-saving interventions.*Clinical Relevance/Application This study validates a deep learning-based tool which can detect AD across a variety of practice environments, thus allowing for fast initiation of time-sensitive treatments.

RESULTS

There were 137 (46%) positive AD cases. CINA correctly identified 289/298 cases as positive or negative. The sensitivity was 96.4%, specificity was 97.5%, accuracy was 97.0%, area under the curve was 0.97, and Matthews correlation coefficient (MCC) was 0.94. Mean "time-to-notification" was estimated to be 36.5 seconds.

CLINICAL RELEVANCE/APPLICATION

This study validates a deep learning-based tool which can detect AD across a variety of practice environments, thus allowing for fast initiation of time-sensitive treatments.

VA01-B2   Where's The Leak? Contrast Enhanced Ultrasound In Problem Solving Endoleak Detection In Abdominal Aortic Aneurysms Post Endograft Repair. A Multimodality Review.

Participants
Kathryn McGillen, MD, Hershey, Pennsylvania (*Presenter*) Speaker, MRI Online

TEACHING POINTS

CTA is gold standard for diagnosing endoleak in abdominal aortic aneurysms (AAA), after endograft repair (EVAR).Ultrasound, specifically contrast ultrasound (CEUS) can play a role in diagnosing endoleaks, particularly in problem solving cases when the type or location is unclear.CEUS can help guide management - preprocedural planning for the interventional radiologist and/or vascular surgeon - differentiate between type II and III endoleaks, identify inflow vessels, particularly in patients with poor renal function.Allows for access side planning, which may streamline number of angiographic runs and total radiation for the procedure.

TABLE OF CONTENTS/OUTLINE

Review endoleak types in AAA, status post EVAR.Review appearances of endoleak on CTA, contrast ultrasound and correlate with findings on diagnostic and therapeutic angiography.Discuss multi-modality and interdisciplinary approach to these patients.

CH03-C1   **Bend But Don't Break: Experience Of A Diverse New York City Lung Cancer Screening Program During The COVID-19 Pandemic**

Participants
Maximilian C. Stahl, BA, Bronx, New York (*Presenter*) Nothing to Disclose

PURPOSE

The COVID-19 pandemic has led to the national shutdown and subsequent reopening of cancer screening programs. Our diverse inner-city program was affected by staffing redeployment, quarantine protocols, increased safety/social distancing measures, and changes in follow up. The purpose of this study was to analyze the effect of the COVID-19 pandemic on our lung cancer screening program.*Methods and Materials Retrospective chart review. All exams of patients enrolled in our New York City lung cancer screening program from March 2019 to March 2021 were included. The pre-pandemic and pandemic period were defined as 3/28/2019-3/21/2020 vs. 3/22/2020-3/17/2021, respectively, dichotomized by the New York State lockdown.*Results 1218 exams were performed in the pre-pandemic period and 857 exams in the pandemic period, a 29.6% decrease. The percentage of exams performed on newly enrolled patients pre-pandemic period vs pandemic period significantly decreased from 32.7% to 13.8% (p<0.001). Demographics for the pre-pandemic period and pandemic period were: mean age (66.9 ± 5.9 and 66.5 ± 6.0), women (51.9% and 51.6%), White (20.7% and 20.3%) Hispanic/Latino (42.0% and 36.3%). There was no significant difference in Lung-RADS scores when comparing the pre-pandemic and pandemic period (p>0.05).Exam volume decreased to a minimum in the initial New York State lockdown in April and May 2020, with 14 and 10 exams per month performed, respectively. From June 2020-November 2020 exam volume returned to a pre-pandemic baseline, with a peak of 131 exams in September 2020. Exam volume declined corresponding to the second COVID-19 wave from December 2020-March 2021, with a trough of 43 exams per month. This parabolic pattern was true across all demographic groups in the pandemic period.*Conclusions The COVID-19 pandemic significantly decreased lung cancer screening volume correlating with surges. New patient enrollment was significantly reduced. There was no significant change in the distribution of Lung-RADS scores when comparing the pre-pandemic and pandemic period.*Clinical Relevance/Application As the nation continues to adapt during the COVID-19 pandemic, it is important to continue to find ways to provide necessary patient care. With lung cancer screening proven to reduce lung cancer mortality, ongoing efforts are needed to overcome the impact of the pandemic on underserved communities.

RESULTS

1218 exams were performed in the pre-pandemic period and 857 exams in the pandemic period, a 29.6% decrease. The percentage of exams performed on newly enrolled patients pre-pandemic period vs pandemic period significantly decreased from 32.7% to 13.8% (p<0.001). Demographics for the pre-pandemic period and pandemic period were: mean age (66.9 ± 5.9 and 66.5 ± 6.0), women (51.9% and 51.6%), White (20.7% and 20.3%) Hispanic/Latino (42.0% and 36.3%). There was no significant difference in Lung-RADS scores when comparing the pre-pandemic and pandemic period (p>0.05).Exam volume decreased to a minimum in the initial New York State lockdown in April and May 2020, with 14 and 10 exams per month performed, respectively. From June 2020-November 2020 exam volume returned to a pre-pandemic baseline, with a peak of 131 exams in September 2020. Exam volume declined corresponding to the second COVID-19 wave from December 2020-March 2021, with a trough of 43 exams per month. This parabolic pattern was true across all demographic groups in the pandemic period.

CLINICAL RELEVANCE/APPLICATION

As the nation continues to adapt during the COVID-19 pandemic, it is important to continue to find ways to provide necessary patient care. With lung cancer screening proven to reduce lung cancer mortality, ongoing efforts are needed to overcome the impact of the pandemic on underserved communities.

CH03-C2   **Lung-RADS Learning Curve? Chest Vs. General Radiologists Over 6 Years**

Participants
Joey Gu, BS, Providence, Rhode Island (*Presenter*) Nothing to Disclose

PURPOSE

The Lung CT Screening Reporting and Data System (Lung-RADS) was introduced in 2014 to standardize the reporting and management of low-dose CT (LDCT) screening results. This study examined: 1) if Lung-RADS rates in our sample changed over the last 6 years; 2) if Lung-RADS rates differed between chest and general radiologists; 3) as a reference, if the Lung-RADS rates from both Aims 1 & 2 differed from the Lung-RADS rates reported in the literature.*Methods and Materials Aims 1 & 2 were screens from a community practice between March 2015-21 (N=11,142). IRB determined this study as a quality project. Aim 3 was a meta-analysis of papers using MEDLINE and EMBASE with PRISMA guidelines; eligible studies examined LDCT lung cancer screening at institutions in the U.S. and reported Lung-RADS scores between 2015-21. Lung-RADS rates 1) over time and 2) between general and chest radiologists and 3) compared with meta-analysis results were modeled using generalized mixed modeling.*Results Of the 11,142 screens, 56% of screens were current smokers and 52% were women. The mean Lung-RADS score was 2, which did not significantly change over the last 6 years (OR: 1.00, p=0.3). Over the last 6 years, Lung-RADS rates were 84.2%, 9.3%, and 6.5% for scores 1&2, 3, and 4, respectively, which were comparable to our meta-analysis results from 22 studies showing scores 1&2, 3,

and 4 to be 84.3% (95% CI [82.1%, 86.3%]), 7.0% (95% CI [5.9%, 8.3%]), and 5.4% (95% CI [4.6%, 6.3%]), respectively. When examining Lung-RADS rates over the last 6 years between 3 chest and 37 general radiologists, there was no difference between chest and general radiologists (p=0.7), nor were there differences observed as a function of time between the two (p=0.6).*Conclusions No differences were found in Lung-RADS scores between chest and general radiologists over 6 years. There was no evidence of a "learning curve" for general compared with chest radiologists; these rates reflect the literature.*Clinical Relevance/Application Lung-RADS scores are consistently applied to LDCT screening studies regardless of radiologist sub-specialization. General radiologists may perform as well as chest radiologists in a community-based lung cancer screening program.

RESULTS

Of the 11,142 screens, 56% of screens were current smokers and 52% were women. The mean Lung-RADS score was 2, which did not significantly change over the last 6 years (OR: 1.00, p=0.3). Over the last 6 years, Lung-RADS rates were 84.2%, 9.3%, and 6.5% for scores 1&2, 3, and 4, respectively, which were comparable to our meta-analysis results from 22 studies showing scores 1&2, 3, and 4 to be 84.3% (95% CI [82.1%, 86.3%]), 7.0% (95% CI [5.9%, 8.3%]), and 5.4% (95% CI [4.6%, 6.3%]), respectively. When examining Lung-RADS rates over the last 6 years between 3 chest and 37 general radiologists, there was no difference between chest and general radiologists (p=0.7), nor were there differences observed as a function of time between the two (p=0.6).

CLINICAL RELEVANCE/APPLICATION

Lung-RADS scores are consistently applied to LDCT screening studies regardless of radiologist sub-specialization. General radiologists may perform as well as chest radiologists in a community-based lung cancer screening program.

CH03-C4   Assessment Of Nodule Growth On Follow-up Screening Low Dose Cts To Detect Lung Cancer: Comparison Between Lung-rads, Nelson, And Subjective Assessment By Radiologist

Participants
Jong Hyuk Lee, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To investigate accuracies of lung cancer identification on follow-up screening low dose CTs (LDCTs), using different criteria for nodule growth evaluation: Lung-RADS version 1.1, volumetric criteria of NELSON, and subjective assessment of radiologist.*Methods and Materials We retrospectively collected baseline and follow-up LDCTs of lung cancer screening participants with an indeterminate nodule on baseline CT by NELSON criteria (solid component volume 50-500 mm3; non-solid component average diameter =8mm). Diameters and volumes of nodules were measured by semiautomated segmentation. Nodule growth (Lung-RADS, absolute diameter increase >1.5mm; NELSON, percentage volume increase =25%) and request for diagnostic procedures (Lung-RADS, category 4B; NELSON: volume doubling time <400 days or new solid component) were determined based on Lung-RADS and NELSON criteria. In addition, one radiologist subjectively reviewed LDCT images to determine nodule growth and request diagnostic procedures independently from semiautomated measurement. Sensitivities and specificities of nodule growth and request for diagnostic procedure defined by three criteria were evaluated against lung cancer diagnosis*Results Among 120 participants (median interval between CTs, 6 months), lung cancer was diagnosed in 30 (25%) participants. Nodule growth defined by Lung-RADS, NELSON criteria, and radiologist's subjective evaluation exhibited sensitivities of 70%, 80%, and 57%, specifities of 96%, 91%, and 99%, respectively. Nodule growth defined by NELSON criteria exhibited higher sensitivity (P=.046) and lower specificity (P=.046) than radiologist's subjective evaluation. Request for diagnostic procedures defined by Lung-RADS, NELSON criteria, and radiologist's subjective evaluation exhibited sensitivities of 40%, 63%, and 80%, specifities of 94%, 97%, and 97%, respectively. Request for diagnostic procedures defined by Lung-RADS exhibited lower sensitivity than NELSON criteria (P=.046) or radiologist's subjective evaluation (P=.001).*Conclusions Radiologist's subject evaluation was less sensitive in terms of nodule growth but more sensitive in terms of adjudication of diagnostic procedures than semiautomated measurements for identifying lung cancer on follow-up LDCTs.*Clinical Relevance/Application Apart from its lower sensitivity for nodule growth than semiautomated measurement, radiologist's subjective evaluations can sensitively identify lung cancer in follow-up screening LDCTs.

RESULTS

Among 120 participants (median interval between CTs, 6 months), lung cancer was diagnosed in 30 (25%) participants. Nodule growth defined by Lung-RADS, NELSON criteria, and radiologist's subjective evaluation exhibited sensitivities of 70%, 80%, and 57%, specifities of 96%, 91%, and 99%, respectively. Nodule growth defined by NELSON criteria exhibited higher sensitivity (P=.046) and lower specificity (P=.046) than radiologist's subjective evaluation. Request for diagnostic procedures defined by Lung-RADS, NELSON criteria, and radiologist's subjective evaluation exhibited sensitivities of 40%, 63%, and 80%, specifities of 94%, 97%, and 97%, respectively. Request for diagnostic procedures defined by Lung-RADS exhibited lower sensitivity than NELSON criteria (P=.046) or radiologist's subjective evaluation (P=.001).

CLINICAL RELEVANCE/APPLICATION

Apart from its lower sensitivity for nodule growth than semiautomated measurement, radiologist's subjective evaluations can sensitively identify lung cancer in follow-up screening LDCTs.

CH03-C5   Prevalence And Predictive Malignancy Features Of Isolated Mediastinal Or Hilar Lymphadenopathy On Low-dose Chest CT Screening For Lung Cancer

Participants
Eunhye Seo, Bucheon, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the prevalence of enlarged mediastinal or hilar lymph nodes (MH-LNs) in low-dose CT (LDCT) screening and to identify features that distinguish benign from malignant lymph nodes.*Methods and Materials This study retrospectively reviewed 624 participants who took a baseline chest LDCT scan between 2017 and 2019 at a single tertiary hospital. Participants who had one or more enlarged (defined as 6 mm or larger) MH-LN on the initial CT scan and were followed up for at least one year were included in this study. For each MH-LN, eight features including the location, size (short and long axis), Hounsfield unit, calcification, fat, shape (oval, round, crescent), contour (sharp, ill-defined, lobulated) were reviewed. Other features related to the participant's underlying lung condition (interstitial lung abnormality, tuberculosis sequalae, emphysema, bronchiectasis, bronchitis), age, sex, and smoking pack-years were also reviewed. Multivariate logistic regression analysis and Mann-Whitney U test were used to detect and compare the features of malignant LN. Further analyses used synthetic minority oversampling techniques (SMOTE) due to the limited number of malignant cases.*Results A total of 531 MH-LNs were identified in 223 participants (mean age 62±6, male 99.1%),

of which 10 MH-LNs from 5 participants were diagnosed as malignant; 2 metastatic LN from pulmonary adenocarcinoma and 8 isolated malignant LN without an identified primary cancer. Short axis length was shown to be the single most significant factor in predicting whether the MH-LN may be malignant (odds ratio 3.409; P<0.001). The short axis length was statistically different when comparing between benign and malignant MH-LN groups (7.4±1.5 mm vs. 16.9±5.4 mm, P<0.001) and all patients with malignancy had at least one MH-LN that is at least 15 mm. After implementing SMOTE, shape (P=0.013), bronchitis (P=0.002), emphysema (P=0.026) also showed to have association with malignancy of MH-LNs.*Conclusions Among features that may suggest malignancy in isolated MH-LNs, short axis length of 15 mm or longer provide the most significant predictive value. Other features such as the shape of lymph node or underlying bronchitis or emphysema in the lung parenchyma may also be important factors when considering further cancer evaluation tests.*Clinical Relevance/Application The lung imaging reporting and data system (Lung-RADS) currently does not include any size criteria related to lymph node enlargement. This study proposes a need to specifically mention that isolated mediastinal or hilar lymph node enlargement of at least 15 mm in short axis length may be suggestive of a Lung-RADS score of 4X. Other features, such as shape, bronchitis, emphysema require further studies to confirm their relevance.

RESULTS

A total of 531 MH-LNs were identified in 223 participants (mean age 62±6, male 99.1%), of which 10 MH-LNs from 5 participants were diagnosed as malignant; 2 metastatic LN from pulmonary adenocarcinoma and 8 isolated malignant LN without an identified primary cancer. Short axis length was shown to be the single most significant factor in predicting whether the MH-LN may be malignant (odds ratio 3.409; P<0.001). The short axis length was statistically different when comparing between benign and malignant MH-LN groups (7.4±1.5 mm vs. 16.9±5.4 mm, P<0.001) and all patients with malignancy had at least one MH-LN that is at least 15 mm. After implementing SMOTE, shape (P=0.013), bronchitis (P=0.002), emphysema (P=0.026) also showed to have association with malignancy of MH-LNs.

CLINICAL RELEVANCE/APPLICATION

The lung imaging reporting and data system (Lung-RADS) currently does not include any size criteria related to lymph node enlargement. This study proposes a need to specifically mention that isolated mediastinal or hilar lymph node enlargement of at least 15 mm in short axis length may be suggestive of a Lung-RADS score of 4X. Other features, such as shape, bronchitis, emphysema require further studies to confirm their relevance.

CH03-C6   Deep Learning-Based Autonomous Robotic Point Of Care Ultrasound Imaging For Detection And Monitoring Of COVID-19 Induced Pulmonary Diseases

Participants
Lidia Al-Zogbi, MS,BEng, Baltimore, Maryland (*Presenter*) Nothing to Disclose

PURPOSE

Point of care ultrasound (POCUS) imaging techniques have emerged as an important tool for diagnosis and staging of patients for COVID-19. In addition to the scarcity of highly skilled sonographers, POCUS requires close contact of radiologists and ultrasound (US) technicians with patients, increasing risk for infection. An autonomous robotic solution would enable a safe environment for medical personnel while facilitating repeated imaging of the same location for monitoring of the disease progression.*Methods and Materials A 6 degrees-of-freedom manipulator was employed for the autonomous US image collection process. A 3D deep convolutional network trained on 550 patients was used to predict 3D positions of 60 landmarks on a human ribcage from a torso surface. These landmarks combined with a patient surface model obtained from a depth camera were used to propose target US probe positions on the patient to image the lungs while avoiding rib obstruction. Due to registration errors and prediction inaccuracies, these algorithms were combined with a real-time force-displacement profile collection methodology to prevent skeletal obstruction during robotic acquisition of US images. The system was evaluated in simulation on n=3 patients and on n=1 full torso US phantom following an 8-point POCUS scanning protocol.*Results Using the L2 norm of the difference between the target and actual final US probe position as an accuracy metric, the methodology's error was 19.8±16.9mm in simulation across 240 data points, allowing the system to image all points of interest in the lungs in a pre-defined sweeping motion. The study on a custom-made full torso US phantom showed that 87.5% of the 24 autonomously acquired US images using real-time force feedback were unobstructed with >90% of the field of view interpretable and a non-shadowed goal point, compared to only 58.3% of the 24 images acquired without force feedback.*Conclusions We have demonstrated preliminary feasibility of a novel real-time solution for autonomously acquired robotic US lung scans by predicting anatomical features of a ribcage from a torso surface model, and using a force-displacement feedback methodology.*Clinical Relevance/Application The proposed robotic solution for POCUS mitigates the scarcity of highly skilled medical personnel and enhances the clinical practice for more consistent patient monitoring.

RESULTS

Using the L2 norm of the difference between the target and actual final US probe position as an accuracy metric, the methodology's error was 19.8±16.9mm in simulation across 240 data points, allowing the system to image all points of interest in the lungs in a pre-defined sweeping motion. The study on a custom-made full torso US phantom showed that 87.5% of the 24 autonomously acquired US images using real-time force feedback were unobstructed with >90% of the field of view interpretable and a non-shadowed goal point, compared to only 58.3% of the 24 images acquired without force feedback.

CLINICAL RELEVANCE/APPLICATION

The proposed robotic solution for POCUS mitigates the scarcity of highly skilled medical personnel and enhances the clinical practice for more consistent patient monitoring.

NMMI01-A1 Preoperative Maximum Standardized Uptake Value Of Primary Lesions Predict Lymph Nodes Metastasis Superior To Traditional Positron Emission Tomography-computed Tomography Criterion With Higher Negative Predictive Value In Peripheral Clinical T1 Non-small-cell Lung Cancer

Participants
Xiaofeng Li, Xu Zhou, China (*Presenter*) Nothing to Disclose

PURPOSE

The sublobar resection is suitable for patients in peripheral cT1 non-small-cell lung cancer (NSCLC) without lymph node metastasis (LNM) according to the guidelines. The traditional Fluorine-18 fluorodeoxyglucose (18F-FDG) positron emission tomography-computed tomography (PET-CT) criterion based on hilar or mediastinal lymph nodes (LNs) = 1.0 cm or LN maximum standardized uptake value (SUVmax) = 2.5 for predicting LNM have unsatisfactory performance, especially for the low negative predictive value (NPV). Therefore, we aimed to explore the clinical role of preoperative SUVmax of the primary lesions for predicting peripheral cT1 NSCLC LNM.*Methods and Materials A total of 172 patients with peripheral cT1 NSCLC underwent preoperative 18F-FDG PET-CT were retrospectively analyzed. The enrolled cases were divided into the LNM group and the non-LNM group according to postoperative pathology. The differences of clinical variables, metabolic and morphological parameters of the primary lesions between the two groups were compared. The independent risk factors of peripheral cT1 NSCLC LNM were determined by univariate and multivariate analysis, and assessed the diagnostic efficacy with the receiver operating characteristic curve (ROC) and area under the ROC (AUC), then calculated the sensitivity (SEN), specificity (SPE), positive predictive value (PPV) and NPV.*Results According to postoperative pathology, the incidence of LNM was 23.8% among the enrolled cases. A univariate analysis showed that preoperative SUVmax, age, CTmean, size, SUVmean, and TLG were significantly correlated with the LNM, the ORs (95% CIs) were (19.80 (4.59-85.40)), (0.96 (0.92-1.01)), (1.01 (1.00-1.02), (2.08 (1.05-4.10)), (1.18 (1.08-1.28)), and (1.02 (1.01-1.04)), respectively. SUVmax > 6.2 of the primary lesions based on 18F-FDG PET-CT was the only independent risk factor of peripheral cT1 NSCLC LNM (OR 10.95, 95% CI, 2.43-49.36; p =0.002) by multivariate analysis. The AUC of SUVmax of the primary lesions to predict LNM was higher than the traditional 18F-FDG PET-CT criterion, and the difference was statistical significance (0.759 vs. 0.601, p-value<0.001). The sensitivity and NPV of SUVmax were superior to the traditional PET-CT criterion (95.1% vs. 80.5%, 97.1% vs. 86.7%). A Hosmer-Lemeshow test showed a goodness-of-fit (p-value 0.479).*Conclusions The preoperative SUVmax of the primary lesion based on 18F-FDG PET-CT to predict LNM has a high clinical role than the traditional PET-CT criterion, since the excellent sensitivity and NPV of the SUVmax could identify the patients at low-risk LNM in peripheral cT1 NSCLC.*Clinical Relevance/Application When SUVmax = 6.2 of the primary tumors in peripheral cT1 NSCLC, the sublobar resection should be performed.

RESULTS

According to postoperative pathology, the incidence of LNM was 23.8% among the enrolled cases. A univariate analysis showed that preoperative SUVmax, age, CTmean, size, SUVmean, and TLG were significantly correlated with the LNM, the ORs (95% CIs) were (19.80 (4.59-85.40)), (0.96 (0.92-1.01)), (1.01 (1.00-1.02), (2.08 (1.05-4.10)), (1.18 (1.08-1.28)), and (1.02 (1.01-1.04)), respectively. SUVmax > 6.2 of the primary lesions based on 18F-FDG PET-CT was the only independent risk factor of peripheral cT1 NSCLC LNM (OR 10.95, 95% CI, 2.43-49.36; p =0.002) by multivariate analysis. The AUC of SUVmax of the primary lesions to predict LNM was higher than the traditional 18F-FDG PET-CT criterion, and the difference was statistical significance (0.759 vs. 0.601, p-value<0.001). The sensitivity and NPV of SUVmax were superior to the traditional PET-CT criterion (95.1% vs. 80.5%, 97.1% vs. 86.7%). A Hosmer-Lemeshow test showed a goodness-of-fit (p-value 0.479).

CLINICAL RELEVANCE/APPLICATION

When SUVmax = 6.2 of the primary tumors in peripheral cT1 NSCLC, the sublobar resection should be performed.

NMMI01-A4 Application Of Dual-stream 3D Convolutional Neural Network Based On 18F-FDG PET/CT In Distinguishing Benign And Invasive Adenocarcinoma In Ground-glass Lung Nodules

Participants
Xiaonan Shao, Changzhou, China (*Presenter*) Nothing to Disclose

PURPOSE

This work aims to train, validate and test a dual-stream three-dimensional convolutional neural network (3D-CNN) based on Fluorine 18 (18F)-fluorodeoxyglucose (FDG) PET/CT to distinguish benign lesions and invasive adenocarcinoma (IAC) in ground-glass nodules (GGNs).*Methods and Materials We retrospectively analyzed patients with suspicious GGNs who underwent 18F-FDG PET/CT examinations in our hospital from November 2011 to November 2020. The patients with benign lesions or IAC were selected for this study. According to the ratio of 7:3, the data was randomly divided into training data and testing data. Partial image feature extraction software was used to segment PET and CT images, and the training data after using the data augmentation was used for the training and validation (5-fold cross-validation) of the three CNNs (PET, CT, and PET/CT networks). According to the average accuracy, recall, and precision, the classification performance of different CNNs on the validation set and testing set was evaluated.*Results A total of 23 benign nodules and 92 IAC nodules from 106 patients were included in this study. In the validation

set, the performance of PET network (accuracy of 0.92 ± 0.02; recall and precision of 0.97 ± 0.03 and 0.94 ± 0.04) were better than CT network (accuracy of 0.84 ± 0.03; recall and precision of 0.90 ± 0.07 and 0.90 ± 0.04); in the testing set, the performance of both networks declined. However, when the precision was close, the accuracy and recall of PET network (0.79 ± 0.05 and 0.90 ± 0.05) were still higher than CT network (0.72 ± 0.05 and 0.79 ± 0.08). For the dual-stream PET/CT network, its performance was almost the same as PET network in the validation set; while in testing set, although its performance decreased (accuracy was 0.81 ± 0.03; recall and precision were 0.92 ± 0.03 and 0.86 ± 0.00), it was still higher than CT or PET networks. Moreover, the accuracy of PET/CT network was higher than two nuclear medicine physicians [Physician 1 (3-year experience): 0.70 and Physician 2 (10-year experience): 0.73].*Conclusions The 3D-CNN based on 18F-FDG PET/CT can be used to distinguish benign lesions and IAC in GGNs, and the performance is better when both CT and PET images are used together.*Clinical Relevance/Application Therefore, in the absence of well-trained and experienced physicians, this CNN may help the differentiation and clinical management of benign and malignant GGNs. Besides, we also expect clinicians to use this CNN for other tumor research suitable for PET/CT imaging.

RESULTS

A total of 23 benign nodules and 92 IAC nodules from 106 patients were included in this study. In the validation set, the performance of PET network (accuracy of 0.92 ± 0.02; recall and precision of 0.97 ± 0.03 and 0.94 ± 0.04) were better than CT network (accuracy of 0.84 ± 0.03; recall and precision of 0.90 ± 0.07 and 0.90 ± 0.04); in the testing set, the performance of both networks declined. However, when the precision was close, the accuracy and recall of PET network (0.79 ± 0.05 and 0.90 ± 0.05) were still higher than CT network (0.72 ± 0.05 and 0.79 ± 0.08). For the dual-stream PET/CT network, its performance was almost the same as PET network in the validation set; while in testing set, although its performance decreased (accuracy was 0.81 ± 0.03; recall and precision were 0.92 ± 0.03 and 0.86 ± 0.00), it was still higher than CT or PET networks. Moreover, the accuracy of PET/CT network was higher than two nuclear medicine physicians [Physician 1 (3-year experience): 0.70 and Physician 2 (10-year experience): 0.73].

CLINICAL RELEVANCE/APPLICATION

Therefore, in the absence of well-trained and experienced physicians, this CNN may help the differentiation and clinical management of benign and malignant GGNs. Besides, we also expect clinicians to use this CNN for other tumor research suitable for PET/CT imaging.

RI02-A1   Ferumoxytol-enhanced MRI Enables Visualization Of The Uteroplacental Interface In A Mouse Model Of Pregnancy

Participants
Andrew Badachhape, PhD, Houston, Texas (*Presenter*) Nothing to Disclose

PURPOSE

Consistent visualization of the uteroplacental interface, or retroplacental clear space (RPCS), has proven to be difficult with ultrasound and conventional magnetic resonance imaging (MRI). Contrast-enhanced MRI (CE-MRI) using conventional gadolinium (Gd) contrast agents is difficult to justify due to concerns over fetal Gd toxicity. While we have previously demonstrated a novel nanoparticle Gd agent that does not cross the placental barrier, it is not yet approved for clinical use. In this pre-clinical study, we evaluated ferumoxytol, an FDA-approved iron oxide nanoparticle agent that is used as a T1-weighted and T2-weighted contrast agent for MRI, for visualizing the retroplacental clear space in a mouse model of pregnancy.*Methods and Materials Imaging studies were performed on a 1T permanent magnet scanner. Ferumoxytol T1 relaxivity (r1) was calculated with inversion recovery spin echo (inversion times: 50-2500 ms). T2 relaxivity (r2) of ferumoxytol was calculated by mapping signal intensity at 4 echo times with a T2* spin echo sequence (TR: 2500 ms, TE: 20, 40, 60, 80 ms). To determine optimal ferumoxytol dose for in vivo T1w-MRI, non-pregnant mice were administered 0.5, 1, 2.5, 5, and 10 mg/kg of ferumoxytol and imaged using a T1-weighted gradient recalled echo (T1w-GRE) sequence (TR: 20 ms, TE: 3.5 ms, voxel size: 300 um3 isotropic). The inferior vena cava (IVC) was chosen as a large caliber blood vessel for assessing signal-to-noise ratio (SNR) relative to background noise. The optimal ferumoxytol dose was used for RPCS characterization in pregnant C57BL/6 mice. Ferumoxytol-enhanced T1w-MRI was performed in pregnant mice at early (12.5 days) and late (16.5 days) stages of gestation (denoted as E12.5 and E16.5). Signal-to-noise ration (SNR) and contrast-to-noise ratio (CNR) was computed for placenta and RPCS for all FPUs in ferumoxytol-enhanced MR images.*Results In vitro studies demonstrated ferumoxytol T1 relaxivity of 18 (mM.s)-1 and T2 relaxivity of 59 (mM.s)-1 at 1T MR field strength. Dose-optimization studies for T1w-MRI in non-pregnant mice demonstrated highest vascular enhancement at 5 mg/kg (SNR: 32.6). Ferumoxytol-enhanced MRI of pregnant mice enabled delineation of RPCS at both E12.5 (Placental-RPCS CNR: 6.9 ± 1.2, n = 29 FPUs) and E16.5 (Placental-RPCS CNR: 8.1 ± 1.5, n= 24 FPUs).*Conclusions Contrast-enhanced MR imaging using ferumoxytol at a dose of 5 mg/kg enabled clear visualization of placental margins and the retroplacental clear space at early and late gestational stages in a pregnant mouse model.*Clinical Relevance/Application Visualization of the retroplacental clear space at the early stages of pregnancy using an FDA approved MR contrast agent may provide a sensitive method for the early detection of invasive placentation.

RESULTS

In vitro studies demonstrated ferumoxytol T1 relaxivity of 18 (mM.s)-1 and T2 relaxivity of 59 (mM.s)-1 at 1T MR field strength. Dose-optimization studies for T1w-MRI in non-pregnant mice demonstrated highest vascular enhancement at 5 mg/kg (SNR: 32.6). Ferumoxytol-enhanced MRI of pregnant mice enabled delineation of RPCS at both E12.5 (Placental-RPCS CNR: 6.9 ± 1.2, n = 29 FPUs) and E16.5 (Placental-RPCS CNR: 8.1 ± 1.5, n= 24 FPUs).

CLINICAL RELEVANCE/APPLICATION

Visualization of the retroplacental clear space at the early stages of pregnancy using an FDA approved MR contrast agent may provide a sensitive method for the early detection of invasive placentation.

RI02-A2   Utility Of MRI In Identifying Uterine Pathology Prior To Uterine Artery Embolization

Participants
Nicole Zanolli, BA, Durham, North Carolina (*Presenter*) Nothing to Disclose

PURPOSE

To understand frequency and concordance of imaging findings reported by pelvic ultrasound and MRI that can change treatment plan or eligibility for uterine artery embolization (UAE).*Methods and Materials Imaging findings were abstracted from radiology reports of women over the age of 18, who had undergone both a pelvic ultrasound and MRI at a single institution between 1/2014 and 12/2018. Patients were excluded if the ultrasound and MRI were performed for different indications. Women with two sets of imaging were recorded separately. Presence of uterine findings that could impact candidacy for UAE including adenomyosis, intracavitary fibroids, a thickened or heterogenous endometrial stripe/concern for uterine malignancy, concern for infection or non-enhancing fibroids were recorded.*Results A total of 1,128 sets of images were collected. Mean age of at the time of MRI was 47.8 years old. Patient self-identified race was Asian (4.4%), Black (43.3%), Hispanic/Latino (7.8%), White (41.8%), and Other (2.7%). The average BMI was 31.6 at the time of MRI. 110 (9.8%) had MRI prior to ultrasound, 32 (2.8%) were performed the same day and 986 (87.4%) had ultrasound prior to MRI. The mean length of time between the two sets of imaging was 1.6 months. Compared to the findings on ultrasound, additional findings made on MRI included adenomyosis (116 cases, 10.3% of total studies), intracavitary fibroids (38, 3.4%), thickened or heterogenous endometrial stripe/concern for uterine malignancy (45, 4.0%), concern for infection (6, 0.5%) and non-enhancing fibroids (28, 2.5%). In total 19.1% of patients had clinically relevant MRI findings not seen on ultrasound that may warrant additional workup or change in clinical management.*Conclusions In a set of 1,128 patients with both a pelvic ultrasound and MRI, 19.1% had MRI findings not seen on ultrasound that may result in consequential changes in

clinical management.*Clinical Relevance/Application Pelvic MRI frequently provides additional findings that are missed on ultrasound but determine candidacy for UAE; MRI should be routinely preformed prior to UAE to ensure appropriate patient care.

RESULTS

A total of 1,128 sets of images were collected. Mean age of at the time of MRI was 47.8 years old. Patient self-identified race was Asian (4.4%), Black (43.3%), Hispanic/Latino (7.8%), White (41.8%), and Other (2.7%). The average BMI was 31.6 at the time of MRI. 110 (9.8%) had MRI prior to ultrasound, 32 (2.8%) were performed the same day and 986 (87.4%) had ultrasound prior to MRI. The mean length of time between the two sets of imaging was 1.6 months. Compared to the findings on ultrasound, additional findings made on MRI included adenomyosis (116 cases, 10.3% of total studies), intracavitary fibroids (38, 3.4%), thickened or heterogenous endometrial stripe/concern for uterine malignancy (45, 4.0%), concern for infection (6, 0.5%) and non-enhancing fibroids (28, 2.5%). In total 19.1% of patients had clinically relevant MRI findings not seen on ultrasound that may warrant additional workup or change in clinical management.

CLINICAL RELEVANCE/APPLICATION

Pelvic MRI frequently provides additional findings that are missed on ultrasound but determine candidacy for UAE; MRI should be routinely preformed prior to UAE to ensure appropriate patient care.

RI02-A3   Placenta Accreta Spectrum Disorder: US And MRI Imaging Findings With Pathological Correlation.

HN05-B1 **Surface-based Amplitude Of Low Frequency Fluctuation Alterations In Patients With Tinnitus Before And After Sound Therapy: A Resting-state Functional MRI Study**

Participants
Xuan Wei, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

Surface-based analysis is a more sensitive measure of cortical local information content than volume analysis.This study aimed to investigate abnormal tinnitus activity by evaluating brain surface-based amplitude of low-frequency fluctuation (ALFF) changes detected by resting-state functional magnetic resonance imaging (RS-fMRI) in patients with idiopathic tinnitus before and after 24 weeks of sound therapy.*Methods and Materials In this prospective observational study, we recruited thirty-three tinnitus patients who had undergone 24 weeks of sound therapy and twenty-six matched healthy controls (HCs).For all participants, 3.0T magnetic resonance imaging (MRI) was acquired with a resting-state functional images of all participants. For the two groups of subjects, we analyzed the spontaneous neural activity of tinnitus patients by cortical ALFF and detected its correlation with clinical indicators of tinnitus. Patients' Tinnitus Handicap Inventory (THI) scores were assessed to determine the severity of their tinnitus before and after treatment. Two-way mixed model analysis of variance (ANOVA) and Pearson's correlation analysis were used in the statistical analysis. Student-Newman-Keuls (SNK) tests were used in the post hoc analysis.*Results Interaction effects between the two groups and between the two scans revealing local neural activity as assessed by ALFF were observed in the bilateral dorsal stream visual cortex (DSVC), bilateral posterior cingulate cortex (PCC), bilateral anterior cingulate and medial prefrontal cortex (ACC&MPC), left temporo-parieto-occipital junction (TPOJ), left orbital and polar frontal cortex (OPFC), left paracentral lobular and mid cingulate cortex (PCL&MCC), right insular and frontal opercular cortex (IFOC) and left early visual cortex (EVC). Importantly, local functional activity in the left TPOJ and right PCC in the patient group was significantly lower than that in the HCs at baseline and was increased to relatively normal levels after treatment. The 24-week sound therapy tinnitus group demonstrated significantly higher ALFF in the left TPOJ and right PCC than in the tinnitus baseline group. Also, compared with the HC baseline group and the 24-week HC group, the 24-week sound therapy tinnitus group demonstrated slightly lower or higher ALFF in the left TPOJ and right PCC, and there were no significant differences between the 24-week sound therapy tinnitus and HC groups.*Conclusions Sound therapy can change auditory, vision, cognitive control and emotional processing, and surface-based RS-fMRI is a more sensitive method to judge local functional activity than other methods.*Clinical Relevance/Application Long-term sound therapy had a normalizing effect on tinnitus patients.

RESULTS

Interaction effects between the two groups and between the two scans revealing local neural activity as assessed by ALFF were observed in the bilateral dorsal stream visual cortex (DSVC), bilateral posterior cingulate cortex (PCC), bilateral anterior cingulate and medial prefrontal cortex (ACC&MPC), left temporo-parieto-occipital junction (TPOJ), left orbital and polar frontal cortex (OPFC), left paracentral lobular and mid cingulate cortex (PCL&MCC), right insular and frontal opercular cortex (IFOC) and left early visual cortex (EVC). Importantly, local functional activity in the left TPOJ and right PCC in the patient group was significantly lower than that in the HCs at baseline and was increased to relatively normal levels after treatment. The 24-week sound therapy tinnitus group demonstrated significantly higher ALFF in the left TPOJ and right PCC than in the tinnitus baseline group. Also, compared with the HC baseline group and the 24-week HC group, the 24-week sound therapy tinnitus group demonstrated slightly lower or higher ALFF in the left TPOJ and right PCC, and there were no significant differences between the 24-week sound therapy tinnitus and HC groups.

CLINICAL RELEVANCE/APPLICATION

Long-term sound therapy had a normalizing effect on tinnitus patients.

RO03-B1 **Prognostication Of Survival After Yttrium-90 Radioembolization For Unresectable Colorectal Liver Metastases: The Benefit Of Volumetric Early Response Assessment With Contrast Enhanced MRI And Its Predictability At Baseline**

Participants
Johannes Kahn, Berlin, Germany (*Presenter*) Nothing to Disclose

PURPOSE

This retrospective study seeks to identify responders of Y-90 radioembolization for colorectal liver metastases (CRLM) both before treatment and early after treatment using baseline clinical variables and volumetric tumor response assessment (quantitative EASL-[qEASL]) on contrast enhanced MRI. The predictability of MR-morphologic response is investigated.*Methods and Materials 155 patients with CRLM who underwent Y-90 radioembolization at our center between 08/2008 and 01/2020 were evaluated for tumour segmentation in arterial and portal venous contrast phase MRI. Exclusion criteria were missing MRI within a defined timeframe, disseminated disease that impeded segmentation and poor imaging quality. Pre- and post-treatment target lesion volumes were measured according to volumetric RECIST and qEASL criteria. The impact of clinical variables and imaging features at baseline as well as MR morphologic response on patient survival was analyzed with Cox regression models. Logistic regression analyses were used to evaluate predictors of MR-morphologic response at baseline.*Results 52 patients were eligible for tumour segmentation. Mean patients' age was 63 years (SD 11), 37% were female. Median survival after treatment was 312 days (95% confidence interval CI [233, 390]). Three months after treatment, application of the qEASL criteria in both arterial and portal venous contrast phases allowed for a significant (p<0.05) separation of the survival curves for partial response, stable disease and progressive disease with a median survival of 412 days (95% CI: [57, 767] in responders. Higher tumour burden and Tc99m lung shunting showed a significant inverse relationship with the probability of patient survival whereas KRAS mutational status and the localization of the primary tumour in either the right or the left hemicolon did not have a significant impact. MR-morphologic response was not predictable at baseline neither with imaging nor available clinical data.*Conclusions MR-morphologic response according to qEASL criteria is the most expedient variable to isolate and measure the impact of Y-90 radioembolization on patient survival. It is the result of a not yet fully understood biological dose-effect relationship and not predictable neither with tumour vascularity or any other baseline variable evaluated.*Clinical Relevance/Application Devascularization on both arterial and portal venous contrast phase MRI is a valuable surrogate endpoint for the benefit of Y-90 radioembolization. Robust biomarkers of radiosensitivity for colorectal cancer subtypes are needed to improve patient selection and dose calculation.

RESULTS

52 patients were eligible for tumour segmentation. Mean patients' age was 63 years (SD 11), 37% were female. Median survival after treatment was 312 days (95% confidence interval CI [233, 390]). Three months after treatment, application of the qEASL criteria in both arterial and portal venous contrast phases allowed for a significant (p<0.05) separation of the survival curves for partial response, stable disease and progressive disease with a median survival of 412 days (95% CI: [57, 767] in responders. Higher tumour burden and Tc99m lung shunting showed a significant inverse relationship with the probability of patient survival whereas KRAS mutational status and the localization of the primary tumour in either the right or the left hemicolon did not have a significant impact. MR-morphologic response was not predictable at baseline neither with imaging nor available clinical data.

CLINICAL RELEVANCE/APPLICATION

Devascularization on both arterial and portal venous contrast phase MRI is a valuable surrogate endpoint for the benefit of Y-90 radioembolization. Robust biomarkers of radiosensitivity for colorectal cancer subtypes are needed to improve patient selection and dose calculation.

BR01-B10 Breast Oncoplasty: What Breast Imagers Should Know

Participants
Eric Fromke, BS, Chapel Hill, North Carolina (*Presenter*) Nothing to Disclose

TEACHING POINTS

1) Introduce the concept of breast oncoplasty.2) Understand surgical management algorithms of breast cancer, including breast oncoplasty via illustrated unique patient cases.3) Learn the common post-operative effects of breast oncoplasty, including fat necrosis.4) Identify these common post-operative imaging findings status post breast oncoplasty.5) Differentiate these common post-operative changes and conditions from tumor recurrence on imaging.

TABLE OF CONTENTS/OUTLINE

- History of breast cancer surgical treatment options- What is breast oncoplasty and who is eligible?- Common post-operative breast changes after breast oncoplasty- Fat necrosis status post breast oncoplasty: what is it and why does it happen?- How to discern between fat necrosis and tumor recurrence in breast tissue status post breast oncoplasty?- Conclusions

BR01-B3 The Meta-analysis Of The Diagnostic Value Of Contrast Enhanced Spectral Mammography Compared With Mri

Participants
Huizhi Cao, PhD, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

To systematically evaluate the accuracy of contrast enhanced spectral mammography(CESM) for diagnosis of breast cancer.*Methods and Materials Systematic review and meta-analysis of diagnosis performance of CESM in finding breast cancer. Literatures of CESM and MRI in diagnosis of breast lesions were retrieved, merged, extracted in the databases published from 2008 to 2021, including CNKI,CBM,Cochrance Library,Web of Science,Springerlink, Embase,PubMed, Wanfang and Ovid. Review Manager5.3 was applied to evaluate the publication bias. STATA13.0 software was applied to generate Deek's funnel plot. After testing the heterogeneity results of literature by using Meta Disc 14. we analyzed the sensitivity, specificity, PLR, NLR and DOR.*Results A total of 354 literatures were searched, 12 literatures were included in this study according to the inclusion and exclusion criteria. The results of summary evaluation for CESM and MRI in diagnosis of breast cancer as follow respectively: The sensitivity were 0.97 and 0.97; the specificity were 0.69 and 0.51; the DOR were 105.44 and 33.73; PLR were 2.94 and 1.95; NLR were 0.05 and 0.07; and the AUC and 95% CI were 0.9645(0.981552~0.9558) and 0.9198(0.946848~0.892752) respectively. The range of 95%CI of CESM didn't overlap that of MRI. the AUC of CESM was larger than MRI, which indicates that CESM had statistically significant difference in comparison with MRI. Deek's funnel plot showed that the publication bias was not significant (P>0.1) in the included articles.*Conclusions Meta-analysis indicates that CEMS is a valuable diagnostic method which had high veracity in the detecting breast cancer.*Clinical Relevance/Application With morphology and the enhancement characteristics of both malignant and benign lesions on contrast enhanced spectral mammography, patients with dense breasts can be benefit from CESM.

RESULTS

A total of 354 literatures were searched, 12 literatures were included in this study according to the inclusion and exclusion criteria. The results of summary evaluation for CESM and MRI in diagnosis of breast cancer as follow respectively: The sensitivity were 0.97 and 0.97; the specificity were 0.69 and 0.51; the DOR were 105.44 and 33.73; PLR were 2.94 and 1.95; NLR were 0.05 and 0.07; and the AUC and 95% CI were 0.9645(0.981552~0.9558) and 0.9198(0.946848~0.892752) respectively. The range of 95%CI of CESM didn't overlap that of MRI. the AUC of CESM was larger than MRI, which indicates that CESM had statistically significant difference in comparison with MRI. Deek's funnel plot showed that the publication bias was not significant (P>0.1) in the included articles.

CLINICAL RELEVANCE/APPLICATION

With morphology and the enhancement characteristics of both malignant and benign lesions on contrast enhanced spectral mammography, patients with dense breasts can be benefit from CESM.

BR01-B5 Background Parenchymal Enhancement In Contrast-Enhanced MR Imaging Suggests Systemic Effects Of Intrauterine Contraceptive Devices.

Participants
Luisa Huck, MD, Aachen, Germany (*Presenter*) Nothing to Disclose

PURPOSE

BPE in DCE-MRI has been established as a sensitive marker of hormonal stimulation of the breast. Levonorgestrel-releasing

BPE in DCE-MRI has been established as a sensitive marker of hormonal stimulation of the breast. Levonorgestrel-releasing intrauterine contraceptive devices (LNG-IUDs) are designed to exhibit only local effects. However, emerging evidence suggests that LNG-IUDs can be associated with systemic side effects similar to those of systemic hormonal medication. We investigated the association between LNG-IUD use and BPE in breast MRI as an established imaging biomarker of hormonal stimulation, to further explore possible systemic effects of LNG-IUDs.*Methods and Materials Our hospital data base was searched to identify premenopausal women without personal history of breast cancer or hormone or antihormone intake who had undergone standardized DCE breast MRI for screening between 01-2014 and 06-2020 at least twice, once with and without an IUD in place, with a minimum time of 4 weeks after IUD placement or removal. To avoid confounding ageing-related effects on BPE, half of included women had to have their first MRI without, the other half had their first study with IUD in place. A total of 48 premenopausal women (mean age, 45 years) were identified. Median time between the two studies was 27 months (range 1-77 months). Degree of BPE was analyzed according to the ACR categories. Statistical analyses were performed on the ACR categories using the Wilcoxon-matched pairs signed-rank test. A p-value less than 0.05 was considered statistically significant.*Results In 24/48 women (50%; [95%-CI: 35.9%-64.1%]), ACR categories did not change with vs. without IUD. In 23/48 patients (48% [33.9%-62.1%]), the ACR category was higher with vs. without IUD; in 1/48 (2% [0%-6%]), the ACR category was lower with vs. without IUD. The change of ACR category depending on presence or absence of an IUD proved highly significant (p<0.001).*Conclusions The application of an IUD is associated with increased BPE in breast MRI. This suggests that IUDs do have a systemic hormonal effect.*Clinical Relevance/Application IUDs can lead to increased BPE with implications on diagnostic accuracy in breast MRI. Moreover, the observed increased BPE supports the observation that IUDs can lead to side effects similar to HRT.

RESULTS

In 24/48 women (50%; [95%-CI: 35.9%-64.1%]), ACR categories did not change with vs. without IUD. In 23/48 patients (48% [33.9%-62.1%]), the ACR category was higher with vs. without IUD; in 1/48 (2% [0%-6%]), the ACR category was lower with vs. without IUD. The change of ACR category depending on presence or absence of an IUD proved highly significant (p<0.001).

CLINICAL RELEVANCE/APPLICATION

IUDs can lead to increased BPE with implications on diagnostic accuracy in breast MRI. Moreover, the observed increased BPE supports the observation that IUDs can lead to side effects similar to HRT.

MK04-D1   **Incidental Findings Detected On Preoperative CT Imaging Obtained For Robotic-assisted Joint Replacements: Clinical Importance And The Effect On The Scheduled Arthroplasty**

Participants
Gary Tran, MD, Ferndale, Michigan (*Presenter*) Nothing to Disclose

PURPOSE

To determine the type and frequency of incidental findings detected on preoperative computed tomography (CT) imaging obtained for robotic-assisted joint replacements and their effect on the planned arthroplasty.*Methods and Materials All preoperative CT exams performed for a robotic-assisted knee or total hip arthroplasty were obtained. This resulted in 1432 exams performed at our institution. Using a diagnosis search, reports were reviewed by 1 musculoskeletal radiologist to catalog all incidental findings and classify as significant or non-significant findings. Significant incidental findings were reserved for those that warranted further work-up, those that could alter a planned surgery and those that would require prompt notification of the ordering orthopaedic surgeon. In those with significant findings, a chart review was performed to record the relevant work-up, outcomes and if the planned arthroplasty was affected. The association between the presence of a significant finding, demographics and type of preoperative CT was evaluated. In those in which the planned arthroplasty was altered due a significant finding, any association between demographics or the type of preoperative CT was assessed. The evaluations used chi-square tests for categorical data and 2-sided sample t-tests for numerical data. Given the samples size this resulted in a power of 0.90.*Results Incidental findings were diagnosed in 740 (51.7%) patients. Of those with incidental findings, 41 (5.5%) were considered significant. A significant finding was more likely to be detected in males (P = 0.007) and on the hip protocol CT (P = 0.014). In 8 patients, these diagnoses resulted in either delay or cancellation of the arthroplasty. A planned total hip arthroplasty was more likely to be altered as compared to a knee arthroplasty (P = 0.018).*Conclusions Incidental findings are commonly detected by radiologists on preoperative CT imaging for robotic-assisted joint replacement. Several were valuable findings and resulted in a delay or even cancellation of the planned arthroplasty after detection of critical diagnoses, which if not identified may have resulted in devastating outcomes.*Clinical Relevance/Application Incidental findings are commonly detected on the preoperative CT imaging for robotic-assisted joint replacement and several were valuable diagnoses, resulting in a delayed or cancelled arthroplasty.

RESULTS

Incidental findings were diagnosed in 740 (51.7%) patients. Of those with incidental findings, 41 (5.5%) were considered significant. A significant finding was more likely to be detected in males (P = 0.007) and on the hip protocol CT (P = 0.014). In 8 patients, these diagnoses resulted in either delay or cancellation of the arthroplasty. A planned total hip arthroplasty was more likely to be altered as compared to a knee arthroplasty (P = 0.018).

CLINICAL RELEVANCE/APPLICATION

Incidental findings are commonly detected on the preoperative CT imaging for robotic-assisted joint replacement and several were valuable diagnoses, resulting in a delayed or cancelled arthroplasty.

MK04-D2   **Weight-bearing Cone Beam CT Arthrogram Of The Ankle**

Participants
Mickael Tordjman, MD, Paris, France (*Presenter*) Nothing to Disclose

PURPOSE

To present the first results of weight-bearing Cone Beam Computed Tomography arthrography of the ankle*Methods and Materials Patients from Raymond Poincaré Hospital (greater Paris region, Assistance Publique des Hopitaux de Paris), France, were included.Weight-bearing Cone Beam Computed Tomography arthrogram (wCBCTA) was performed using PedCAT LineUp (Curvebeam) after intra-articular contrast injection +/- infiltration of steroids.This examen was performed to evaluate the performance of wCBCTA to detect cartilaginous lesions of the ankle (tibiotalar joint) in comparaison with CT arthrogram. 2 radiologists reviewed independently wCBCTA and CT arthrogram. Correlation coefficients between the readers were estimated. We also compared the mean radiation dose of arthro-CBCT with CT-arthrogram of the ankle.*Results 18 patients were included in this preliminary study.wCBCTA was as accurate as CT arthrogram to detect tibiotalar cartilage lesions (correlation coefficient>0.8), with good spatial resolution and image quality. It was helpful to evaluate the stability of osteochondral defects. Median radiation dose of wCBCTA (CTDI= 2.72 mGy) was decreased compared to CT arthrogram (CTDI=16.20 mGy).*Conclusions wCBCT arthrogram is an interesting exam with good evaluation of tibiotalar cartilage, and lower radiation dose compared to conventional CT arthrogram.*Clinical Relevance/Application With low radiation dose and good evaluation of cartilage lesions,wCBCT arthrogram could be an interesting alternative to CT arthrogram, with additional weight-bearing capabilities.

RESULTS

18 patients were included in this preliminary study.wCBCTA was as accurate as CT arthrogram to detect tibiotalar cartilage lesions (correlation coefficient>0.8), with good spatial resolution and image quality. It was helpful to evaluate the stability of

osteochondral defects. Median radiation dose of wCBCTA (CTDI= 2.72 mGy) was decreased compared to CT arthrogram (CTDI=16.20 mGy).

CLINICAL RELEVANCE/APPLICATION

With low radiation dose and good evaluation of cartilage lesions,wCBCT arthrogram could be an interesting alternative to CT arthrogram, with additional weight-bearing capabilities.

MK04-D3   Osteomyelitis On MRI As A Key Predictor Of Septic Shoulder Recurrence

Participants
Ji Hwan Kim, Yangsan-si, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the clinical and radiologic predictors of septic shoulder recurrence after surgery using multivariable analysis.*Methods and Materials Patients who underwent surgery for septic shoulder between January 2011 and October 2019 were retrospectively enrolled. An orthopedic surgeon assessed the clinical (age, sex, comorbidity, duration from symptom onset to MRI and surgery, surgery method, and antibiotic usage), laboratory (serum white blood cell [WBC] count, C-reactive protein [CRP] level, and synovial cell count), and surgical (culture, biopsy results) findings. Two musculoskeletal radiologists evaluated the MRI findings (bone marrow lesions [reactive osteitis, osteomyelitis, and osteochondral erosion] and soft tissue lesions [synovitis, bursitis, and muscle edema]). Septic shoulder recurrence was evaluated at a follow-up of at least 12 months. Univariable analysis, using the Mann-Whitney or Fisher's exact test, and multivariable logistic regression analysis were used to determine the best predictor of septic shoulder recurrence. Inter-reader reliability of MRI findings was also assessed.*Results Forty-three patients (mean age, 65 years ± 13 [standard deviation]; 24 women [56%]) were enrolled and the overall rate of septic shoulder recurrence was 32.5% (14/43). On univariable analysis, mean age (P=.04), mean duration from symptom onset to surgery (P=.02), serum WBC count (P=.04), CRP level (P=.01), and presence of osteomyelitis on MRI (P<.01 for both readers) significantly differed between patients with and without recurrence, whereas on multivariable analysis, only the presence of osteomyelitis on MRI was significantly associated with septic shoulder recurrence for both readers (P=.02 and .01 for each reader respectively). The inter-reader agreement was good (?=.62-.72) for all MRI findings, except for muscle edema (fair, ?=.37).*Conclusions Osteomyelitis on MRI was the best predictor associated with septic shoulder recurrence.*Clinical Relevance/Application We recommend that clinicians routinely check for the presence of osteomyelitis on T1-weighted MRI in patients with septic shoulder; if osteomyelitis is present, more aggressive surgical treatment should be considered.

RESULTS

Forty-three patients (mean age, 65 years ± 13 [standard deviation]; 24 women [56%]) were enrolled and the overall rate of septic shoulder recurrence was 32.5% (14/43). On univariable analysis, mean age (P=.04), mean duration from symptom onset to surgery (P=.02), serum WBC count (P=.04), CRP level (P=.01), and presence of osteomyelitis on MRI (P<.01 for both readers) significantly differed between patients with and without recurrence, whereas on multivariable analysis, only the presence of osteomyelitis on MRI was significantly associated with septic shoulder recurrence for both readers (P=.02 and .01 for each reader respectively). The inter-reader agreement was good (?=.62-.72) for all MRI findings, except for muscle edema (fair, ?=.37).

CLINICAL RELEVANCE/APPLICATION

We recommend that clinicians routinely check for the presence of osteomyelitis on T1-weighted MRI in patients with septic shoulder; if osteomyelitis is present, more aggressive surgical treatment should be considered.

MK04-D4   Multimodality Imaging Of Chronic Recurrent Multifocal Osteomyelitis

Participants
Sahejmeet Guraya, MD, Cleveland Heights, Ohio (*Presenter*) Nothing to Disclose

TEACHING POINTS

- CRMO is a diagnosis of exclusion, demonstrates a wide variability in terms of initial presentation, number of affected sites, rate of recurrence, and overall prognosis.- CRMO is an important pathology to recognize to avoid unnecessary biopsies, inappropriate surgeries, and antibiotic treatment.- The purpose of this educational exhibit is to present a multimodality imaging review of CRMO utilizing radiographs, CT, PET-CT, and MRI.- Understand how to distinguish CRMO from infectious and malignant processes.

TABLE OF CONTENTS/OUTLINE

Background :- Epidemiology- Etiology: Inflammatory versus autoimmune- Imaging approach Diagnostic Criteria- Diagnosis of exclusion : Rule out malignancy and infectious etiologies- Aseptic bone biopsy- Radiographic findings- CT findings- MR findings during active and chronic phases- Bone scintigraphy/PET Clinical Presentation- Onset- Duration (prolonged clinical course with multiple relapses)- Most frequently affected locations: Phenotypic differences based on location (spine vs tubular bones)- Associated conditions- SAPHO syndrome- Complications Differential Diagnosis- Infectious osteomyelitis- Eosinophilic granuloma- Hypophosphatemia- Osteonecrosis- Fracture- Bone contusion- Malignancies (leukemia, lymphoma, Ewing sarcoma, osteosarcoma, neuroblastoma metastasis, osteoid osteoma, osteoblastoma) Treatment- NSAIDS- TNF-alpha inhibitors- Alternative therapies

NR02-B1   The Role Of Advanced Structural And Functional MRI Methods In The Diagnosis Of Epilepsy

Participants
Vasileios K. Katsaros, MD,PhD, Athens, Greece (*Presenter*) Nothing to Disclose

PURPOSE

In cases of focal epilepsy, localization of the epileptogenic zone is required for probable surgical planning if drug resistance is evident and symptoms are uncontrolled. Patients with MRI-defined lesions have a greater percentage of post surgery epileptic free status than those undergoing surgery with no MRI demonstrated lesions. The role of structural MRI is fundamental to the identification of lesions responsible for seizures, with some limitations, demanding the further practice of harmonized neuroimaging of epilepsy structural sequences-(HARNESS)-MRI protocol and post-processing methods such as Volumetry.*Methods and Materials This is a prospective single-center study in a cohort of 24 patients with a medical history of drug-resistant epilepsy and no identified brain lesion in conventional MRI. They were further examined with advanced MRI techniques by 3D-?1-weighted MPRAGE (voxel-size 1mm x 1mm x 1mm), before and after intravenous administration of 15ml Gadovist, 3D-SPACE-?2 weighted and 3D-SPACE-FLAIR-fat saturation (voxel size 0.9mm x 0.9mm x 0.9 mm) volumetric sequences. Echo-planar ?OLD (Blood Oxygenation Level Dependent) for task-based and resting state fMRI (RS-fMRI), as well as diffusion tensor imaging (DTI-FT) sequences were acquired in order to define lateralization of language and memory, and if possible, to visualize epileptogenic zones. For postprocessing of task-based fMRI and DTI-FT, BrainMagix (Imagilys- Belgium), for RS-fMRI GraphICA (Brainet-Canada), and for Volumetric Quantitative Evaluation SurferMagix (platform which integrates Free-Surfer into BrainMagix), were used.*Results Advanced and quantitative imaging techniques revealed lesions responsible for epileptic seizures in 19 out of 24 patients not detected by conventional MRI. After surgery, 15 out of 16 patients, were free of disabling seizures (Engel class I), with one-year follow-up, while 3 out of 19 patients have not yet undergone surgery*Conclusions HARNESS-MRI protocol combined with advanced and quantitative imaging techniques have the potential to reveal unidentified brain lesions by conventional MRI providing a delineating planning for surgery patients candidates by simultaneous defining the lateralization of language and memory, as a probable exclusion surgical criterion. *Clinical Relevance/Application The clinical relevance of this presentation is to delineate the importance of HARNESS-MRI protocol in patients with drug resistant epilepsy who are candidates for surgery.

RESULTS

Advanced and quantitative imaging techniques revealed lesions responsible for epileptic seizures in 19 out of 24 patients not detected by conventional MRI. After surgery, 15 out of 16 patients, were free of disabling seizures (Engel class I), with one-year follow-up, while 3 out of 19 patients have not yet undergone surgery

CLINICAL RELEVANCE/APPLICATION

The clinical relevance of this presentation is to delineate the importance of HARNESS-MRI protocol in patients with drug resistant epilepsy who are candidates for surgery.

NR02-B4   Ct Angiographic Radiomics Signature For Risk-Stratification In Anterior Large Vessel Occlusion (LVO) Stroke

Participants
Emily Avery, BA, New Haven, Connecticut (*Presenter*) Nothing to Disclose

PURPOSE

As "time is brain" in acute stroke triage, the need for automated prognostic tools continues to increase, particularly in rapidly expanding tele-stroke settings. We aimed to predict discharge and long-term outcomes of anterior circulation LVO patients based on admission CTA radiomics to guide time-sensitive treatment decisions regarding implementation of endovascular thrombectomy (ET).*Methods and Materials We automatically extracted 1116 radiomics features from the anterior circulation territory on admission CTAs of 829 acute LVO patients who underwent ET in 2 academic centers. We trained, optimized, validated & compared different machine learning models to predict favorable outcome (modified Rankin Scale<3) at discharge and 3-month follow-up using 3 different input sets: "Radiomics", "Radiomics+Treatment" (reperfusion success mTICI), and "Combined" (clinical, radiomics & treatment variables).*Results Our datasets totaled 496 Yale patients for training (age 70.4±15.6, admission NIHSS 15(10-19), 46% female), 101 Yale patients for independent validation (age 69.2±14.0, NIHSS 15(7-19), 49% female), and 232 Geisinger Health patients for external validation (age 70.4±15.6, NIHSS 18(12-23), 46% female). For discharge outcome prediction, models were optimized/trained on n=494 and validated on n=100 patients from Yale. In receiver operating characteristic analysis of the independent validation cohort, there was no significant difference between Combined models (area under the curve, AUC=0.77) vs Radiomics+Treatment (AUC=0.78, p=0.78) or Radiomics (AUC=0.78, p=0.55). For long-term outcome prediction, models were optimized/trained on n=373 and validated on n=72 patients from Yale, as well as n=232 patients from Geisinger. In the Yale independent validation cohort, there was no significant difference between Combined models (AUC=0.76) vs Radiomics+Treatment (AUC=0.72, p=0.39) or Radiomics (AUC=0.72, p=0.39). However, in external validation, the Combined model (AUC=0.74) outperformed Radiomics+Treatment (AUC=0.66, p<0.001) and Radiomics (AUC=0.68, p<0.01) models for long-term prediction.*Conclusions We could successfully train and validate radiomics models for prediction of LVO outcome at both discharge

and long-term, even in the absence of clinical training data. Models including clinical input variables demonstrated more stable generalizability on external validation.*Clinical Relevance/Application Automated assessment of admission CTA radiomics can provide prognostic information in acute LVO stroke candidates for ET. Such objective and time-sensitive risk-stratification can guide treatment decisions, particularly in tele-stroke settings, and may help increase the number of patients eligible for ET.

RESULTS

Our datasets totaled 496 Yale patients for training (age 70.4±15.6, admission NIHSS 15(10-19), 46% female), 101 Yale patients for independent validation (age 69.2±14.0, NIHSS 15(7-19), 49% female), and 232 Geisinger Health patients for external validation (age 70.4±15.6, NIHSS 18(12-23), 46% female). For discharge outcome prediction, models were optimized/trained on n=494 and validated on n=100 patients from Yale. In receiver operating characteristic analysis of the independent validation cohort, there was no significant difference between Combined models (area under the curve, AUC=0.77) vs Radiomics+Treatment (AUC=0.78, p=0.78) or Radiomics (AUC=0.78, p=0.55). For long-term outcome prediction, models were optimized/trained on n=373 and validated on n=72 patients from Yale, as well as n=232 patients from Geisinger. In the Yale independent validation cohort, there was no significant difference between Combined models (AUC=0.76) vs Radiomics+Treatment (AUC=0.72, p=0.39) or Radiomics (AUC=0.72, p=0.39). However, in external validation, the Combined model (AUC=0.74) outperformed Radiomics+Treatment (AUC=0.66, p<0.001) and Radiomics (AUC=0.68, p<0.01) models for long-term prediction.

CLINICAL RELEVANCE/APPLICATION

Automated assessment of admission CTA radiomics can provide prognostic information in acute LVO stroke candidates for ET. Such objective and time-sensitive risk-stratification can guide treatment decisions, particularly in tele-stroke settings, and may help increase the number of patients eligible for ET.

NR02-B5 Comparison Of Quantification Software Tools For Reproducibility Of GABA+ In The Human Brain By Mr Spectroscopy At 3 Tesla

Participants
Xiaopeng Zhou, West Lafayette, Indiana (*Presenter*) Nothing to Disclose

PURPOSE

GABA has been detected most widely with MEGA-PRESS [1] in healthy and diseased brain [2-5] and quantified with different software tools, such as LCModel [7], Gannet [8], or JMRUI [9]. A study [10] with MEGA-PRESS datasets from 2 GE and 2 Philips scanners showed that there was moderate agreement between software tools. However, there was no ground-truth GABA level to determine which software provided more accurate results. Another study [11] using phantoms with known GABA concentrations showed that LCModel can provide more accurate results, but Gannet was the most consistent tool among 5 software tools. In this study we extended this comparison of LCModel and Gannet to test the reproducibility of in vivo GABA measurements at 3 T.*Methods and Materials 8 healthy subjects (29 ± 2 years; 4 F) were scanned with MEGA-PRESS (TR/TE = 2000/68 ms, Averages =160) on a Siemens Prisma 3T scanner. Written consent was obtained from each subject. All scans were acquired in parietal lobe (voxel size of 3×3×3 cm3). Each subject underwent two sessions with the same MR sequences on the same day. Gannet [8] was used for preprocessing data with frequency and phase correction. Fitting of the preprocessed data to obtain GABA+/tCr was done once with Gannet, and once with LCModel. In LCModel, the special 'mega-press-2' scheme version 6.3-0L was used to fit the GABA-edited difference spectra. Edit-off spectra were fitted with LCModel to obtain tCr.*Results Inter-individual CVs and GABA/tCr (mean±SD) values were: LCModel, 7.1% and 0.13±0.01 for scan 1, 15.3% and 0.12±0.02 for scan 2; Gannet, 14.1% and 0.11±0.02 for scan 1, 10.5% and 0.11±0.01 for scan 2. Intra-individual CVs for repeated GABA+/tCr measurements were: 8.1± 10.0% for LCModel, 5.1 ± 3.7% for Gannet. Only LCModel and Gannet for scan1 GABA/tCr were significantly different (p=0.0049). A significant positive correlation was observed between GABA/tCr of test-repeat sessions with Gannet (r =0.79, p= 0.019), but not with LCModel. Our results suggest that results from Gannet and LCModel are comparable, but Gannet results are more reproducible. This finding agrees with the phantom study that showed higher reproducibility for Gannet.*Conclusions This finding suggests that Gannet and LCModel are comparable, but Gannet is more robust for reproducibility studies. Testing different settings for LCModel, and using data from more scanners with repeated sessions will be necessary to verify the performance of analysis tools for quantification of GABA and provide a standard for clinical studies.*Clinical Relevance/Application GABA is the primary inhibitory neurotransmitter, which is a potential biomarker for surrogating neurological and many psychiatric disorders. Accurately quantifying GABA is still challenging and needs continuing effort.

RESULTS

Inter-individual CVs and GABA/tCr (mean±SD) values were: LCModel, 7.1% and 0.13±0.01 for scan 1, 15.3% and 0.12±0.02 for scan 2; Gannet, 14.1% and 0.11±0.02 for scan 1, 10.5% and 0.11±0.01 for scan 2. Intra-individual CVs for repeated GABA+/tCr measurements were: 8.1± 10.0% for LCModel, 5.1 ± 3.7% for Gannet. Only LCModel and Gannet for scan1 GABA/tCr were significantly different (p=0.0049). A significant positive correlation was observed between GABA/tCr of test-repeat sessions with Gannet (r =0.79, p= 0.019), but not with LCModel. Our results suggest that results from Gannet and LCModel are comparable, but Gannet results are more reproducible. This finding agrees with the phantom study that showed higher reproducibility for Gannet.

CLINICAL RELEVANCE/APPLICATION

GABA is the primary inhibitory neurotransmitter, which is a potential biomarker for surrogating neurological and many psychiatric disorders. Accurately quantifying GABA is still challenging and needs continuing effort.

NR02-B6 Improved Statistical Confidence Via Locally Low-rank Denoising Of Task Functional MRI Data

Participants
Nolan Meyer, BS, Rochester, Minnesota (*Presenter*) Nothing to Disclose

PURPOSE

This work applies locally low-rank (LLR) denoising of clinically specialized task-based functional MRI data to improve statistical confidence in localizing activation areas for motor and language tasks.*Methods and Materials Eleven healthy subjects were scanned under an IRB-approved protocol on a compact 3T MRI scanner with high spatial resolution (2.5mm and 1.9mm isotropic) echo planar imaging (EPI) pulse sequences during task-based fMRI studies. Tasks selected are used in clinical practice at our institution for presurgical language and motor mapping, including rhyming, sentence completion, and bilateral finger tapping. LLR denoising was completed on complex-valued EPI data. Conventional and LLR data were then processed equivalently with fMRI software used clinically at our institution.Assessment of fMRI results was completed by four board-certified neuroradiologists who set statistical thresholds of activation maps in consensus. For conventional, non-denoised data and LLR-denoised data, thresholds

were set for the supplementary motor area (SMA), cerebellum, non-dominant and dominant motor regions, and in aggregate for finger tapping data; and for Broca's area, Wernicke's area, and in aggregate for language data. Statistical threshold data were compared with nonparametric statistical tests. Matched-pairs rank-biserial correlations were computed as nonparametric effect size estimates.*Results LLR denoising required approximately 32 seconds per slice for 1.9 mm data and 9 seconds for 2.5 mm data. Reporting results as rank-biserial correlations r and p-values, LLR denoising produced statistically significant increases in neuroradiologists' consensus thresholds for all regions except the cerebellum ($r = 0.546$, $p = 0.062$). Consensus t-statistics were significantly increased for the SMA ($r = 0.606$, $p = 0.042$), non-dominant motor ($r = 0.879$, $p = 3.42 \times 10^{-3}$) and dominant motor ($r = 1$, $p = 4.88 \times 10^{-4}$) regions, and aggregate maps ($r = 0.849$, $p = 4.88 \times 10^{-3}$). Language thresholds were increased for Broca's area for rhyming ($r = 1$, $p = 4.88 \times 10^{-4}$) and sentence completion ($r = 0.964$, $p = 1.95 \times 10^{-3}$), Wernicke's area for rhyming ($r = 0.636$, $p = 0.042$) and sentence completion ($r = 1$, $p = 9.77 \times 10^{-4}$), and in aggregate for rhyming ($r = 0.849$, $p = 4.88 \times 10^{-3}$) and sentence completion ($r = 0.891$, $p = 4.88 \times 10^{-3}$).*Conclusions LLR denoising produces significant increases in t-statistic thresholds, set in consensus by four neuroradiologists, for task fMRI data. At thresholds selected for conventional data, additional active cortex areas are revealed on maps derived from denoised data.*Clinical Relevance/Application LLR denoising allows radiologists interpreting functional activation maps increased confidence in localizing eloquent cortex in presurgical imaging.

RESULTS

LLR denoising required approximately 32 seconds per slice for 1.9 mm data and 9 seconds for 2.5 mm data. Reporting results as rank-biserial correlations r and p-values, LLR denoising produced statistically significant increases in neuroradiologists' consensus thresholds for all regions except the cerebellum ($r = 0.546$, $p = 0.062$). Consensus t-statistics were significantly increased for the SMA ($r = 0.606$, $p = 0.042$), non-dominant motor ($r = 0.879$, $p = 3.42 \times 10^{-3}$) and dominant motor ($r = 1$, $p = 4.88 \times 10^{-4}$) regions, and aggregate maps ($r = 0.849$, $p = 4.88 \times 10^{-3}$). Language thresholds were increased for Broca's area for rhyming ($r = 1$, $p = 4.88 \times 10^{-4}$) and sentence completion ($r = 0.964$, $p = 1.95 \times 10^{-3}$), Wernicke's area for rhyming ($r = 0.636$, $p = 0.042$) and sentence completion ($r = 1$, $p = 9.77 \times 10^{-4}$), and in aggregate for rhyming ($r = 0.849$, $p = 4.88 \times 10^{-3}$) and sentence completion ($r = 0.891$, $p = 4.88 \times 10^{-3}$).

CLINICAL RELEVANCE/APPLICATION

LLR denoising allows radiologists interpreting functional activation maps increased confidence in localizing eloquent cortex in presurgical imaging.

NR02-B7   CT Myelography With Renal Contrast: Analysing Beyond CSF Leak

Participants
Mika Shibuya, MD, Sao Paulo, Brazil (*Presenter*) Nothing to Disclose

PURPOSE

This study aims to demonstrate that the presence of early iodinated contrast in the renal excretory system in CT myelography can also be found in isolated leakage at the lumbar puncture site, even in patients without suspicion of CSF leak.*Methods and Materials Thirty-six CT myelography scans between June 2011 and December 2020 performed for different causes besides hypotension CSF were retrospectively evaluated by two neuroradiologists and one interventional radiologist for the presence of contrast in the renal excretory system, leakage at the lumbar puncture site and signs of CSF leak, like epidural collections or hyperdense paraspinal vein sign.*Results Among the 36 CT myelography evaluated, two were excluded for having performed a gadolinium MRI in the last 48 hours before CT myelography. Of the 34 exams, the presence of renal iodinated contrast excretion was found in 14 cases (41%), 5 with leakage at the puncture site (35,7%), 5 with both leakage at the puncture site and epidural / foraminal collection (35,7%), 3 only with epidural collection (21.4%) and 1 without epidural collection and neither leakage at the puncture site (7.2%).*Conclusions Although it is known that many cases of CSF leak, especially CSF venous fistulas, are difficult to diagnose and have already been associated with renal excretion of contrast media after intrathecal administration, we consider that the presence of renal iodinated contrast in CT myelography can also be found in cases of extravasation of the iodinated contrast at the puncture site, regardless of the epidural collections. Despite the limited sample of cases in our study, this finding is consistent with those found in radionuclide cisternographies, and should be carefully evaluated in cases of CSF leak.*Clinical Relevance/Application Despite the literature shows as a specific finding of CSF leak the presence of early renal excretion of the iodinated contrast in CT myelography, this finding must be carefully evaluated, since we found it in patients even without suspicion of CSF hypotension, especially when there is leakage of the iodinated contrast at the lumbar puncture site.

RESULTS

Among the 36 CT myelography evaluated, two were excluded for having performed a gadolinium MRI in the last 48 hours before CT myelography. Of the 34 exams, the presence of renal iodinated contrast excretion was found in 14 cases (41%), 5 with leakage at the puncture site (35,7%), 5 with both leakage at the puncture site and epidural / foraminal collection (35,7%), 3 only with epidural collection (21.4%) and 1 without epidural collection and neither leakage at the puncture site (7.2%).

CLINICAL RELEVANCE/APPLICATION

Despite the literature shows as a specific finding of CSF leak the presence of early renal excretion of the iodinated contrast in CT myelography, this finding must be carefully evaluated, since we found it in patients even without suspicion of CSF hypotension, especially when there is leakage of the iodinated contrast at the lumbar puncture site.

NR02-B9   Deep Learning With Graph Convolutional Neural Networks Using Connectivity-based Features From Functional MRI For Diagnosis Of Autism Spectrum Disorder

Participants
Axel Wismueller, MD,PhD, Pittsford, New York (*Presenter*) Research Grant, Aidoc Medical Ltd;Advisory Board Member, Aidoc Medical Ltd

PURPOSE

To develop, test, and evaluate a graph convolutional neural network deep learning framework using connectivity-based functional MRI features for classifying Autism Spectrum Disorder (ASD) patients in a large patient cohort (Autism Brain Imaging Data Exchange - ABIDE).*Methods and Materials It has been shown in the literature that Autism Spectrum Disorder (ASD) is associated with changes in brain network connectivity. ABIDE I is currently the largest publicly available preprocessed dataset for ASD collected from 16 international sites containing 1112 resting-state fMRI (rsfMRI) datasets, including 539 ASD patients and 573 typical controls. We used the data from the CPAC preprocessing pipeline, which encompasses two steps of structural and functional processing. The AAL human brain atlas was used to extract 116 brain region-specific fMRI time-series. A graph convolutional neural

network (GCN) with three layers including two convolution and average pooling layers and one fully-connected layer was trained for the classification task, where the upper triangle of the cross-correlation connectivity matrix for each dataset served as 6670-dimensional input feature vector to the GCN. Strict training/test data separation was performed in a 10-fold cross-validation approach.*Results Mean and best classification accuracies for identifying ASD patients in the ABIDE I dataset were 66±5 % and 74 %, respectively, which is comparable to the performance of the best state-of-the-art methods in the literature for this dataset. This is noteworthy, because only imaging-based features were used for classification in our study, whereas other studies frequently include non-imaging features, such as age and gender.*Conclusions Our results suggest that the connectivity structure derived from fMRI analysis can be used as an imaging biomarker for classifying ASD patients from control subjects. By combining deep learning with handcrafted brain connectivity features, state-of-the-art classification accuracy can be achieved on the challenging multi-institutional ABIDE I data.*Clinical Relevance/Application Combining graph-convolutional deep learning approaches with brain connectivity features shows potential for development of diagnostic fMRI biomarkers in Autism Spectrum Disorder.

RESULTS

Mean and best classification accuracies for identifying ASD patients in the ABIDE I dataset were 66±5 % and 74 %, respectively, which is comparable to the performance of the best state-of-the-art methods in the literature for this dataset. This is noteworthy, because only imaging-based features were used for classification in our study, whereas other studies frequently include non-imaging features, such as age and gender.

CLINICAL RELEVANCE/APPLICATION

Combining graph-convolutional deep learning approaches with brain connectivity features shows potential for development of diagnostic fMRI biomarkers in Autism Spectrum Disorder.

GI04-A10   Artificial Intelligence Can Aid In Predicting Individual Lymph Node Metastasis In Gastric Cancer

Participants

Yun Qin, MD, Chengdu, China (*Presenter*) Nothing to Disclose

PURPOSE

Accurate preoperative lymph node (LN) metastasis assessment in gastric cancer (GC) is imperative but challenging, particularly on a per-LN basis. Therefore, we aimed to develop an artificial intelligence (AI) model based on preoperative CT images to predict individual LN metastasis and to investigate whether it could be used to improve radiologist interpretation accuracies.*Methods and Materials Consecutive GC patients of whom the resected LNs could be matched rigidly on preoperative CT images were retrieved from a prospectively-collected database spanning 5 years. An AI model, integrating handcraft radiomics and deep learning features, was generated based on both the LNs and corresponding primary tumors. LN metastasis was predicted independently by three radiologists and the AI model against histopathology. Diagnostic performances were characterized by area under the receiver operating characteristic curve (AUC), sensitivity, specificity, accuracy, and net reclassification index (NRI).*Results A total of 1381 LNs (739 [53.5%] metastasis positive) in 666 patients (median age, 61 years; range, 29-86 years; 462 males) were included. In the validation set, the AUC of the AI model was 0.804 for predicting individual LN metastasis. Compared with radiologist consensus interpretation, the AI model demonstrated a higher specificity (70.6% vs. 58.5%, p<0.001) and accuracy (72.3% vs. 67.5%), but a lower sensitivity (73.9% vs. 85.8%, p<0.001). The NRI analysis revealed a 19.34% net diagnostic improvement of the AI model than radiologists (NRI: 0.1987, p<0.001). The specificity of radiologist consensus interpretation with AI assistance improved significantly than that without AI assistance (60.3% vs. 48.5%, p<0.001), whereas the sensitivities remained comparable (81.5% vs. 85.8%, p=0.052).*Conclusions In GC patients, we developed a CT-based AI model with high accuracy for predicting the metastasis status of individual LNs. The AI model also showed promise in assisting radiologists to improve their diagnostic accuracies.*Clinical Relevance/Application The CT-based AI model demonstrated high accuracy for predicting LNs metastasis which can help radiologists to improve diagnostic accuracies and clinicians to optimize treatment plan.

RESULTS

A total of 1381 LNs (739 [53.5%] metastasis positive) in 666 patients (median age, 61 years; range, 29-86 years; 462 males) were included. In the validation set, the AUC of the AI model was 0.804 for predicting individual LN metastasis. Compared with radiologist consensus interpretation, the AI model demonstrated a higher specificity (70.6% vs. 58.5%, p<0.001) and accuracy (72.3% vs. 67.5%), but a lower sensitivity (73.9% vs. 85.8%, p<0.001). The NRI analysis revealed a 19.34% net diagnostic improvement of the AI model than radiologists (NRI: 0.1987, p<0.001). The specificity of radiologist consensus interpretation with AI assistance improved significantly than that without AI assistance (60.3% vs. 48.5%, p<0.001), whereas the sensitivities remained comparable (81.5% vs. 85.8%, p=0.052).

CLINICAL RELEVANCE/APPLICATION

The CT-based AI model demonstrated high accuracy for predicting LNs metastasis which can help radiologists to improve diagnostic accuracies and clinicians to optimize treatment plan.

GI04-A2   The Value Of Multi-material Decomposition Algorithm Based On CT Spectral Imaging In Quantitative Diagnosis Of Chemotherapy Related Fatty Liver Disease

Participants

Mengyuan Jing, Lanzhou, China (*Presenter*) Nothing to Disclose

PURPOSE

To explore whether quantitative measurements of liver fat, based on multi-material decomposition (MMD) spectral imaging,may become a novel tool to evaluate chemotherapy related fatty liver disease (CRFLD).*Methods and Materials Eighty one patients who underwent enhanced CT spectral scans after chemotherapeutic treatment were retrospectively recruited. These patients had no history of fatty liver, liver disease, liver tumors and large alcohol intake before treatment. Due to the results of ultrasonic or magnetic resonance after chemotherapy, patients were divided into CRFLD group and non-CRFLD groups. Spectral data was post-processed by Hepatic VCAR to generate liver fat images in venous phase, on which three physicians measured the fat fraction(FF)of the whole liver. The average value of three measurements was calculated and regarded as the final value of FF. On unenhanced CT images, the same three doctors measured CT values of spleen and liver, and calculated average values to acquirethe Liver-to-spleen ratio (LSR,LSR = CT valueliver/CT valuespleen) . The FF and liver-to-spleen ratio (LSR) were compared between two groups. The receiver operating characteristics (ROC) curve was generated to evaluate the performance of FF and LSR.*Results Age and gender performed no significant difference between groups (P>0.05). The FF in CRFLD group was higher than that in non-CRFLD group (8.166±3.690 VS 3.801±1.266, P<0.05). The area under the curve (AUC) of FF in diagnosing CRFLD was 0.881 with the sensitivity and specificity of 82.4% and 87.2%, respectively. The LSR in CRFLD group was lower than that in non-CRFLD group(1.057±0.149 VS 1.173±0.119 P<0.05). The AUC of LSR was 0.740 with the sensitivity and specificity of 66.0% and 73.5%, respectively.*Conclusions MMD algorithm can provide whole liver FF using noninvasive method, which is a reliable indicator to quantitatively assess CRFLD.*Clinical Relevance/Application Quantitative CT measurement of liver fat based on the technique of

CT MMD spectral imaging is not only a novel tool for liver fat quantification, but also has high diagnostic efficiency.

RESULTS

Age and gender performed no significant difference between groups (P>0.05). The FF in CRFLD group was higher than that in non-CRFLD group (8.166±3.690 VS 3.801±1.266, P<0.05). The area under the curve (AUC) of FF in diagnosing CRFLD was 0.881 with the sensitivity and specificity of 82.4% and 87.2%, respectively. The LSR in CRFLD group was lower than that in non-CRFLD group(1.057±0.149 VS 1.173±0.119 P<0.05). The AUC of LSR was 0.740 with the sensitivity and specificity of 66.0% and 73.5%, respectively.

CLINICAL RELEVANCE/APPLICATION

Quantitative CT measurement of liver fat based on the technique of CT MMD spectral imaging is not only a novel tool for liver fat quantification, but also has high diagnostic efficiency.

GI04-A6   Prediction Early Recurrence Of <= 5cm Solitary Hepatocellular Carcinoma By Radiomic Analysis Of Mri

Participants
Leyao Wang, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the value of radiomic model based on preoperative magnetic resonance images (MRI) in predicting early recurrence (ER, =2 years) of = 5cm solitary hepatocellular carcinoma (HCC) after radical hepatectomy.*Methods and Materials 190 HCC patients confirmed by pathology in our hospital from January 2012 to December 2017 were enrolled retrospectively. All patients were divided into training and validation cohort according to 7:3 proportion, and subdivided into ER and non-ER subgroups. 1316 radiomics features were extracted from preoperative MRI in regions of the entire tumor. General univariate analysis, correlation analysis, mRMR and LASSO regression model, was applied to select features and construct model. Multivariate logistic regression analysis was used to determine the factors associated with ER. The prediction performance was evaluated by area under the receiver operation characteristic curves (AUC), sensitivity, specificity and accuracy.*Results This study included 80 patients in ER group and 110 patients in non-ER group. Multivariate analysis showed that cirrhosis (OR, 2.98 [95%CI, 1.20 to 7.39], P=0.019), non-smooth tumor margin (OR, 0.42 [95%CI, 0.16 to 1.05], P=0.064), arterial peritumoral enhancement (OR, 5.03 [95%CI, 1.18 to 21.43], P=0.029), satellite nodule (OR, 6.21 [95%CI, 1.45 to 26.62], P=0.014), serosal invasion (OR, 2.08 [95%CI, 0.91 to 4.73], P=0.082) and ALB (OR, 0.89 [95%CI, 0.80 to 0.99], P=0.032) were associated with ER.The above imaging features and clinicopathological factors were used to construct the combined radiomics-clinicopathological nomogram. The AUC value, sensitivity, specificity and accuracy of the combined nomogram in the training group and the validation group were 0.90, 71.83%, 91.94%, 81.20% and 0.88, 85.71%, 83.33%, 84.21%, respectively. The calibration prediction curve fits well with the standard curve.*Conclusions The nomogram incorporating clinicopathological factors and radiomic features derived from MRI achieved satisfactory prediction of the individualized risk of ER in patients with =5 cm solitary HCC.*Clinical Relevance/Application In patients with early-stage HCC, liver resection is accepted as the first-line treatment option. Nevertheless, the long-term outcome remains unsatisfactory because of the high recurrence incidence up to 70% within 5 years. The time to recurrence is an independent survival factor, and HCC patients with ER after hepatic resection tend to have lower overall survival and poor prognosis. Thus, it is crucial to identify sensitive biomarkers related to the ER of HCC to guide further surveillance and treatment.

RESULTS

This study included 80 patients in ER group and 110 patients in non-ER group. Multivariate analysis showed that cirrhosis (OR, 2.98 [95%CI, 1.20 to 7.39], P=0.019), non-smooth tumor margin (OR, 0.42 [95%CI, 0.16 to 1.05], P=0.064), arterial peritumoral enhancement (OR, 5.03 [95%CI, 1.18 to 21.43], P=0.029), satellite nodule (OR, 6.21 [95%CI, 1.45 to 26.62], P=0.014), serosal invasion (OR, 2.08 [95%CI, 0.91 to 4.73], P=0.082) and ALB (OR, 0.89 [95%CI, 0.80 to 0.99], P=0.032) were associated with ER.The above imaging features and clinicopathological factors were used to construct the combined radiomics-clinicopathological nomogram. The AUC value, sensitivity, specificity and accuracy of the combined nomogram in the training group and the validation group were 0.90, 71.83%, 91.94%, 81.20% and 0.88, 85.71%, 83.33%, 84.21%, respectively. The calibration prediction curve fits well with the standard curve.

CLINICAL RELEVANCE/APPLICATION

In patients with early-stage HCC, liver resection is accepted as the first-line treatment option. Nevertheless, the long-term outcome remains unsatisfactory because of the high recurrence incidence up to 70% within 5 years. The time to recurrence is an independent survival factor, and HCC patients with ER after hepatic resection tend to have lower overall survival and poor prognosis. Thus, it is crucial to identify sensitive biomarkers related to the ER of HCC to guide further surveillance and treatment.

VA01-A

Vascular Imaging Sunday Poster Discussions

Sub-Events

VA01-A2   **Advances In Vascular Ultrasound**

Awards
Certificate of Merit

Participants
Margarita Revzin, MD, Wilton, Connecticut (*Presenter*) Nothing to Disclose

TEACHING POINTS

1. Familiarize radiologists with current problems and limitations of traditional vascular ultrasound imaging 2. Review various new ultrasound technologies that are available on a market for evaluation of slow flow, their benefits and limitations 3. Discuss role of new vascular imaging in identification of slow flow with specific emphasis on basic principles and image optimization of new vascular US techniques as a key to accurate interpretation 4. Recognize future directions and challenges in vascular ultrasound

TABLE OF CONTENTS/OUTLINE

1. Traditional Doppler US and its limitations 2. Advancements in vascular US imaging: basic principles, usage, limitations, availability 3. Role of advanced vascular US: a. Directional power Doppler (flow direction) b. Contrast-enhanced US (tumor neovascularity, thrombosis, post EVAR eval) c. B-flow imaging (plaque ulceration, flow sensitivity) d. Microvascular flow (neovascularity, thrombosis, stenosis) e. Photo-acoustic imaging (acute vs chronic blood clot, vulnerable plaque, patency of peripheral arterial system) f. Intravascular imaging (IR guidance (stent and catheter placement), endoluminal measurement, guidance for dissection flap fenestration) g. Elastography (vascular wall disease, acute vs chronic clot) h. 3D vascular imaging (3D imaging of neck vasculature & abdominal aorta, plaque characterization) 4. Future directions and challenges of the vascular US (market availability, research & data driven projects, cost analysis, comparison to other modalities: CTA and MRA)

IR01-A1   Immune Modulation Following Radioembolization: An Observational Studies.

Participants
Shamar Young, MD, Minnespolis, Minnesota (*Presenter*) Consultant, Boston Scientific Corporation;Consultant, BTG International Ltd;Consultant, Galil Medical Ltd;Consultant, Galvanize

PURPOSE

The ability to deliver very high doses of radiation to the tumor suggest that radioembolization may be an ideal candidate for synergistic treatment algorithms with immunotherapies. However, little data is available in terms of immunomodulatory effects of radioembolization, this study aims to fill that gap.*Methods and Materials This is a prospective observational study (NCT03889093). Patients who enrolled had blood draws prior to radioembolization and then at 1, 4, and 12 weeks following treatment. They also underwent biopsy prior to and 2 weeks after treatment. The blood was separated into cellular and serum components and then stored for batch analysis. To date 11 patients have enrolled with several still in the collection phase. Data from the first 5 patients is presented here.*Results Cytokines and peripheral blood monocytes were collected at on the day of but prior to treatment and at 1, 4, and 12 weeks. The mean serum TNF-a was 4.62 ± 2.31, 3.55 ± 1.69, 3.19 ± 1.09, and 2.05 ± 0.31 respectively (p=0.05). The average serum IFN-? was 0.45 ± 0.57, 0.42 ± 0.57, 0.29 ± 0.35, and 0.11 ± 0.16 respectively (p=0.18). The average serum IL-6 was 5.84 ± 5.69, 6.31 ± 4.91, 5.3 ± 6.61, and 6.96 ± 9.03 respectively (p=0.41). The average serum Fit-3 ligand was 74.49 ± 35.07, 82.62 ± 10.78, 64.6 ± 11.48, and 66.71 ± 14.56 31 respectively (p=0.36). The mean population of CD4+CD45RA+CCR7- cells at baseline, 1, 4 and 12 weeks was 1.41 ± 0.78, 1.31 ± 0.79, 0.93 ± 0.19, and 0.65 ± 0.16 respectively. The mean population of CD4+CD45RA-CCR7- cells was 22.36 ± 6.8, 17.58 ± 8.82, 17.72 ± 9.85, and 13.54 ± 9.25 respectively. The mean population of CD4+CD45RA-CD27- cells was 15.36 ± 9.21, 14.37 ± 8.08, 14.23 ± 11.54, and 9.8 ± 8.95 respectively. The mean population of CD8+CD45RA+CCR7- cells was 35.36 ± 29.49, 26.92 ± 33.89, 32.21 ± 33.36, and 33.54 ± 47.2 respectively. The mean population of CD8+CD45RA-CCR7- cells was 12.98 ± 6.38, 5.21 ± 1.21, 8.54 ± 4.08, and 4.01 ± 1.15 respectively. The mean population of CD8+CD45RA-CD27- cells was 4.9 ± 2.4, 3.85 ± 3.03, 4.68 ± 3.84, and 1.81 ± 0.62 respectively. The mean number of natural killer T cells was 7.49 ± 14.94, 8.56 ± 18.14, 6.92 ± 12.86, 12.7 ± 20.56 respectively.*Conclusions This early data suggests that radioembolization does have the ability to modulate the immune system, however, further data is needed to determine the extent and specific clonal populations being effected.*Clinical Relevance/Application The development of immunotherapies has revolutionized cancer therapy. The next phase will likely be synergistic treatment algorithms with immunotherapies and loco-regional treatments. This trial provides information on the immunomodulatory effects of radioembolization, an important building block to design synergistic trials.

RESULTS

Cytokines and peripheral blood monocytes were collected at on the day of but prior to treatment and at 1, 4, and 12 weeks. The mean serum TNF-a was 4.62 ± 2.31, 3.55 ± 1.69, 3.19 ± 1.09, and 2.05 ± 0.31 respectively (p=0.05). The average serum IFN-? was 0.45 ± 0.57, 0.42 ± 0.57, 0.29 ± 0.35, and 0.11 ± 0.16 respectively (p=0.18). The average serum IL-6 was 5.84 ± 5.69, 6.31 ± 4.91, 5.3 ± 6.61, and 6.96 ± 9.03 respectively (p=0.41). The average serum Fit-3 ligand was 74.49 ± 35.07, 82.62 ± 10.78, 64.6 ± 11.48, and 66.71 ± 14.56 31 respectively (p=0.36). The mean population of CD4+CD45RA+CCR7- cells at baseline, 1, 4 and 12 weeks was 1.41 ± 0.78, 1.31 ± 0.79, 0.93 ± 0.19, and 0.65 ± 0.16 respectively. The mean population of CD4+CD45RA-CCR7- cells was 22.36 ± 6.8, 17.58 ± 8.82, 17.72 ± 9.85, and 13.54 ± 9.25 respectively. The mean population of CD4+CD45RA-CD27- cells was 15.36 ± 9.21, 14.37 ± 8.08, 14.23 ± 11.54, and 9.8 ± 8.95 respectively. The mean population of CD8+CD45RA+CCR7- cells was 35.36 ± 29.49, 26.92 ± 33.89, 32.21 ± 33.36, and 33.54 ± 47.2 respectively. The mean population of CD8+CD45RA-CCR7- cells was 12.98 ± 6.38, 5.21 ± 1.21, 8.54 ± 4.08, and 4.01 ± 1.15 respectively. The mean population of CD8+CD45RA-CD27- cells was 4.9 ± 2.4, 3.85 ± 3.03, 4.68 ± 3.84, and 1.81 ± 0.62 respectively. The mean number of natural killer T cells was 7.49 ± 14.94, 8.56 ± 18.14, 6.92 ± 12.86, 12.7 ± 20.56 respectively.

CLINICAL RELEVANCE/APPLICATION

The development of immunotherapies has revolutionized cancer therapy. The next phase will likely be synergistic treatment algorithms with immunotherapies and loco-regional treatments. This trial provides information on the immunomodulatory effects of radioembolization, an important building block to design synergistic trials.

IR01-A7   Pictorial Storyboard Of Uterine Artery Embolization Complications: What Every Radiology Trainee Ought To Know

Awards
Certificate of Merit

Participants
Shuchi Zinzuwadia, Forest Park, Illinois (*Presenter*) Nothing to Disclose

TEACHING POINTS

1.Discuss the spectrum of complications after uterine artery embolization. Complication rarity and low index of suspicion can lead to

delay in diagnosis and poor outcomes2. Recognize the key imaging features of a broad spectrum of uterine artery embolization complications3. Outline the clinical and periprocedural considerations necessary to prevent and manage the critical and delayed complications of uterine artery embolization

TABLE OF CONTENTS/OUTLINE

1. Differentiate clinical presentations of post embolization syndrome and infection2. Understand the complications, sequalae and management of fibroid expulsiona. Fibroid size and location are important risk factors to consider prior to UAEb. MR imaging is helpful to characterize location of fibroid, degree of infarction and uterine wall attachment, presence of pus or fluid, and state of cervix, and if tissue is prolapsing through the cervix3. Inflammatory adhesions post UAE can lead to bowel and urinary tract obstruction. Larger fibroids are more likely to develop adhesions compared to smaller fibroids.4. Recognize imaging features of leiomyomas and leiomyosarcoma.5. Recognize vascular access complications post procedure6. Prevention, recognition and management of critical early and delayed complications of an uterine artery embolization including fibroid expulsion, infection, inflammatory adhesions leading to obstruction, venous thromboembolic events, access site thrombosis, and missed uterine malignancies.

CH05-A1   Relationship Between Quantitative Features Of Thoracic Aorta Measured By Artificial Intelligence On Non-enhanced Chest CT And Hypertension

Participants
Jinrong Yang, Wuhan, China (*Presenter*) Nothing to Disclose

PURPOSE

To analyze the relationship between quantitative features of thoracic aorta and hypertension, and the predictive risk and diagnostic efficacy of these quantitative features for hypertension were further evaluated.*Methods and Materials A total of 804 patients who were admitted to the geriatric department of our hospital and underwent chest CT examination were included. Morphological features (including diameters and areas at nine levels recommended by the AHA guidelines, and volume and length at two adjacent levels) of the thoracic aorta were automatically measured by AI on non-enhanced chest CT. Next, we analyzed the relationship between these morphological features and age, blood pressure, and further evaluated the predictive risk and diagnostic value of these morphological features for hypertension.*Results All the diameters, areas, volumes and length of ascending aorta (L2_3, L3_4) and descending aorta (L6_7, L7_8) were different between the hypertensive group and the non-hypertensive group (P<0.01). Only the diameter and area of the 7th level (MD), and the volume (V6_7, V7_8) and length (L6_7, L7_8) of descending aorta were different among the grades of hypertension (P<0.05). The diameter and area of MD level, the volume (V6_7, V7_8) and length (L6_7, L7_8) of descending aorta were relatively strong correlated with age and SBP. When SBP was in the range of 110mmHg~160mmHg, the diameters and areas of 9 levels increased with the increase of SBP, otherwise they decreased with the increase of SBP. The volume (V6_7, V7_8) and length (L6_7, L7_8) of descending aorta increased rapidly at first and then slowly with the increase of SBP. The diameter and area of 7th level (MD) was an independent predictor of hypertension (OR=1.168,1.460) after adjusted for clinical data and they were most effective at identifying patients with hypertension (AUC=0.740). The volume (V6_7, V7_8) and length (L6_7, L7_8) of descending aorta had a higher predictive effect on hypertension (AUC =0.602~ 0.717).*Conclusions The diameter and area of the 7th level (MD), and the volume (V6_7, V7_8) and length (L6_7, L7_8) of descending aorta had a relatively strong correlation with blood pressure. The morphological features of thoracic aorta measured by AI were of great value for further understanding the influence of hypertension on thoracic aorta morphology.*Clinical Relevance/Application We analyzed the relationship between the morphological features of thoracic aorta calculated by AI and blood pressure, and evaluated the predictive risk and diagnostic efficacy for hypertension, which had a practical guiding role in evaluating the relationship between the degree of vascular deformation and blood pressure in clinical practice.

RESULTS

All the diameters, areas, volumes and length of ascending aorta (L2_3, L3_4) and descending aorta (L6_7, L7_8) were different between the hypertensive group and the non-hypertensive group (P<0.01). Only the diameter and area of the 7th level (MD), and the volume (V6_7, V7_8) and length (L6_7, L7_8) of descending aorta were different among the grades of hypertension (P<0.05). The diameter and area of MD level, the volume (V6_7, V7_8) and length (L6_7, L7_8) of descending aorta were relatively strong correlated with age and SBP. When SBP was in the range of 110mmHg~160mmHg, the diameters and areas of 9 levels increased with the increase of SBP, otherwise they decreased with the increase of SBP. The volume (V6_7, V7_8) and length (L6_7, L7_8) of descending aorta increased rapidly at first and then slowly with the increase of SBP. The diameter and area of 7th level (MD) was an independent predictor of hypertension (OR=1.168,1.460) after adjusted for clinical data and they were most effective at identifying patients with hypertension (AUC=0.740). The volume (V6_7, V7_8) and length (L6_7, L7_8) of descending aorta had a higher predictive effect on hypertension (AUC =0.602~ 0.717).

CLINICAL RELEVANCE/APPLICATION

We analyzed the relationship between the morphological features of thoracic aorta calculated by AI and blood pressure, and evaluated the predictive risk and diagnostic efficacy for hypertension, which had a practical guiding role in evaluating the relationship between the degree of vascular deformation and blood pressure in clinical practice.

CH05-A2   CT Lung Parenchymal Patterns As Significant Prognostic Imaging Biomarkers In Pulmonary Hypertension With Lung Disease

Participants
Krit Dwivedi, MD, Sheffield, United Kingdom (*Presenter*) Nothing to Disclose

PURPOSE

Pulmonary hypertension (PH) is a heterogenous, incurable condition with untreated survival poorer than most cancers. Patients presenting with CT features of both PH and lung disease pose a diagnostic dilemma between two phenotypes - idiopathic pulmonary arterial hypertension (IPAH) and PH secondary to chronic lung disease (PH-CLD). Accurate phenotyping is vital as it informs treatment, management and prognosis. Only patients with IPAH are eligible for PAH therapeutic agents, which significantly improve survival. The prognostic significance of commonly identified CT lung parenchymal patterns is unknown.*Methods and Materials All patients with IPAH or PH-CLD between Feb 2001 - Jan 2019 were identified in a specialist tertiary PH referral centre using the ASPIRE (Assessing the Spectrum of Pulmonary Hypertension Identified at a Referral Centre) registry. CT scans performed within one

year prior to diagnosis were termed 'incident'. All scans and reports were analysed blinded to clinical data. CT reports were searched using a regular expression string-search for 6 CT features - emphysema, ground glass (GG), centrilobular ground glass (CGG), consolidation and fibrosis. Emphysema and fibrosis severity was scaled as mild, moderate or severe. Results were manually validated to ensure they represented true positives. Multivariate regression analysis was performed adjusting for known significant predictors of age, gender and mean pulmonary arterial pressure.*Results Cohort included 660 consecutive incident patients (335 IPAH, 325 PH-CLD) over 18 years. Honeycombing (HR 2.79), fibrosis (HR 2.38), emphysema (HR 2.09) and combined emphysema and fibrosis (CPFE, HR 2.20) were highly significant (p<0.001) adverse predictors of increased mortality. GG (HR 0.53) and CGG (HR 0.36) were highly significant (p<0.001) protectors. The prognostic effect of fibrosis (mild HR 1.94; moderate HR 2.74; severe HR 3.18) and emphysema (mild HR 1.77; moderate HR 2.17; severe HR 2.92) scaled with severity and was highly significant (p<0.001) at each level. CGG (HR 0.51), fibrosis (HR 1.79), emphysema (HR 1.53) and CPFE (HR 1.53) remained significant (p<0.02) at multivariate analysis.*Conclusions This study demonstrates commonly encountered lung CT patterns prognosticating PH patients with lung disease and being imaging biomarkers for mortality. Presence of emphysema and fibrosis predict poor survival. Ground glass change, including centrilobular ground glass change, predicts better survival, as these more likely represent patients with IPAH.*Clinical Relevance/Application Prognostic significance of CT lung parenchymal disease patterns in PH is unknown. This study identifies significant protective & adverse patterns as imaging biomarkers that predict survival.

RESULTS

Cohort included 660 consecutive incident patients (335 IPAH, 325 PH-CLD) over 18 years. Honeycombing (HR 2.79), fibrosis (HR 2.38), emphysema (HR 2.09) and combined emphysema and fibrosis (CPFE, HR 2.20) were highly significant (p<0.001) adverse predictors of increased mortality. GG (HR 0.53) and CGG (HR 0.36) were highly significant (p<0.001) protectors. The prognostic effect of fibrosis (mild HR 1.94; moderate HR 2.74; severe HR 3.18) and emphysema (mild HR 1.77; moderate HR 2.17; severe HR 2.92) scaled with severity and was highly significant (p<0.001) at each level. CGG (HR 0.51), fibrosis (HR 1.79), emphysema (HR 1.53) and CPFE (HR 1.53) remained significant (p<0.02) at multivariate analysis.

CLINICAL RELEVANCE/APPLICATION

Prognostic significance of CT lung parenchymal disease patterns in PH is unknown. This study identifies significant protective & adverse patterns as imaging biomarkers that predict survival.

CH05-A5   **Fourier Decomposition Magnetic Resonance Imaging (FD-MRI) For Non-contrast-enhanced Assessment Of Lung Perfusion In Patients With Cystic Fibrosis During Respiratory Tract Exacerbation**

Participants
Andrea Mazzaro, MD, Verona, Italy (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate Fourier Decomposition MRI (FD-MRI) to assess respiratory tract exacerbation (RTE) in cystic fibrosis (CF) patients.*Methods and Materials CF patients underwent clinical examination, pulmonary function test (PFT) and chest-MRI on the same day. Patients with RTE were identified using Rosenfeld criteria. A follow-up examination was performed after antibiotic therapy in the RTE group and after 20-30 days in the stable group. MRI protocol consisted of untriggered coronal 2D SSFP sequence. SSFP data were converted into perfusion maps using FD brand software. Two readers independently analyzed FD maps for perfusion defects using a field-based semi-quantitative scoring system. Intra- and inter-rater agreement was assessed with k statistics. Ability to differentiate RTE and stable patients was performed with Odds Ratio (OR) and correlation with PFT using Kendall's Tau test.*Results We selected 32 consecutive CF patients (median age: 21 years, range: 13-58). Fourteen (14) patients met the RTE criteria (median: 21 years, range: 17-41[PC2] [PC3]). Inter- and intra-rater agreement was good to excellent with K of 0.85 and 0.93 (p<0.05) respectively. RTE patients had a significantly higher amount of perfusion defects than stable CF patients at baseline (OR:4.0, C.I. 95%:1.4-12.3), but not at follow-up (OR:1.1, C.I. 95%:0.4-2.5). The perfusion score showed a negative moderate correlation with PFT parameters in RTE patients, both at baseline (Tau range: -0.58;-0.66, p<0,05) and follow-up examination (Tau range: -0.41;-0.58, p<0.05). No correlation was found for stable patients.*Conclusions The score applied to FD-MRI perfusion maps showed a good reproducibility and it appeared to be effective in differentiating CF patients with pulmonary exacerbation. It also seems useful in detecting after therapy changes demonstrating a good correlation with spirometry parameters.*Clinical Relevance/Application Lung perfusion assessment with FD-MRI can differentiate CF patients with resiratory tracts exacerbation and can be used as a monitoring tool to assess response to treatment, providing functional informations without the use of contrast agents and of ionizing radiations.

RESULTS

We selected 32 consecutive CF patients (median age: 21 years, range: 13-58). Fourteen (14) patients met the RTE criteria (median: 21 years, range: 17-41[PC2] [PC3]). Inter- and intra-rater agreement was good to excellent with K of 0.85 and 0.93 (p<0.05) respectively. RTE patients had a significantly higher amount of perfusion defects than stable CF patients at baseline (OR:4.0, C.I. 95%:1.4-12.3), but not at follow-up (OR:1.1, C.I. 95%:0.4-2.5). The perfusion score showed a negative moderate correlation with PFT parameters in RTE patients, both at baseline (Tau range: -0.58;-0.66, p<0,05) and follow-up examination (Tau range: -0.41;-0.58, p<0.05). No correlation was found for stable patients.

CLINICAL RELEVANCE/APPLICATION

Lung perfusion assessment with FD-MRI can differentiate CF patients with resiratory tracts exacerbation and can be used as a monitoring tool to assess response to treatment, providing functional informations without the use of contrast agents and of ionizing radiations.

Abstract Archives of the RSNA, 2021

NR02-A11 **A Deep-learned Time-signal Intensity Pattern Analysis Characterizes Magnetic Resonance Perfusion Heterogeneity For Epidermal Growth Factor Receptor Amplification In Glioblastoma**

Participants
Suyoung Yun, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Dynamic susceptibility contrast (DSC) MRI retains complex dynamic information of time-signal intensity curves that may hold information of common molecular subtype of epidermal growth factor receptor (EGFR). An autoencoder can learn representative time-signal intensity patterns to improve molecular subtyping using perfusion MRI. The aim of this study was to investigate whether an autoencoder-based pattern analysis in tumor and peritumoral area using perfusion MRI predicts EGFR mutation in isocitrate dehydrogenase [IDH]-wild type glioblastoma.*Methods and Materials Preoperative DSC-MRI were obtained for 93 patients with IDH-wild type glioblastoma and known EGFR mutation status. The autoencoder was applied DSC MRI time-signal intensity curves on tumor and peritumoral area. Representative perfusion patterns were defined by voxel-wise k-means clustering using autoencoder latent features. The perfusion patterns were analyzed for baseline, signal drop, and percent recovery. The prediction performance for EGFR mutation using percentage of perfusion patterns in tumor and peritumoral area was calculated with logistic regression analysis and measured using area under the curve (AUC) of the receiver operating characteristics analysis.*Results Total 93 patients were enrolled (41 amplified and 52 nonamplified EGFR). Autoencoder obtained 3 time-signal intensity patterns in each tumor and peritumoral area, characterized tissues of hypovascular tumor, arterial-dominant tumor, and venous-dominant tumor (Figure 1). Proportion of all tumor characters were significantly different between amplified and nonamplified group in both tumor and peritumoral area (largest P = 0.013), with a proportion of arterial-dominant tumor become a significant predictor (P <0.001) for EGFR amplification. The autoencoder predicted EGFR with AUC of 0.78 (95% confidence interval 0.71-0.89).*Conclusions The autoencoder perfusion pattern analysis enables tissue characterization within tumor and peritumoral area, which may be useful imaging biomarkers for EGFR amplification in IDH-wild type glioblastoma and will augment perfusion analysis by providing heterogeneity and dynamic information.*Clinical Relevance/Application EGFR mutation is known to be associated with perfusion parameters, but previous perfusion studies utilized model-based calculation of relative cerebral blood volume requires sophisticated assumption. Noninvasive prediction of the EGFR amplification status using time-signal intensity patterns may improve clinical decision-making by enabling recognition of subgroups of patients who may benefit from treatment.

RESULTS

Total 93 patients were enrolled (41 amplified and 52 nonamplified EGFR). Autoencoder obtained 3 time-signal intensity patterns in each tumor and peritumoral area, characterized tissues of hypovascular tumor, arterial-dominant tumor, and venous-dominant tumor (Figure 1). Proportion of all tumor characters were significantly different between amplified and nonamplified group in both tumor and peritumoral area (largest P = 0.013), with a proportion of arterial-dominant tumor become a significant predictor (P <0.001) for EGFR amplification. The autoencoder predicted EGFR with AUC of 0.78 (95% confidence interval 0.71-0.89).

CLINICAL RELEVANCE/APPLICATION

EGFR mutation is known to be associated with perfusion parameters, but previous perfusion studies utilized model-based calculation of relative cerebral blood volume requires sophisticated assumption. Noninvasive prediction of the EGFR amplification status using time-signal intensity patterns may improve clinical decision-making by enabling recognition of subgroups of patients who may benefit from treatment.

NR02-A12 **Pineal Abnormalities In The Pediatric Population - Review Of Anatomy, Histology, Immunochemistry, Pathology And Imaging.**

Participants
Carol C. V. Lima, MEd, Troy, Michigan (*Presenter*) Nothing to Disclose

TEACHING POINTS

1- Pineal gland lesions are responsible for 3-8% of pediatric intracranial tumors.2- Our aim is to review anatomy, histology, normal development, immunochemistry tumor markers, imaging and pathology of pineal gland lesions in the pediatric population.3- Radiologists should be aware of the peculiarities of these lesions to minimize errors of interpretation.

TABLE OF CONTENTS/OUTLINE

1. Anatomy, histology and normal development of the pineal gland.2. Germ cell tumor types and tumor markers. Image 1: Germinoma secondary to synchronous development at multiple sites. Post-contrast MRI reveals multiple areas of enhancement including the foramen of Monroe and basal cisterns. 3. Pineal parenchymal tumors and immunohistochemistry. Image 2: Pineoblastoma. CT/MRI showing mass effect and CNS spread.4. Glial Tumors and Pineal cystic lesions. Image 3: Multiloculated partially cystic process in the pineal gland with enhancement along the septations. The second one is a pineal cyst case with hemorrhage. 5. Miscellaneous. Image 4 showing an Atypical teratoid/rhabdoid tumor with CNS spread to pineal gland.

NR02-A2   Classification Of Paediatric Posterior Fossa Tumors Using Radiomics Features Of T2w Images.

Participants
ABHILASHA INDORIA, MENG,BEng, Bengaluru, India (*Presenter*) Nothing to Disclose

PURPOSE

About half of the major paediatric tumours (Medulloblastoma, Ependymoma and Pilocytic Astrocytoma) originate in the posterior fossa. Knowing the tumor type pre-operatively is desirable because of different management strategies and outcomes. These three tumors can demonstrate similar visual appearance on an MRI scan which is the key technique for visualization and management of all brain tumors. Histopathological examination of biopsy samples, which is an invasive technique, is the gold standard for definite diagnoses. The purpose of this study is to explore the machine learning classification model using radiomics features of T2-weighted images for discriminating between major paediatric posterior fossa brain tumors non-invasively.*Methods and Materials 87 subjects (32 Medulloblastoma, 30 Ependymoma and 25 Pilocytic astrocytoma) MRI data was retrieved from PACS. ROI was manually drawn on pre-processed T2W images using 3D slicer. 18 first order and 23 GLCM features were extracted. Dataset was split into training and testing data. Features were reduced based on feature importance calculated from training dataset using randomized search cross validation. Boxplots were created to study the relation of selected features with tumor type. Fourfold cross validation was carried out on the training dataset to obtain the cross-validation score. Random forest classifier was trained on reduced feature set and performance was assessed. Average intensity histogram for the ROIs were calculated for the three groups.*Results 87% mean accuracy score was achieved after cross validation. The classifier also performed well on the test dataset with an accuracy of 83.14%. Calculation of average intensity histogram revealed the intensity overlap between the three groups. A higher feature importance score was assigned to second-order features as compared to first-order features by a randomized search algorithm. The top three features in the analysis included only the second-order features i.e., 'glcm IMC1', 'glcm jointenergy' and 'glcm InverseVariance'. First-order features included in the analysis are 'skewness', 'energy', and 'minimum'.*Conclusions First order statistical features derived from T2W images are useful for discriminating between the three major paediatric brain tumors.*Clinical Relevance/Application This study provides a foundation for utilization of radiomics and machine learning methods to create tools that can assist in making an early diagnosis, reduction in invasive methods for diagnosis and improve management of paediatric tumors.

RESULTS

87% mean accuracy score was achieved after cross validation. The classifier also performed well on the test dataset with an accuracy of 83.14%. Calculation of average intensity histogram revealed the intensity overlap between the three groups. A higher feature importance score was assigned to second-order features as compared to first-order features by a randomized search algorithm. The top three features in the analysis included only the second-order features i.e., 'glcm IMC1', 'glcm jointenergy' and 'glcm InverseVariance'. First-order features included in the analysis are 'skewness', 'energy', and 'minimum'.

CLINICAL RELEVANCE/APPLICATION

This study provides a foundation for utilization of radiomics and machine learning methods to create tools that can assist in making an early diagnosis, reduction in invasive methods for diagnosis and improve management of paediatric tumors.

NR02-A3   A Magnetic Resonance Imaging Based Radiomics Model To Predict Mitosis In Cerebral Meningioma Grading Prior To Surgery

Participants
Hermann Kraehling, MD, Muenster, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Image analysis of intracranial tumors by machine learning is a highly evolving part of modern medicine. The aim of this study was to develop a magnetic resonance imaging (MRI) based Radiomics model to predict mitosis cycles in cerebral meningioma grading prior to surgery.*Methods and Materials Preoperative contrast-enhanced T1 weighted cerebral MRI imaging data of 172 meningioma patients from the years 2015 to 2020 were obtained, preprocessed and segmented using the 3D Slicer software and the PyRadiomics plugin. In total 158 Radiomics features of the T1 post contrast MRI images were computed. Data processing involved Yeo-Johnson-Transformation, followed by the stepwise reduction of variables to receive a final training model with only 18 features using the ´Naive-Bayes-Procedure´. For comparison, alternative models based on the 18 final variables using ´logistic regression´ or ´LASSO´ regression were performed as well.*Results The Radiomics features correlated with histologically found number of mitosis in CNS meningiomas. Performance of the ´Naive-Bayes-Procedure´ showed an accuracy of the training data of 76,81% (Receiver operating characteristics ROC AUC 0,77) and test data accuracy was 73,53%. Performance of the ´logistic regression with stepwise procedure´ showed an accuracy of the training data of 78,26%, ROC 71,6 %, test data accuracy was 70,59%. Performance of the ´least absolute shrinkage and selection operator (LASSO)´ Regression showed an accuracy of the training data of 77,54%, ROC 74,6 %, test data accuracy was 70,59%.*Conclusions The MRI-based Radiomics prediction of mitosis cycles in cerebral meningioma is a reliable prediction model prior to surgery and might have broad perspectives for clinical practice.*Clinical Relevance/Application The MRI-based Radiomics prediction of cerebral meningiomas could be a new reliable diagnostic tool prior to surgery.

RESULTS

The Radiomics features correlated with histologically found number of mitosis in CNS meningiomas. Performance of the ´Naive-Bayes-Procedure´ showed an accuracy of the training data of 76,81% (Receiver operating characteristics ROC AUC 0,77) and test data accuracy was 73,53%. Performance of the ´logistic regression with stepwise procedure´ showed an accurancy of the training data of 78,26%, ROC 71,6 %, test data accuracy was 70,59%. Performance of the ´least absolute shrinkage and selection operator (LASSO)´ Regression showed an accuracy of the training data of 77,54%, ROC 74,6 %, test data accuracy was 70,59%.

CLINICAL RELEVANCE/APPLICATION

The MRI-based Radiomics prediction of cerebral meningiomas could be a new reliable diagnostic tool prior to surgery.

NR02-A5   Deep Learning-based Thin-section MRI Reconstruction Improves Tumour Detection and Delineation In Pre- and Post-treatment Pituitary Adenoma

Participants
Da Hyun Lee, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Deep learning-based reconstruction (DLR) using magnetic resonance imaging (MRI) enables high-resolution thin-section imaging with noise reduction. In the present study, we compared the performance of 1-mm DLR MRI with that of 3-mm routine MRI to detect and delineate pituitary adenoma.*Methods and Materials This single-institution retrospective study included 201 patients (mean age ± standard deviation: 52 ± 14 years; 113 women) who underwent a combined imaging protocol including 3-mm routine MRI and 1-mm DLR to evaluate pituitary adenoma between August 2019 and October 2020. Four readers (two experienced and two less-experienced) assessed the adenoma detection and delineation preferences of the normal pituitary stalk and gland in a pairwise fashion, with 1-mm DLR compared with 3-mm routine MRI. The signal-to-noise ratio was quantitatively assessed. Detection accuracy and image preference data were analysed and compared according to the readers' experience using the McNemar test.*Results New detection of adenoma by 1-mm DLR that was not visualised using 3-mm routine MRI (overall: 6.5% [13/201]) was more common than the inverse. To delineate normal pituitary stalk and gland, readers preferred 1-mm DLR over 3-mm routine MRI (overall superiority 56%). The less-experienced readers preferred 1-mm DLR over 3-mm routine (69% and 82%, p < 0.001). The signal-to-noise ratio of 1-mm DLR was 1.25-times higher than that of the 3-mm routine.*Conclusions The 1-mm DLR thin-slice sectioning achieved higher sensitivity in the detection of pituitary adenoma and provided better delineation of normal pituitary gland than 3-mm routine MRI with incremental clinical value.*Clinical Relevance/Application 1. Deep learning-based reconstruction (DLR) enables thin slice section and achieves new detection of pituitary adenoma. 2. Neuroradiologists preferred 1mm-DLR over 3-mm routine MRI for delineation of pituitary adenoma and pituitary stalk.3. DLR provides higher signal-to-noise ratio compared with routine MRI.

RESULTS

New detection of adenoma by 1-mm DLR that was not visualised using 3-mm routine MRI (overall: 6.5% [13/201]) was more common than the inverse. To delineate normal pituitary stalk and gland, readers preferred 1-mm DLR over 3-mm routine MRI (overall superiority 56%). The less-experienced readers preferred 1-mm DLR over 3-mm routine (69% and 82%, p < 0.001). The signal-to-noise ratio of 1-mm DLR was 1.25-times higher than that of the 3-mm routine.

CLINICAL RELEVANCE/APPLICATION

1. Deep learning-based reconstruction (DLR) enables thin slice section and achieves new detection of pituitary adenoma. 2. Neuroradiologists preferred 1mm-DLR over 3-mm routine MRI for delineation of pituitary adenoma and pituitary stalk.3. DLR provides higher signal-to-noise ratio compared with routine MRI.

NR02-A6 Artificial Intelligence Substantially Improves Differential Diagnosis Of Dementia - Added Diagnostic Value Of Rapid Brain Volumetry

Participants
Jens Opalka, MD, Berlin, Germany (*Presenter*) Employee, Mediaire GmbH

PURPOSE

Brain volumetry is a key aspect in dementia diagnostics. We applied an artificial intelligence (AI) system based on a Convolutional Neural Network (CNN) which aims to perform lobe-separated rapid brain volumetry (< 1/2 hour) of three-dimensional T1-weighted magnetic resonance imaging (MRI) with automated segmentation as well as comparison to age- and gender-adapted percentiles. Our aim was to quantify the added value in the differential diagnostics of dementia.*Methods and Materials A total of 55 patients - 17 with confirmed diagnosis of Alzheimer's disease (AD), 18 with confirmed diagnosis of frontotemporal dementia (FTD) and 20 healthy controls - received T1-weighted three- dimensional Magnetization Prepared - RApid Gradient Echo (MP-RAGE) MRI. Images were retrospectively assessed by one board-certified neuroradiologist (BCNR) and two radiology residents (RR) - one of whom had received 6 months of neuroradiology training (RR1). All cases were evaluated in a two-step reading process - beginning without AI-support and followed by an AI-supported reading (AI tool: mdbrain version 3.3.0). For each subject, the suspected diagnostic category (AD, FTD and healthy controls) was determined using a likelihood score (0-5), adding up to a sum of 5 for all three diagnostic categories. Individual reader performance with and without AI support was statistically evaluated using receiver operating characteristics (ROC).*Results AI support substantially improved AD diagnosis in all three readers. The effect was most pronounced for RR2 who had not undergone neuroradiology training (area under the curve [AUC] without AI support [- AI]: 0.629, AI supported [+ AI]: 0.885). But, even for the BCNR, a substantial benefit was measurable (AUCs: BCNR - AI: 0.827, + AI: 0.882; RR1 - AI: 0.713, + AI: 0.834). In diagnosing FTD RR2 improved with AI support (AUCs: - AI: 0.610, + AI: 0.754), while BCNR and RR1 had comparable reading performances with and without AI support (AUCs: BCNR - AI: 0.843, + AI: 0.828; RR1 - AI: 0.865, + AI: 0.868).*Conclusions Even experienced BCNR can improve their diagnostic accuracy for AD by using AI based rapid brain volumetry and readily available comparison with the age- and gender-matched reference cohorts. In diagnosing FTD, especially radiologists who are less experienced in dementia differential diagnosis can strongly benefit from AI support.*Clinical Relevance/Application AI support in the radiological work-up of dementia patients is feasible and can substantially improve diagnostic accuracy, which might lead to earlier diagnosis and therefore optimized patient management. The presented AI tool is readily available in the reporting workflow as it offers rapid data processing and full PACS integration.

RESULTS

AI support substantially improved AD diagnosis in all three readers. The effect was most pronounced for RR2 who had not undergone neuroradiology training (area under the curve [AUC] without AI support [- AI]: 0.629, AI supported [+ AI]: 0.885). But, even for the BCNR, a substantial benefit was measurable (AUCs: BCNR - AI: 0.827, + AI: 0.882; RR1 - AI: 0.713, + AI: 0.834). In diagnosing FTD RR2 improved with AI support (AUCs: - AI: 0.610, + AI: 0.754), while BCNR and RR1 had comparable reading performances with and without AI support (AUCs: BCNR - AI: 0.843, + AI: 0.828; RR1 - AI: 0.865, + AI: 0.868).

CLINICAL RELEVANCE/APPLICATION

AI support in the radiological work-up of dementia patients is feasible and can substantially improve diagnostic accuracy, which might lead to earlier diagnosis and therefore optimized patient management. The presented AI tool is readily available in the reporting workflow as it offers rapid data processing and full PACS integration.

NR02-A7 Incorporating Algorithmic Uncertainty Into A Clinical Deep Learning Algorithm For Head CTs

Participants
Byung Yoon, MD,PhD, Boston, Massachusetts (*Presenter*) Nothing to Disclose

PURPOSE

Me t   b y th   d   t ti   f i t   i l h   m

Most algorithms developed for the detection of intracranial abnormalities rely on dichotomous classification where an algorithm determines whether an abnormality is present or not. However, many imaging findings may be indeterminate. We incorporated the concept of "algorithmic uncertainty" and investigated whether acute findings on head CT can be classified into 2 categories based on high and low probabilities for abnormality, and a separate algorithmically uncertain category. Any differences in clinical outcomes were also evaluated.*Methods and Materials 1000 consecutive noncontrast head CTs (855 adult patients, some with multiple scans) obtained at our institution between 10/26/2020 and 11/13/2020 were processed by the AI algorithm, which was originally developed for acute intracranial hemorrhage detection (PMID: 30948806) but was found to detect other acute abnormalities. After exclusion of algorithmically uncertain (AU) cases, algorithm results were classified into high (IC+) and low (IC-) probability for significant intracranial abnormalities that included acute hemorrhage, large lesion, or edema with extensive tissue shift, and diffuse cerebral edema. Infarcts were not evaluated by the algorithm.*Results Among 1000 cases, 164 were deemed uncertain, leaving 103 IC+ cases (93 true positives and 10 false positives) and 733 IC- cases (686 true negatives, 47 false negatives). The positive and negative predictive values were 0.903 and 0.936, respectively. The rates of admission, 30-day mortality, neurointervention were 75%, 10%, and 35%, respectively for IC+, compared to 43%, 3%, and 4% for IC- with odds ratios (95% CI) of 3.83 (2.13, 6.88; p<0.001), 3.43 (1.33, 8.89; p=0.011), and 11.95 (6.32, 22.61; p<0.001). The respective rates for AU were 53%, 9%, and 12%.*Conclusions Incorporating uncertainty into a deep learning algorithm for head CTs results in refined algorithmic results with high positive and negative predictive values that are clinically useful. The rate of algorithmic uncertain cases is substantial at 16.4% and is a focus of further research with respect to the causes and possible reduction.*Clinical Relevance/Application Incorporation of uncertainty may result in more clinically relevant algorithms with high predictive values and help expedite identification and triage of patients that need urgent medical care.

RESULTS

Among 1000 cases, 164 were deemed uncertain, leaving 103 IC+ cases (93 true positives and 10 false positives) and 733 IC- cases (686 true negatives, 47 false negatives). The positive and negative predictive values were 0.903 and 0.936, respectively. The rates of admission, 30-day mortality, neurointervention were 75%, 10%, and 35%, respectively for IC+, compared to 43%, 3%, and 4% for IC- with odds ratios (95% CI) of 3.83 (2.13, 6.88; p<0.001), 3.43 (1.33, 8.89; p=0.011), and 11.95 (6.32, 22.61; p<0.001). The respective rates for AU were 53%, 9%, and 12%.

CLINICAL RELEVANCE/APPLICATION

Incorporation of uncertainty may result in more clinically relevant algorithms with high predictive values and help expedite identification and triage of patients that need urgent medical care.

BR04-A3 Breast Cancer During Pregnancy And Lactation In Brca Carriers

Participants
Renata Faermann, MD, Kiryat Ono, Israel (*Presenter*) Nothing to Disclose

PURPOSE

Women harboring BRCA1 or BRCA2 germline pathogenic sequence variants (PSVs) mutations have a substantially increased lifetime risk for developing breast cancer estimated at 70-75%, at times diagnosed at an early age (<40 years). Approximately 12% of women whose breast cancer was diagnosed = 40 years carry BRCA1 or BRCA2 PSVs. While breast cancer surveillance imaging including MRI alternating with mammography from age 25-30 years is well established for BRCA PSV carriers, optimal breast imaging surveillance during pregnancy and breastfeeding is not well established. At our institute, we offer breast exam and breast ultrasound (US) every 3 months for pregnant and breastfeeding BRCA carriers. The aim of our study was to assess the utility and yield of this screening protocol.*Methods and Materials A retrospective, IRB approved observational study, evaluating pregnant and breastfeeding BRCA PSV carriers who are being followed up at the Meirav high risk clinic during 2015-2021. Using the OpisoftCare software, all patients undergoing surveillance, during pregnancy and lactation were identified. Breast imaging examinations, biopsies, and number of cancers were retrieved for all pregnant and breastfeeding patients.*Results During the study period, 593 breast ultrasounds were performed in 263 pregnant BRCA carriers and 409 breast ultrasounds for 175 breastfeeding women. Thirty two of the breastfeeding women had a mammogram in addition to the breast US. Overall, 36 biopsies in pregnant women were performed, and in 2 (2/263=0.7% - 5.5% of biopsies) breast cancer was detected (one invasive ductal carcinoma and one invasive lobular carcinoma, both triple negative), and 2 of 23 biopsies that were performed in breastfeeding women (2/175=1.1% - 8.7% of biopsies) were malignant (both invasive ductal carcinoma, one triple negative and the other estrogen receptor positive).*Conclusions Breast cancer during pregnancy and lactation in BRCA patients is rare, and rates of detection are below 2% in our center. Moreover, even when radiologically suspicious lesions are detected, positive predictive value was 5.5-8.7% in pregnant and breastfeeding women, respectively. Based on these preliminary data, imaging surveillance with ultrasound at longer intervals during pregnancy and breastfeeding, should be considered and validated in a larger dataset.*Clinical Relevance/Application Although young patients harboring BRCA1 or BRCA2 mutations have a substantially increased lifetime risk for developing breast cancer, we show that it is rare during pregnancy and lactation, suggesting that imaging surveillance with ultrasound at longer intervals during pregnancy and breastfeeding should be considered.

RESULTS

During the study period, 593 breast ultrasounds were performed in 263 pregnant BRCA carriers and 409 breast ultrasounds for 175 breastfeeding women. Thirty two of the breastfeeding women had a mammogram in addition to the breast US. Overall, 36 biopsies in pregnant women were performed, and in 2 (2/263=0.7% - 5.5% of biopsies) breast cancer was detected (one invasive ductal carcinoma and one invasive lobular carcinoma, both triple negative), and 2 of 23 biopsies that were performed in breastfeeding women (2/175=1.1% - 8.7% of biopsies) were malignant (both invasive ductal carcinoma, one triple negative and the other estrogen receptor positive).

CLINICAL RELEVANCE/APPLICATION

Although young patients harboring BRCA1 or BRCA2 mutations have a substantially increased lifetime risk for developing breast cancer, we show that it is rare during pregnancy and lactation, suggesting that imaging surveillance with ultrasound at longer intervals during pregnancy and breastfeeding should be considered.

BR04-A4 First Results Of Dynamic Contrast-enhanced (DCE) Photon-counting Breast CT (PC-BCT) Imaging Of DCIS

Participants
Caroline Wilpert, MD, Aachen, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Photon counting breast CT (PC-BCT) is a novel method that offers a substantially higher spatial and contrast resolution than conventional CT, at a significantly lower radiation dose; therefore, dynamic image acquisitions similar to DCE-MRI is feasible. We describe enhancement patterns of DCIS in DCE PC-BCT, in direct comparison to MRI.*Methods and Materials Intra-individual comparative study on 18 patients (mean aged 57.2 ± 9.3 years) with biopsy-confirmed DCIS who underwent breast MRI and PC-BCT either on the same day or within a maximum of 2 days. A dedicated photon counting breast CT scanner (Nu:View) was used that operates with an ultra-high-resolution CdTe detector suitable for single-breast imaging. Images were acquired with 60kV, 32 mAs at a 691 x 691 matrix, yielding a non-interpolated spatial resolution of 0.3 x 0.3 x 0.3 mm. Dynamic contrast enhanced PC-BCT was performed before and three times after bolus injection of 1.5 ml/kg BW iodinated contrast agent @ 3 ml/s. Each dynamic scan took 26 sec to acquire, plus 23 sec data handling time, yielding a temporal resolution of 49 seconds. Breast MRI was acquired at 1.5 T using a multichannel breast coil before and after 4 times bolus injection of 0.1 ml/kg BW Gadobutrol @ 3 ml/s, temporal resolution 60 s; spatial resolution 0.4 x 0.5 x 3 mm.*Results There was non-mass related enhancement observable, although to a variable degree, in DCIS lesions on post-contrast subtracted PC-BCT images. Mean CNR increased from 23.6 ± 17 to 35.2 ± 22 after

contrast injection. Relative CNR increase (CNRpost vs. CNRpre-contrast) in PC-CT was similar to relative SI increase observable in breast MRI (65% ± 59% vs. 49% ± 33%). Comparing CNR of both methods, CNR of PC-BCT (5,0 ± 4,5) was significantly lower than that of MRI (11,8 ± 15); p<0.017. DCIS exhibited steady enhancement, with maximum enhancement achieved in the respective last dynamic acquisition, with similar maximum enhancement (100% vs. 94%) for PC-BCT vs. MRI.*Conclusions DCIS that is associated with enhancement on breast MRI appears to be also associated with contrast enhancement on PC-BCT.*Clinical Relevance/Application PC-BCT allows detection of microcalcifications (abstract no 14812) and of contrast enhancement of DCIS. PC-BCT may thus combine advantages of mammography with those of breast MRI for detection/characterization of DCIS.

RESULTS

There was non-mass related enhancement observable, although to a variable degree, in DCIS lesions on post-contrast subtracted PC-BCT images. Mean CNR increased from 23.6 ± 17 to 35.2 ± 22 after contrast injection. Relative CNR increase (CNRpost vs. CNRpre-contrast) in PC-CT was similar to relative SI increase observable in breast MRI (65% ± 59% vs. 49% ± 33%). Comparing CNR of both methods, CNR of PC-BCT (5,0 ± 4,5) was significantly lower than that of MRI (11,8 ± 15); p<0.017. DCIS exhibited steady enhancement, with maximum enhancement achieved in the respective last dynamic acquisition, with similar maximum enhancement (100% vs. 94%) for PC-BCT vs. MRI.

CLINICAL RELEVANCE/APPLICATION

PC-BCT allows detection of microcalcifications (abstract no 14812) and of contrast enhancement of DCIS. PC-BCT may thus combine advantages of mammography with those of breast MRI for detection/characterization of DCIS.

BR04-A8 The Impact Of Screening Intervals On Stage Of Breast Cancer At Time Of Detection Using Real-world Evidence

Participants
Emily F. Conant, MD, Philadelphia, Pennsylvania (*Presenter*) Research Grant, Hologic, Inc;Advisory Panel, Hologic, Inc;Research Grant, OM1, Inc;Research Grant, iCad, Inc;Advisory Panel, iCad, Inc;Speaker, Medscape, LLC

PURPOSE

Early detection of breast cancer (BC) with screening mammography improves patient outcomes. Longer screening intervals (SIs) due to pandemic-related or other delays and/or decreases in screenings are of concern. Using retrospective multi-center BC screening data, this study examined the association between SIs and cancer size and stage at detection to estimate effects of screening delays on patient outcomes to inform screening recommendations.*Methods and Materials The study used integrated EMR, RIS, and tumor registry data from 4 large healthcare organizations. Women 40-79 years old with =1 screening mammogram and incident BC from 2015-2019 were included. Women with prior breast implants or BC were excluded. SI was defined as the time between the last 2 screens for women with =2 screens or the time from site data availability to screen date for women with 1 screen. Advanced BC was defined as TNM stage =II at diagnosis. Chi-square test, analysis of variance, and logistic regression were used to compare patient characteristics and BC outcomes by SI (>24 vs. = 24 months).*Results Among 701,207 women screened, 2,844 women had incident BC. Compared to the 81% with SI =24 months, women with SI >24 months were younger (mean: 59 vs. 61 years), less often had heterogeneously (42% vs. 47%) or extremely dense breasts (5% vs. 9%), were screened more often with digital breast tomosynthesis vs. digital mammography at BC detection (78% vs. 62%), and had larger tumors (mean: 17 vs. 14mm) (all p<0.01). A higher proportion of women with SI >24 months had advanced BC (p=0.02) and/or tumors =21mm, and a lower proportion had tumors <11mm (Figure 1). Tumor size differences, however, were not statistically significant (p=0.16). After adjustment for age, modalities, and density, the odds ratio for advanced BC in women with SI >24 vs. =24 months was 1.21 (95% confidence interval: 0.95,1.54). When restricted to women with =2 screens (n=1,110), trends for status and tumor size remained but differences were not statistically significant.*Conclusions More advanced BC and larger tumor sizes were observed for SI >24 months, suggesting that longer SIs may adversely impact patient outcomes.*Clinical Relevance/Application Compared to =24 months, a mammography screening interval >24 months increased likelihood of advanced breast cancer at diagnosis. Repeat screening within 24 months may improve breast cancer outcomes.

RESULTS

Among 701,207 women screened, 2,844 women had incident BC. Compared to the 81% with SI =24 months, women with SI >24 months were younger (mean: 59 vs. 61 years), less often had heterogeneously (42% vs. 47%) or extremely dense breasts (5% vs. 9%), were screened more often with digital breast tomosynthesis vs. digital mammography at BC detection (78% vs. 62%), and had larger tumors (mean: 17 vs. 14mm) (all p<0.01). A higher proportion of women with SI >24 months had advanced BC (p=0.02) and/or tumors =21mm, and a lower proportion had tumors <11mm (Figure 1). Tumor size differences, however, were not statistically significant (p=0.16). After adjustment for age, modalities, and density, the odds ratio for advanced BC in women with SI >24 vs. =24 months was 1.21 (95% confidence interval: 0.95,1.54). When restricted to women with =2 screens (n=1,110), trends for status and tumor size remained but differences were not statistically significant.

CLINICAL RELEVANCE/APPLICATION

Compared to =24 months, a mammography screening interval >24 months increased likelihood of advanced breast cancer at diagnosis. Repeat screening within 24 months may improve breast cancer outcomes.

BR04-A9 Distance Of Largest Axillary Lymph Node To Axillary Vein Can Predict Reactive Versus Malignant Lymphadenopathy On Breast MRI

Participants
Beatriu Reig, MD, New York, New York (*Presenter*) Nothing to Disclose

PURPOSE

To develop a simple imaging metric to differentiate vaccine-related lymphadenopathy (LAD) from metastatic axillary LAD on breast MRI.*Methods and Materials We retrospectively reviewed breast MRI reports between 7/1/2019 and 11/30/2020 to identify patients with breast cancer and biopsy-proven metastatic axillary LAD; patients with mastectomy, prior axillary surgery, or neoadjuvant therapy were excluded. We reviewed breast MRI reports between 1/1/2021 and 4/1/2021 to identify patients with recent COVID-19 vaccine and ipsilateral LAD seen on MRI; patients with concurrent ipsilateral breast cancer were excluded. One radiologist reviewed the images and recorded: the number of enlarged lymph nodes (LN), and axillary levels (I, II, III) with LAD. The distance from the largest LN (based on short axis measurement on axial images) to the axillary vein on sagittal postcontrast fat-saturated T1-weighted images was measured. Whether the largest LN was the most inferior lymph node identified on axial images was recorded. Mann-Whitney U test was calculated in SPSS.*Results 15 patients were identified in each group. The distance of the largest LN to

the axillary vein was significantly different between the groups. The distance ranged 17-86 mm (mean 41 mm) in the malignant LAD group, versus 1-45 mm (mean 11.7 mm) in the vaccine LAD group (p=.0001). All cancer patients had a distance of greater than 15 mm, while only 3/15 vaccine patients had a distance greater than 15 mm. The largest LN was the most inferior LN identified on axial images in 9/15 cancer patients, and only in 1/15 vaccine patients. Only level I (not level II or III) axillary LN were involved in 12/15 cancer patients, and in 6/15 vaccine patients. 4/15 vaccine patients had involvement of levels I and II, while 5/15 patients had involvement of levels I, II, and III.*Conclusions Vaccine-related LAD is closer to the axillary vessels while malignant LAD is closer to the breast, which may be expected given lymphatic drainage patterns of the deltoid muscle and breast. A simple test to determine whether axillary LAD seen on MRI could be malignant is the measurement of the largest LN to the axillary vein on sagittal view. A cut-off value of > 15 mm would identify potentially malignant LAD, which could be further evaluated with ultrasound or biopsy. Patients with LAD </= 15 mm from the axillary vein could be considered reactive and may not need follow up. Vaccine-related LAD often involves deep axillary levels (II and III), and this extensive involvement should not dissuade radiologists from diagnosing reactive LAD.*Clinical Relevance/Application Incidental vaccine-related LAD has been identified on breast MRI and a simple at-the-workstation test could help triage patients in order to avoid unnecessary follow up exams.

RESULTS

15 patients were identified in each group. The distance of the largest LN to the axillary vein was significantly different between the groups. The distance ranged 17-86 mm (mean 41 mm) in the malignant LAD group, versus 1-45 mm (mean 11.7 mm) in the vaccine LAD group (p=.0001). All cancer patients had a distance of greater than 15 mm, while only 3/15 vaccine patients had a distance greater than 15 mm. The largest LN was the most inferior LN identified on axial images in 9/15 cancer patients, and only in 1/15 vaccine patients. Only level I (not level II or III) axillary LN were involved in 12/15 cancer patients, and in 6/15 vaccine patients. 4/15 vaccine patients had involvement of levels I and II, while 5/15 patients had involvement of levels I, II, and III.

CLINICAL RELEVANCE/APPLICATION

Incidental vaccine-related LAD has been identified on breast MRI and a simple at-the-workstation test could help triage patients in order to avoid unnecessary follow up exams.

RI04-B1   **Prenatal Brain Volumetry In Fetal Growth Restriction With Superresolution Fetal MRI**

Participants
Gregor Dovjak, MD, Vienna, Austria (*Presenter*) Nothing to Disclose

PURPOSE

Fetal growth restriction (FGR) is associated with different short- and long-term complications such as perinatal asphyxia, hypoglycemia, necrotizing enterocolitis, chronic lung disease and cognitive impairment. Furthermore, FGR newborns are more susceptible to infections and more likely to develop allergies and chronic diseases such as diabetes and hypertension. Therefore, an early diagnosis and subsequent monitoring is crucial. Fetal MRI is particularly well suited for detailed imaging of the fetal brain and provides an advanced, complementary imaging tool to assess brain maturation and also the volumes of different fetal brain compartments.*Methods and Materials This study aimed to compare the transverse cerebellar diameter (TCD) and the volumes of the supratentorial brain, ventricles, cerebellum, brainstem and the supra- and infratentorial cerebrospinal fluid (CSF) spaces between FGR fetuses and age-matched normal fetuses. Fetal MRI with an isovoxel "superresolution" sequence, reconstructed from 1.5 Tesla or 3 Tesla T2-weighted sequences in all three planes, were included. The volumes were three-dimensionally segmented with the open-source software ITK-SNAP.*Results A total of 26 fetuses (13 FGR fetuses and 13 age-matched normal fetuses) with a gestational age of 27.0 ± 3.9 weeks (mean ± standard deviation) ranging from 20+0 to 35+5 weeks were included. In the FGR group, all assessed volumes except for the brainstem were smaller compared to the control group. The supratentorial brain volume (p=0.018), cerebellar volume (p=0.005), supra- (p=0.002) and infratentorial CSF spaces (p=0.04) were significantly smaller in the FGR group, whereas the ventricles (p=0.058) and brainstem (p=0.676) volume, as well as the TCD (p=0.154) showed no significant differences between groups.*Conclusions This study implemented a high-quality fetal MRI based superresolution quantification of intracranial compartments and identified volume changes of specific fetal brain regions. Cerebellar hypoplasia is strongly associated with FGR and is exclusively detectable by three-dimensional fetal MRI volumetry.*Clinical Relevance/Application High-quality reconstructed "superresolution" fetal MRI volumetry quantifies FGR associated volume changes of the fetal brain, which are undetectable by linear measurements.

RESULTS

A total of 26 fetuses (13 FGR fetuses and 13 age-matched normal fetuses) with a gestational age of 27.0 ± 3.9 weeks (mean ± standard deviation) ranging from 20+0 to 35+5 weeks were included. In the FGR group, all assessed volumes except for the brainstem were smaller compared to the control group. The supratentorial brain volume (p=0.018), cerebellar volume (p=0.005), supra- (p=0.002) and infratentorial CSF spaces (p=0.04) were significantly smaller in the FGR group, whereas the ventricles (p=0.058) and brainstem (p=0.676) volume, as well as the TCD (p=0.154) showed no significant differences between groups.

CLINICAL RELEVANCE/APPLICATION

High-quality reconstructed "superresolution" fetal MRI volumetry quantifies FGR associated volume changes of the fetal brain, which are undetectable by linear measurements.

RI01-B1   **Characterization Of Abnormal Vascularization And Loss Of The Retroplacental Clear Space In A Murine Model Of Placenta Accreta Spectrum (PAS) Using Nanoparticle Contrast-enhanced MRI**

Participants
Andrew Badachhape, PhD, Houston, Texas (*Presenter*) Nothing to Disclose

PURPOSE

Placenta Accreta Spectrum (PAS) is a condition where placental tissue invades the myometrium and complicates delivery. This condition, seen in 1 in 1000 pregnancies, is responsible for severe morbidity at delivery. Visualization of the uteroplacental interface, or retroplacental clear space (RPCS), is an indicator of normal placentation, but is difficult to assess with ultrasound and conventional magnetic resonance imaging (MRI). In this study, we demonstrate use of a liposomal gadolinium (liposomal-Gd) MRI contrast agent to identify disruption of the RPCS in a mouse model of PAS.*Methods and Materials In vivo studies were performed on the 16th day of gestation in GAB3-/- mice that demonstrate placental invasion in fetoplacental units (FPUs) across the RPCS. Pregnant GAB3+/+ mice that do not express this phenotype were used as controls. Contrast-enhanced MRI (CE-MRI) was performed on a 1T scanner using a T1-weighted 2D gradient-recalled echo sequence (100x100x600 um3 voxels). Post-contrast images were acquired following intravenous administration of liposomal-Gd (0.15 mmol Gd/kg). Contrast-enhanced computed tomography (CE-CT), using a liposomal-iodine contrast agent (1.1 g I/kg), was performed to acquire higher spatial resolution (70 um voxels) images. CE-MR images underwent blinded review by two observers to assess RPCS conspicuity (0 - obscured, 1 - partially obscured, 2 - not obscured). Signal-to-noise ratio (SNR) was computed for placenta and RPCS for all FPUs. This enabled estimation of contrast-to-noise ratio (CNR) which was the difference in RPCS and placental SNR. Post-mortem histological analysis of FPUs was performed for comparison.*Results CE-MR and CE-CT images in GAB3-/- FPUs demonstrated a heterogeneous and interrupted RPCS relative to GAB3+/+ counterparts. Histological analysis of FPUs from GAB3-/- mice confirmed placenta accreta as evidenced by a higher degree of vascularization and the invasion of placental cells across the RPCS. Blinded review of CE-MR images demonstrated lower mean visibility score of the RPCS in GAB3-/- mice (28 FPUs,1.10 ± 0.48) relative to GAB3+/+ (30 FPUs,1.55 ± 0.43) mice. Higher Placental-RPCS CNR values in GAB3+/+ FPUs indicated that GAB3-/- FPUs had higher RPCS SNR and thus a higher degree of vascularization and infiltration across the RPCS.*Conclusions Contrast-enhanced MRI using a liposomal-Gd blood-pool agent enabled visualization of placental invasion across the RPCS in a mouse model of PAS.*Clinical Relevance/Application An MRI-based method for visualizing the RPCS in a mouse model of PAS will enable the translation of sensitive early detection methods for clinical diagnosis of invasive placentation.

RESULTS

CE-MR and CE-CT images in GAB3-/- FPUs demonstrated a heterogeneous and interrupted RPCS relative to GAB3+/+ counterparts. Histological analysis of FPUs from GAB3-/- mice confirmed placenta accreta as evidenced by a higher degree of vascularization and the invasion of placental cells across the RPCS. Blinded review of CE-MR images demonstrated lower mean visibility score of the RPCS in GAB3-/- mice (28 FPUs,1.10 ± 0.48) relative to GAB3+/+ (30 FPUs,1.55 ± 0.43) mice. Higher Placental-RPCS CNR values in GAB3+/+ FPUs indicated that GAB3-/- FPUs had higher RPCS SNR and thus a higher degree of vascularization and infiltration across the RPCS.

CLINICAL RELEVANCE/APPLICATION

An MRI-based method for visualizing the RPCS in a mouse model of PAS will enable the translation of sensitive early detection methods for clinical diagnosis of invasive placentation.

PD01-A3   **Role Of Imaging In Pediatric Epilepsy Surgery- All You Wanted To Know But Were Afraid To Ask!**

Participants
Alexandra Foust, DO, North Royalton, Ohio (*Presenter*) Nothing to Disclose

TEACHING POINTS

1. Understanding the goals of epilepsy surgical procedures can help improve the quality and utility of radiology reports of imaging studies in pediatric patients with drug-resistant epilepsy.2. Multimodality fusion improves surgical planning in pediatric epilepsy.3. Knowledge about intraoperative and post-operative appearances in these patients can aid in differentiate complications from expected post-surgical change and identify residual abnormalities causing seizure recurrence.

TABLE OF CONTENTS/OUTLINE

1. Familiarise radiologists with goals & techniques of common neurosurgical interventions undertaken to treat medically resistant pediatric epilepsy.2. Illustrate typical intraoperative, immediate, and longer-term postoperative findings on imaging studies acquired after procedures including grids & strips placement, stereo EEG placement, lobectomies, lesionectomies, lobar disconnection procedures, functional hemispherectomy, corpus callosotomy, non-lesional cortical resection, multiple subpial transections, and laser interstitial thermal therapy.3. Discuss the role of palliative procedures including VNS, DBS, and RNS.4. Highlight the role of advanced imaging techniques and multimodality fusion to combine information from multiple data sources with case examples.5. List key points to include on reports of pre, intra- & post-operative pediatric epilepsy imaging studies.

MS02-B1   **Traumatic Intracranial Hemorrhage In Adult Patients On Antithrombotic Therapy After Ground Level Fall**

Participants
Zeynep Vardar, MD, Worcester, Massachusetts (*Presenter*) Nothing to Disclose

PURPOSE

Anticoagulant and antiplatelet medications increase the risk and severity of traumatic intracranial hemorrhage (tICH), even with minor head trauma. Our objective was to examine the rate and characteristics of tICH in antithrombotic (AT) therapy patients with minor head injuries after ground-level fall.*Methods and Materials We performed a retrospective analysis of all trauma patients age = 18 at a level 1 trauma center, who fell from ground-level height with minimal-mild head trauma (initial ED Glasgow Coma Scale score >13) between January 1 and December 31, 2020. Based on the electronic medical record, patients who had preinjury use of AT therapy were selected. The control group of patients had no AT use was matched for age and mechanism of injury. Demographic, hospital course and outcome data were analyzed. Head CT images were analyzed for presence/type of tICH, midline shift and regional mass effect.*Results A total of 1630 patients (mean age 80 years ± 12 years, 42.5% male) were included in the analysis. 954 were on AT therapy (608 anticoagulant, 226 antiplatelet, and 120 both) and 676 were not. The overall tICH rate was 3.9% (95% CI = 2.9-4.8%). The tICH rate in the AT group was 4.4%, not significantly different than the 3.1% rate in the control group (p=0.24). Patients on anticoagulants had a tICH rate of 4.6% (95% CI = 2.9%-6.3%), patients on antiplatelets 0.4% (95% CI = 1.4%-6.5%), and patients on both 4.2% (%95 CI = 0.6%-7%). Most tICH had a subdural component (38% in AT, 62% in control group). The rate of hematoma expansion in the AT group was 21% (n=9), whereas no hematoma expansion was observed in the control group (p= 0.04). The rate of midline shift was 7% in AT group and 4.8% in the control group (p=0.7). Regional mass effect rate was 23% in AT group and 9.5% in the control group (p=0.2).*Conclusions There was no statistical difference in the rate of tICH between patients on AT therapy versus those not on AT therapy, after falling from standing height with good neurological status. The results suggest that AT therapy does not independently cause tICH but promotes and increases the extent of bleeding once hemorrhage has occurred.*Clinical Relevance/Application Antithrombotic therapy does not independently cause traumatic intracranial hemorrhage in adult patients suffering minor head injury after ground-level fall but promotes hematoma expansion once hemorrhage has occurred.

RESULTS

A total of 1630 patients (mean age 80 years ± 12 years, 42.5% male) were included in the analysis. 954 were on AT therapy (608 anticoagulant, 226 antiplatelet, and 120 both) and 676 were not. The overall tICH rate was 3.9% (95% CI = 2.9-4.8%). The tICH rate in the AT group was 4.4%, not significantly different than the 3.1% rate in the control group (p=0.24). Patients on anticoagulants had a tICH rate of 4.6% (95% CI = 2.9%-6.3%), patients on antiplatelets 0.4% (95% CI = 1.4%-6.5%), and patients on both 4.2% (%95 CI = 0.6%-7%). Most tICH had a subdural component (38% in AT, 62% in control group). The rate of hematoma expansion in the AT group was 21% (n=9), whereas no hematoma expansion was observed in the control group (p= 0.04). The rate of midline shift was 7% in AT group and 4.8% in the control group (p=0.7). Regional mass effect rate was 23% in AT group and 9.5% in the control group (p=0.2).

CLINICAL RELEVANCE/APPLICATION

Antithrombotic therapy does not independently cause traumatic intracranial hemorrhage in adult patients suffering minor head injury after ground-level fall but promotes hematoma expansion once hemorrhage has occurred.

MS02-B2   **Vitamins - Imaging The "Highs ; Lows"**

Participants
Melih Akyuz, MD, Chicago, Illinois (*Presenter*) Nothing to Disclose

TEACHING POINTS

1. Vitamins are essential micronutrients to sustain normal daily body functions. Since the discovery precise daily requirement has been controversial. 2. Vitamin imbalance is a broad term including both vitamin deficiency and excess, both of which have been a worldwide public health concern since the discovery of the first vitamin in the early 20th century. 3. Not all vitamin imbalances have imaging manifestations. Most common vitamin deficiencies with imaging manifestations include Vitamin D [Rickets & osteomalacia], B1 [Wernicke encephalopathy], B12 [subacute combined degeneration], & C [Scurvy]. Other vitamin deficiencies might present with nonspecific imaging findings. 4. Excess fat-soluble vitamins with imaging manifestations include hypervitaminosis A & D. 5. Excess water-soluble vitamins are rare and most commonly secondary to overtreatment and do not have imaging manifestations. 6. Untreated vitamin imbalances might increase morbidity/mortality, such as hypovitaminosis B1 might complicate with 'Karsakoff syndrome' or hypervitaminosis C might complicate with 'obstructive uropathy' etc.

TABLE OF CONTENTS/OUTLINE

1. List various vitamin imbalance & their clinical manifestations with emphasis on those with imaging manifestations2. Briefly discuss

the sources, mechanisms of actions of different vitamins, risk factors, and management of vitamin imbalance3. Case-based imaging review of vitamin abnormalities in both children and adults. Approach to making diagnosis and evaluating the probable complications.

NR01-A10   Assessment Of Tripod Adherence In Articles Applying Machine Learning For Differentiation Of Glioma From Brain Metastasis

Participants
Leon Jekel, Essen, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Machine learning (ML) applications in predictive models in neuro-oncology have become an increasingly investigated subject of research. For their incorporation into clinical workflow, rigorous assessment and validation to reduce bias is needed. Several reports have indicated utility of ML applications in differentiation of glioma from brain metastasis. However, a systematic assessment of quality of methodology and reporting in these studies has not been done yet. We examined the adherence of 29 published reports in this field to the TRIPOD (Transparent Reporting of a multivariable prediction model for Individual Prognosis Or Diagnosis) statement.*Methods and Materials Our systematic review was conducted in accordance with PRISMA guidelines. Four databases, Ovid Embase, Ovid MEDLINE, Cochrane trials (CENTRAL) and Web of science core-collection were searched, first in October 2020 and a second time in February 2021. Keywords and controlled vocabulary included artificial intelligence, machine learning, deep learning, radiomics, magnetic resonance imaging, glioma, and glioblastoma. Assessment of TRIPOD adherence was performed by an AI graduate student and a medical student according to reporting guidelines. Individual item performance was assessed by adherence index (ADI), generated by dividing the mean achieved score of screened reports by highest possible score per TRIPOD item.*Results In a preliminary analysis of 8 out of 29 studies, average TRIPOD adherence score was found to be 0.48 (i.e., 14.25 out of 30 TRIPOD items were fulfilled) with the individual scores ranging from 0.27 (8/30) to 0.60 (18/30). Best overall item performance was seen in item 3 (background/objectives), 16 (model performance), 19 (interpretation), which were satisfied in every study. With an ADI of 0, poorest performance was detected in item 1 (Title) and 2 (abstract), followed by item 7 (predictors) and 9 (missing data) with an ADI of 0.19 and 0.13, respectively.*Conclusions Preliminary TRIPOD analysis results confirm the concern of lack of reproducibility in studies employing ML models for distinction between glioma and brain metastasis. An average TRIPOD adherence score of 0.48 indicates insufficient quality of reporting and outlines the need for increased utilization of quality scoring systems in study design and documentation. Systematic evaluation of quality score adherence will allow us to identify common flaws in this field of research and to formulate recommendations for translation of models into clinical workflow.*Clinical Relevance/Application Clinical translation of ML for differentiation of glioma from brain metastases provides a non-invasive approach for diagnosis but requires further research to address the systematic biases in the literature.

RESULTS

In a preliminary analysis of 8 out of 29 studies, average TRIPOD adherence score was found to be 0.48 (i.e., 14.25 out of 30 TRIPOD items were fulfilled) with the individual scores ranging from 0.27 (8/30) to 0.60 (18/30). Best overall item performance was seen in item 3 (background/objectives), 16 (model performance), 19 (interpretation), which were satisfied in every study. With an ADI of 0, poorest performance was detected in item 1 (Title) and 2 (abstract), followed by item 7 (predictors) and 9 (missing data) with an ADI of 0.19 and 0.13, respectively.

CLINICAL RELEVANCE/APPLICATION

Clinical translation of ML for differentiation of glioma from brain metastases provides a non-invasive approach for diagnosis but requires further research to address the systematic biases in the literature.

NR01-A11   Approach To High Resolution CNS MRI Of Vascular Wall (VW) Imaging: What Radiologists Need To Know?

Awards
Certificate of Merit

Participants
Moataz Ahmed Sayed Mohammed Soliman, BMBCh, CHICAGO, Illinois (*Presenter*) Nothing to Disclose

TEACHING POINTS

- Understand the imaging protocols and technical factors involved in vascular wall imaging. - Identify different indications and the added value of VW imaging. - Recognize imaging characteristics of various VW diseases. - Structured reporting of vascular wall imaging studies. - Identifying common imaging pitfalls.

TABLE OF CONTENTS/OUTLINE

1. Introduction 2. Evolution of cerebral vascular wall imaging. 3. Technique:- Preprocedural patient preparation.- Imaging protocol.- Contrast-enhanced images. 4. Advantages (added value) of vessel wall imaging. • Targeted vessel biopsy • Role in multiple aneurysms • Prediction of complications in un-ruptured intracranial aneurysms 5. Vascular wall diseases: • Atherosclerotic plaque (site, activity) • Arterial dissection • Aneurysm • Vasospastic conditions • Vessel wall inflammation (vasculitis) • Infections and viral infectious diseases (e.g. Varicella-zoster vasculopathy) 6. Important imaging pitfalls: • Slow flow • Vasa vasorum • Veins

assessment • Post thrombectomy evaluation 7. Study interpretation: • Anatomical background: - Gross anatomy of the cerebral circulation. - Vascular wall histology. • Clinical evaluation • Imaging interpretation- Anatomical evaluation- Vasculitic vascular luminal narrowing- Atherosclerotic plaques (site, activity)- Aneurysm (site, size, neck, wall thickness, wall enhancement)- Non-specific vascular wall enhancement- Post embolectomy vascular wall changes. 8. Future perspectives

NR01-A2 Application of Single Rotation on Wide-detector CT in The Examination Of Adult Patients With Acute Cerebral Hemorrhage

Participants
Jiandong Lai, Ankang, China (*Presenter*) Nothing to Disclose

PURPOSE

To demonstrate the advantages of single rotation on 16cm wide-detector CT in the examination of adult patients with acute cerebral hemorrhage.*Methods and Materials 45 patients (Group 1,29male and 16 female, age range 40-90 years) with acute cerebral hemorrhage (1.5-10 hours) were prospectively enrolled and scanned on a 256-row, 16cm detector CT system using single rotation axial scan mode with 120kVp/120mA and 1.0s/r. Images were reconstructed using ASIR-V at 70% level. The scan parameters (exposure time and radiation dose), quantitative image quality (CT value and SD value of the hemorrhage, cerebellar hemisphere, centrum semiovale (background), signal to noise ratio (SNR), contrast noise ratio (CNR)) and qualitative image quality were compared with those of a historic group (Group 2, n=45,25male and 20 female, age range 41-80 years) scanned on a 64-row CT with 4cm detector in axial scan mode using multiple rotations with 120kVp/180mA and 0.5s/r. Images were reconstructed using a conventional filtered back projection in Group 2. Statistical analysis was performed using SPSS 2.0 software, the independent samples Student t test was used to assess continuous variables, and Mann-Whitney rank test was used to evaluate image quality.*Results The exposure time in Group 1 was 1.0s, 90.8% faster than the 10.9±1.14s in Group 2; The two groups had similar CT value in the hemorrhage (p>0.05). There was no difference in radiation dose between the two groups (240.82±12.33mGy vs. 233.96±21.94mGy, p>0.05), however, Group 1 on the 16cm CT system had significantly lower image noise (3.70±0.57HU vs. 6.35±0.58HU in the centrum semiovale) and higher SNR and CNR values than Group 2 (all p<0.001). All images were acceptable for diagnosis, but group 1 had better image quality than Group 2 in terms of motion artifacts,beam hardening artifacts,contrast between grey and white matters,contrast between hemorrhagic and peripheral edema,overall image quality) (p<0.05). In addition, Group 1 required 0 repeat scan while Group 2 required 5 (out of 45) repeat scans due to motion artifacts.*Conclusions Single rotation axial scan on 16cm wide-detector can reduce examination time, improve the success rate and improve the image quality for patients with acute cerebral hemorrhage, compared with narrow collimation CT systems.*Clinical Relevance/Application Compared to 64-row CT, 16cm wide-detector system enables fast and wide coverage to generate high quality images for patients with acute cerebral hemorrhage.

RESULTS

The exposure time in Group 1 was 1.0s, 90.8% faster than the 10.9±1.14s in Group 2; The two groups had similar CT value in the hemorrhage (p>0.05). There was no difference in radiation dose between the two groups (240.82±12.33mGy vs. 233.96±21.94mGy, p>0.05), however, Group 1 on the 16cm CT system had significantly lower image noise (3.70±0.57HU vs. 6.35±0.58HU in the centrum semiovale) and higher SNR and CNR values than Group 2 (all p<0.001). All images were acceptable for diagnosis, but group 1 had better image quality than Group 2 in terms of motion artifacts,beam hardening artifacts,contrast between grey and white matters,contrast between hemorrhagic and peripheral edema,overall image quality) (p<0.05). In addition, Group 1 required 0 repeat scan while Group 2 required 5 (out of 45) repeat scans due to motion artifacts.

CLINICAL RELEVANCE/APPLICATION

Compared to 64-row CT, 16cm wide-detector system enables fast and wide coverage to generate high quality images for patients with acute cerebral hemorrhage.

NR01-A4 Brain Metastases In Non-small Cell Lung Cancer: Fully Automated Detection And Segmentation Using A Trained Deep Learning Model

Participants
Ulrike Hoyer, MD, Cologne, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Non-small cell lung cancer (NSCLC) is the most common tumor entity spreading to the brain with up to 50% of patients developing brain metastases (BMs). Detection of BMs on MRI proves to be challenging with an inherent risk of missed diagnosis. The purpose of this study was to train and evaluate a deep learning model (DLM) for fully automated detection and 3D segmentation of BMs in NSCLC on clinical routine MRI.*Methods and Materials This was a retrospective study that included 98 patients who were treated for NSCLC at a tertiary care university hospital and received MRI of the head to screen for BMs between January 2012 and March 2020. Multiparametric MRI datasets (T1-/T2-weighted, T1-weighted contrast-enhanced (T1CE), and FLAIR) at 1.0, 1.5, and 3.0 T from various vendors acquired at a single-center in 65 patients and at referring institutions in 33 patients were used. Patients were randomly allocated into a training (66 patients/248 BMs, pre-treatment) as well as independent test (17 patients/67 BMs, pre-treatment) and control sets (15 patients/0 BMs). A 3D convolutional neural network (DeepMedic) was trained on the training cohort using five-fold-cross-validation and evaluated on the test and control sets employing a majority-voting scheme to fuse the five individual models from the five-fold-cross-validation training approach. 3D voxel-wise manual segmentations of BMs by a neurosurgeon and a radiologist on T1CE (consensus reading) served as the reference standard. To compare the spatial overlap between manual and automated segmentations, the dice similarity coefficient (DSC) was calculated. Pearson's correlation coefficient (r) was determined to evaluate the relationship between quantitative volumetric measurements of segmentations.*Results In the test set, the fused DLM detected 57 of the 67 BMs (mean volume: 0.99±4.24 cm3; sensitivity of 85.1%) while FP findings of 1.5 per scan were observed. Missed BMs had a significantly smaller volume (0.05±0.04 cm3) than detected BMs (0.96±2.4 cm3, P=.0009). Compared to the reference standard, automated segmentations achieved a median DSC of 0.72 and a good volumetric correlation (r=0.95). In the control set, 1.8 FPs/scan were observed.*Conclusions Despite the small lesion size, deep learning provides a high detection sensitivity and good segmentation performance for BMs in NSCLC on heterogeneous scanner data while yielding a low number of FP findings.*Clinical Relevance/Application Without being impaired by a high number of FP findings, the proposed DLM can assist physicians by automated detection of BMs while providing 3D segmentation of BMs for lesion contouring in radiosurgery or for assessment of tumor burden.

RESULTS

In the test set, the fused DLM detected 57 of the 67 BMs (mean volume: 0.99±4.24 cm3; sensitivity of 85.1%) while FP findings of

1.5 per scan were observed. Missed BMs had a significantly smaller volume (0.05±0.04 cm3) than detected BMs (0.96±2.4 cm3, P=.0009). Compared to the reference standard, automated segmentations achieved a median DSC of 0.72 and a good volumetric correlation (r=0.95). In the control set, 1.8 FPs/scan were observed.

CLINICAL RELEVANCE/APPLICATION

Without being impaired by a high number of FP findings, the proposed DLM can assist physicians by automated detection of BMs while providing 3D segmentation of BMs for lesion contouring in radiosurgery or for assessment of tumor burden.

NR01-A5   Calibrated Multiphase CT Angiography Perfusion (mCTA Perfusion) Thresholds For Acute Ischemic Stroke

Participants
Luis Souto Maior Neto, MSc, Calgary, Alberta (*Presenter*) Developer, Circle Cardiovascular Imaging Inc

PURPOSE

Multiphase CT Angiography (mCTA) is the addition of two low radiation CTA Head acquisitions to single phase CT angiography Head and Neck in acute ischemic stroke. The StrokeSENS mCTA Perfusion software uses mCTA to estimate CT perfusion (CTP) parameters (mCTA Perfusion). In this report, we validate a calibration process to improve the accuracy of perfusion maps derived from mCTA when compared to CTP.*Methods and Materials 390 studies with mCTA and CTP were included. TMAX perfusion maps were extracted using GE CTP 4D and StrokeSENS mCTA Perfusion. A derivation subset (n=312) was used to calibrate the mCTA TMAX predictions via optimization of thresholded map agreement. Thresholds ranging from 0 to 23 seconds were applied to both mCTA TMAX and CTP TMAX. For each threshold in the CTP TMAX, we evaluated the lesion volume mean absolute difference (MAD) in the corresponding mCTA TMAX maps at multiple threshold levels. A mapping from CTP lesion threshold to optimal mCTA lesion threshold based on the minimum lesion volume MAD was calculated and applied to calibrate the mCTA TMAX maps. In the remaining unseen 78 test cases, predicted mCTA and reference CTP maps were compared at a lesion threshold of TMAX>15.8s. Regional accuracy in estimating lesion was evaluated via ASPECTS AUC, and affected side prediction accuracy, and volumetric accuracy was evaluated via MAD and Intraclass Correlation Coefficient (ICC).*Results For both calibrated and non-calibrated algorithms, the affected side was predicted correctly in 100% of the cases. Significant improvement in lesion volume performance was observed with calibrated MAD (33ml) vs. non-calibrated MAD (46ml), one-sided t-test p-value<0.001. ICC improved from 60.3% (non-calibrated) to 77.9% (calibrated). Regional lesion estimation accuracy improved from an ASPECTS AUC of 85.9% (95% CI: [0.802,0.915]) non-calibrated to 91.9% (95% CI: [0.881,0.957]) on the calibrated TMAX map, with some overlap in the confidence interval range.*Conclusions Calibration during image post-processing improves estimation of TMAX maps derived from multiphase CT angiography when compared to CT perfusion.*Clinical Relevance/Application CT perfusion (CTP) is used to assess the extent and degree of severity of acute ischemic stroke in affected brain regions. CTP is often inaccessible outside large academic centres, needs expertise in acquiring and interpreting, and results in additional radiation and contrast exposure to the patient. Multiphase CTA, on the other hand, is an extension of standard care single-phase CTA, is widely available, requires no additional contrast and only minimal additional radiation. In this work, we show that Perfusion maps generated from mCTA post-processed via calibration are comparable to CTP Perfusion maps.

RESULTS

For both calibrated and non-calibrated algorithms, the affected side was predicted correctly in 100% of the cases. Significant improvement in lesion volume performance was observed with calibrated MAD (33ml) vs. non-calibrated MAD (46ml), one-sided t-test p-value<0.001. ICC improved from 60.3% (non-calibrated) to 77.9% (calibrated). Regional lesion estimation accuracy improved from an ASPECTS AUC of 85.9% (95% CI: [0.802,0.915]) non-calibrated to 91.9% (95% CI: [0.881,0.957]) on the calibrated TMAX map, with some overlap in the confidence interval range.

CLINICAL RELEVANCE/APPLICATION

CT perfusion (CTP) is used to assess the extent and degree of severity of acute ischemic stroke in affected brain regions. CTP is often inaccessible outside large academic centres, needs expertise in acquiring and interpreting, and results in additional radiation and contrast exposure to the patient. Multiphase CTA, on the other hand, is an extension of standard care single-phase CTA, is widely available, requires no additional contrast and only minimal additional radiation. In this work, we show that Perfusion maps generated from mCTA post-processed via calibration are comparable to CTP Perfusion maps.

NR01-A6   3D U-Net For Automated Detection Of Multiple Sclerosis Lesions

Participants
Stephen Wahlig, MD, San Francisco, California (*Presenter*) Nothing to Disclose

PURPOSE

To establish the effect of number of training cases on automated MS-lesion segmentation U-net performance.*Methods and Materials Sixty FLAIR sequences from MS follow-up studies from our institution were manually segmented and randomly split into 50 training studies and 10 test studies. A baseline 3D patch-based U-Net model for disease-invariant FLAIR lesion segmentation (Duong et al., 2019, AJNR), previously trained on 51 studies with varying pathologies causing FLAIR abnormality, was fine-tuned by training with varying numbers of MS-specific training data. As a comparison, the same U-Net architecture was trained from scratch with the same MS-specific training data. Performance of these models on the test data was assessed using the Dice coefficient (DSC) and lesion-wise sensitivity (L-Sens). L-Sens performance was also stratified by individual lesion size. Statistical analysis was performed with Wilcoxon signed rank tests (median DSC) and paired t-tests (mean L-Sens), with Bonferroni correction.*Results Compared to the baseline generic FLAIR model (DSC 0.40±0.21, L-Sens 0.38±0.14), using only 10 disease-specific training studies for either fine-tuning (0.59±0.15 p=0.006, 0.67±0.12 p<0.001) or for training a new model (0.56±0.16 p=0.007, 0.59±0.15 p=0.007) yielded significantly improved results in line with those in the published literature. Only slight further improvement was seen with 50 training studies for fine-tuning (0.66±0.12 p=0.12, 0.69±0.12 p=0.42) or a new model (0.65±0.13 p=0.03, 0.69±0.13 p=0.02). There was no significant difference in DSC between the fine-tuning and new model methods within each training set size (p>0.01) and a small but significant difference in L-Sens at 10 (fine-tune 0.67±0.12, new 0.59±0.15 p=0.004) and 20 training studies (0.62±0.14, 0.49±0.17 p=0.001). All models demonstrated improved L-Sens with increasing lesion size.*Conclusions An effective automated U-Net model for segmentation of MS-specific FLAIR lesions can be generated with as few as 10 manually segmented studies. There was a small but significant benefit to fine-tuning a baseline generic FLAIR model versus training a new model when using fewer than 30 training studies.*Clinical Relevance/Application This study explores how to use minimal manually segmented training data to create an effective automated model for detection of MS FLAIR lesions.

RESULTS

Compared to the baseline generic FLAIR model (DSC 0.40±0.21, L-Sens 0.38±0.14), using only 10 disease-specific training studies for either fine-tuning (0.59±0.15 p=0.006, 0.67±0.12 p<0.001) or for training a new model (0.56±0.16 p=0.007, 0.59±0.15 p=0.007) yielded significantly improved results in line with those in the published literature. Only slight further improvement was seen with 50 training studies for fine-tuning (0.66±0.12 p=0.12, 0.69±0.12 p=0.42) or a new model (0.65±0.13 p=0.03, 0.69±0.13 p=0.02). There was no significant difference in DSC between the fine-tuning and new model methods within each training set size (p>0.01) and a small but significant difference in L-Sens at 10 (fine-tune 0.67±0.12, new 0.59±0.15 p=0.004) and 20 training studies (0.62±0.14, 0.49±0.17 p=0.001). All models demonstrated improved L-Sens with increasing lesion size.

CLINICAL RELEVANCE/APPLICATION

This study explores how to use minimal manually segmented training data to create an effective automated model for detection of MS FLAIR lesions.

NR01-A7   Automated Correction Of Background Phase Error For Cerebrovascular 4D Flow MRI

Participants
Shanmukha Srinivas, La Jolla, California (*Presenter*) Nothing to Disclose

PURPOSE

During 4D Flow MRI acquisition, electromagnetic induced eddy currents may cause phase error. In this study, we assessed the impact of eddy current-related background phase error on flow measurement in the cerebral vasculature, evaluated the benefit of manual image-based correction, and developed a convolutional neural network (CNN) approach to automate correction for cerebrovascular 4D Flow MRI.*Methods and Materials This study was performed with IRB waiver of informed consent. We retrospectively identified 98 MRI exams from 48 patients with cerebral arteriovenous malformations undergoing 4D Flow MRI as part of routine clinical care at one institution from October 2015 to October 2020. Manual correction was performed using segmented static tissue. Data from 23 scans (11 patients) were reserved for testing. Remaining data was used to train a U-Net CNN. Volumetric flow measurements of the anterior, posterior, and venous circulation were performed to assess inflow-outflow consistency and the benefit of phase-error correction. Statistical analyses included Bland-Altman, F-tests, Wilcoxon-signed rank (WSR) tests and Spearman correlation.*Results For all patients, without correction, there was a difference (L/min) between inflow and outflow (median: -0.040, 95% CI: -0.208, 0.117) with the largest discrepancy in the venous circulation (median: -0.080, 95% CI: -0.273, 0.103). For each location, manual phase error correction improved inflow-outflow consistency with improved correlation (?=0.835-0.936 to ?=0.950-0.985) and decreased variance (p<0.001, F-test) between inflow and outflow. In the test cases, fully automated CNN correction was non-inferior to manual correction with no significant differences in variance (p=0.087, F-test), bias (p=0.802, WSR) or correlation (?=0.978 vs ?=0.987) for inflow and outflow measurements.*Conclusions We confirm that background phase error affects cerebrovascular flow volume measurements, and that agreement between inflow and outflow improves with both manual and CNN correction.*Clinical Relevance/Application Deep learning can facilitate phase error correction to improve cerebrovascular blood flow measurements within 4D Flow MRI. This may improve the availability of 4D Flow MRI for guiding clinical management of patients with cerebrovascular disease.

RESULTS

For all patients, without correction, there was a difference (L/min) between inflow and outflow (median: -0.040, 95% CI: -0.208, 0.117) with the largest discrepancy in the venous circulation (median: -0.080, 95% CI: -0.273, 0.103). For each location, manual phase error correction improved inflow-outflow consistency with improved correlation (?=0.835-0.936 to ?=0.950-0.985) and decreased variance (p<0.001, F-test) between inflow and outflow. In the test cases, fully automated CNN correction was non-inferior to manual correction with no significant differences in variance (p=0.087, F-test), bias (p=0.802, WSR) or correlation (?=0.978 vs ?=0.987) for inflow and outflow measurements.

CLINICAL RELEVANCE/APPLICATION

Deep learning can facilitate phase error correction to improve cerebrovascular blood flow measurements within 4D Flow MRI. This may improve the availability of 4D Flow MRI for guiding clinical management of patients with cerebrovascular disease.

NR01-A8   Appearance Of Medullary And Cortical Veins On Multiphase CT-angiography In Patients With Acute Ischemic Stroke

Participants
Aleksandr Drozdov, MD, El Paso, Texas (*Presenter*) Nothing to Disclose

PURPOSE

Previous studies suggest reduced cortical (CV) or medullary venous (MV) drainage demonstrated on CT angiogram (CTA) can independently predict clinical outcomes in patients with acute ischemic stroke (AIS). We sought to determine if of the combined findings of reduced CV and MV drainage can provide a more accurate prediction of outcome in patients with AIS when compared to reduced CV or MV drainage alone.*Methods and Materials We retrospectively reviewed a database of patients with AIS in a middle cerebral artery (MCA) distribution, who were evaluated by multiphase CTA. The pre-treatment CTAs were reviewed, cortical veins were evaluated by adopted Prognostic Evaluation based on Cortical vein score difference In Stroke (PRECISE) system and MV were evaluated by the presence of asymmetry between hemispheres as we described in the previous publication. A good clinical outcome was defined as a Modified Rankin Scale (mRS) of 0-2 at 90 days.*Results 64 patients with MCA distribution AIS were included. The adopted PRECISE score was associated with a good clinical outcome in patients with AIS (OR=3.29; 95% CI: 1.16 - 9.30; p=0.023), and had a stronger association with clinical outcome (AUC=0.644) as compared to the asymmetry of MV (AUC=0.609). In a multivariable logistic regression model, the combined MV and the adapted PRECISE score were independently associated with clinical outcome. The multivariable model resulted in AUC=0.721.*Conclusions This study shows that 1) CV status, measured by adopted PRECISE score, is associated with clinical outcome in patients with AIS independently from MV status, 2) combined CV and MV status has a stronger predictor of clinical outcome compared to CV or MV status alone.*Clinical Relevance/Application In this report we were able to demonstrate that the cortical and medullary systems not only independently predict the clinical outcome, but that the combined status of the MV and CV significantly increase the accuracy of stratification for the clinical outcome. As far as we are aware, this observation has not been previously reported.

RESULTS

64 patients with MCA distribution AIS were included. The adopted PRECISE score was associated with a good clinical outcome in

patients with AIS (OR=3.29; 95% CI: 1.16 - 9.30; p=0.023), and had a stronger association with clinical outcome (AUC=0.644) as compared to the asymmetry of MV (AUC=0.609). In a multivariable logistic regression model, the combined MV and the adapted PRECISE score were independently associated with clinical outcome. The multivariable model resulted in AUC=0.721.

CLINICAL RELEVANCE/APPLICATION

In this report we were able to demonstrate that the cortical and medullary systems not only independently predict the clinical outcome, but that the combined status of the MV and CV significantly increase the accuracy of stratification for the clinical outcome. As far as we are aware, this observation has not been previously reported.

PH04-A1 **Semantic Segmentation Of Multi-class Regions In Supine And Prone Breast Mr Images With Convolutional Neural Network**

Participants
Sungwon Ham, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate robust breast segmentation in breast MRI without considering supine and prone position using transfer learning with convolutional neural net (CNN).*Methods and Materials All the breasts flipped into right breast (N=116) of 29 patients with supine and prone MRIs were used. Prone-supine paired breast MRIs with T1-weighted contrast-enhanced images were acquired at XX. The four classes including lungs and heart, muscles and bones, parenchyma with cancer, and skin and fat were manually confirmed by an expert surgeon. Various kinds of semantic segmentations including 2D U-Net, 2D nnU-Net, 3D U-Net and 3D nnU-Net with each single breast MRI of supine, prone, transferred from prone to supine, and pooled supine and prone MRIs were trained and their performances of a test set were compared by evaluating Dice Similarity Coefficient (DSC), Jaccard Similarity Coefficient (JSC), and Hausdorff distance (HD).*Results The average DSCs of the lungs and heart, muscles and bones, parenchyma with cancer, and skin and fat were 0.987 ± 0.003, 0.966 ± 0.011, 0.870±0.085 and 0.956 ± 0.016 in prone and 0.988 ± 0.001, 0.953 ± 0.021, 0.8068 ± 0.115 and 0.943 ± 0.030 in supine of the pooled data of 2D U-Net. While there are significant differences among the 2D nnU-Net, 3D U-Net and 3D nnU-Net models, 2D U-Net with the pooled data shows significant better accuracies.*Conclusions 2D and 3D semantic segmentations with base U-Net, nnU-Net with or without considering supine and prone position were performed. 2D U-Net with the pooled data shows significant better accuracies, which could be used in the actual clinical settings.*Clinical Relevance/Application This automatic multi-class regions segmentation algorithm in breast MRIs will help to reduce time when printing models for volumetric analysis, 3D planning, 3D printing and virtual and augmented reality, which could be used to quantitatively evaluate changes in volume or area of ??tissues and cancer around the breast in time.

RESULTS

The average DSCs of the lungs and heart, muscles and bones, parenchyma with cancer, and skin and fat were 0.987 ± 0.003, 0.966 ± 0.011, 0.870±0.085 and 0.956 ± 0.016 in prone and 0.988 ± 0.001, 0.953 ± 0.021, 0.8068 ± 0.115 and 0.943 ± 0.030 in supine of the pooled data of 2D U-Net. While there are significant differences among the 2D nnU-Net, 3D U-Net and 3D nnU-Net models, 2D U-Net with the pooled data shows significant better accuracies.

CLINICAL RELEVANCE/APPLICATION

This automatic multi-class regions segmentation algorithm in breast MRIs will help to reduce time when printing models for volumetric analysis, 3D planning, 3D printing and virtual and augmented reality, which could be used to quantitatively evaluate changes in volume or area of ??tissues and cancer around the breast in time.

PH04-A10 **Evaluation Of Image Reconstruction Algorithms For A Helical Tomotherapy System**

Participants
Riley Tegtmeier, BS, Middleton, Wisconsin (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate available image reconstruction algorithms on the Radixact helical tomotherapy system used in image-guided and adaptive radiation therapy.*Methods and Materials A Catphan CT image quality phantom was scanned across all available image acquisition modes and images were reconstructed using both the Standard filtered backprojection (FBP) and IR General iterative reconstruction (IR) algorithms available to the user. Image quality metrics including noise, uniformity, contrast, spatial resolution, mean CT numbers, and CT number linearity were evaluated and compared for both algorithms.*Results Application of the IR algorithm reduced noise levels by over 50% when compared to the FBP algorithm. IR performed best for contrast metrics, as contrast-to-noise ratio and low contrast visibility were both improved by at least a factor of two on average. Slight "capping" artifact was evident in both reconstructed sets, while FBP showed improved image uniformity as differences in CT numbers between periphery and center regions of interest in a homogenous phantom module were roughly half those seen in IR. Spatial resolution was also better for FBP, as average MTF values at both the 50% and 10% critical frequencies were improved by approximately 10-15%. Mean CT numbers for each algorithm differed by less than 1% on average across all phantom inserts, and both algorithms exhibited near perfect CT number linearity.*Conclusions The IR algorithm showed explicit improvement over the FBP algorithm for metrics most important to IGRT and ART - mainly image contrast and noise - allowing for improved target localization and contour refinement and reduced dosimetric uncertainties. While uniformity and spatial resolution were worse for IR, these values were still within vendor specifications and should not appreciably hinder the system in its uses. The algorithms performed equally well for CT number linearity, which is one possible indication of the ability to produce accurate dose calculations in a treatment planning system using these images.*Clinical Relevance/Application The addition of an IR algorithm is a notable improvement between Radixact and its predecessor, TomoTherapy. While both FBP and IR algorithms are available to the user for MVCT image reconstruction, the authors are not aware of any previous study that objectively compares the quality of reconstructed images for each method on this system. This work illustrates the overall improvement in image quality using the IR algorithm, a clear benefit to

any clinical routine. It is important to note as well that since all other imaging parameters remain the same between each algorithm, the application of IR allows for noise reduction and much improved image contrast without increasing imaging dose.

RESULTS

Application of the IR algorithm reduced noise levels by over 50% when compared to the FBP algorithm. IR performed best for contrast metrics, as contrast-to-noise ratio and low contrast visibility were both improved by at least a factor of two on average. Slight "capping" artifact was evident in both reconstructed sets, while FBP showed improved image uniformity as differences in CT numbers between periphery and center regions of interest in a homogenous phantom module were roughly half those seen in IR. Spatial resolution was also better for FBP, as average MTF values at both the 50% and 10% critical frequencies were improved by approximately 10-15%. Mean CT numbers for each algorithm differed by less than 1% on average across all phantom inserts, and both algorithms exhibited near perfect CT number linearity.

CLINICAL RELEVANCE/APPLICATION

The addition of an IR algorithm is a notable improvement between Radixact and its predecessor, TomoTherapy. While both FBP and IR algorithms are available to the user for MVCT image reconstruction, the authors are not aware of any previous study that objectively compares the quality of reconstructed images for each method on this system. This work illustrates the overall improvement in image quality using the IR algorithm, a clear benefit to any clinical routine. It is important to note as well that since all other imaging parameters remain the same between each algorithm, the application of IR allows for noise reduction and much improved image contrast without increasing imaging dose.

PH04-A11   Improvement Of Stent Image Quality In High-resolution Coronary Computed Tomography Angiography Using A New Deep Learning Image Reconstruction Algorithm

Participants
Fang Wang, Yinchuan, China (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the performance of deep learning reconstruction technology (DLIR) for noise reduction in high resolution coronary stent imaging with 256 row detector CT.*Methods and Materials 25 stents of 14 patients undergoing coronary CT angiography (CCTA) using high resolution (Hi-Res) acquisition mode on a 256 row detector scanner (Revolution CT, GE Healthcare)were included in this study after PCI operation. Images were reconstructed with sharp kernels of detail, HD-detail and deep learning reconstruction respectively. In-stent contrast attenuation and image noise were assessed. CT value difference between inside stent and outside stent were calculated and compared among groups. Image quality was subjectively by two radiologists on a 5-points Likert scale(5 for excellence and 1 for poor). One-way ANOVA and Kruskall-Wallis test were used to compare quantitative and subjective data respectively; p value <0.05 was considered significant.*Results There was no significant difference in CT values between detail, HD-detail, DLIR-H among three reconstructions (108.44 ±94.28), (101.56 ±93.07), (97.09 ±51.95) (F = 0.145, P = 0.865). SD value was found the lowest in DLIR-H reconstruction group (31.32 ± 10.38), which was significantly different from those in detail (47.78 ±14.07) and HD-detail (77.24 ± 19.34) groups (F = 59.719, P1 < 0.001, P2 < 0.001, P3 < 0.001).Subjective image score of stent was found significantly different among three reconstruction groups(H=45.689, P<0.001).*Conclusions Compared with sharp kernels of Detail and HD-detail, deep learning reconstruction (DLIR) with high resolution acquisition mode can significantly reduce the image noise in stent lumen and improve the image quality of coronary stent.*Clinical Relevance/Application By reducing image noise, DLIR could expand the use of Hi-Res acquisition mode for CCTA in clinical routine and improve coronary stenosis depiction.

RESULTS

There was no significant difference in CT values between detail, HD-detail, DLIR-H among three reconstructions (108.44 ±94.28), (101.56 ±93.07), (97.09 ±51.95) (F = 0.145, P = 0.865). SD value was found the lowest in DLIR-H reconstruction group (31.32 ± 10.38), which was significantly different from those in detail (47.78 ±14.07) and HD-detail (77.24 ± 19.34) groups (F = 59.719, P1 < 0.001, P2 < 0.001, P3 < 0.001).Subjective image score of stent was found significantly different among three reconstruction groups(H=45.689, P<0.001).

CLINICAL RELEVANCE/APPLICATION

By reducing image noise, DLIR could expand the use of Hi-Res acquisition mode for CCTA in clinical routine and improve coronary stenosis depiction.

PH04-A12   Effect Of Deep Learning Reconstruction Algorithms On The Visualization Of Small-diameter Coronary Stents

Participants
Fang Wang, Yinchuan, China (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the visibility of mall-diameter coronary stents under different levels of deep learning reconstruction algorithms using 256-detector CT scanner.*Methods and Materials 19 stents (<3mm) of 11 patients undergoing coronary CT angiography (CCTA) on a 256 row detector scanner (Revolution CT, GE Healthcare) were evaluated in this study. Images were reconstructed with three levels of deep learning reconstruction (DLIR-L, DLIR-M, DLIR-H) respectively. In-stent contrast attenuation and image noise were assessed. CT value difference between inside stent and outside stent were calculated and compared among groups. Image quality improved by removing the hardening beam artifacts was subjectively evaluated by two radiologists on a 5-points Likert scale (5 for excellence and 1 for poor). One-way ANOVA and Kruskall-Wallis test were used to compare quantitative and subjective data respectively; p value <0.05 was considered significant.*Results Interobserver agreement was excellent regarding image quality (kappa=0.84). Image quality in DLIR-H group (4.47±0.61) was significantly better than that in DLIR-M group (3.95±0.78) and DLIR-L group (3.16±0.60), (H=22.916, P<0.001).There was no significant difference in the CT attenuation difference inside stent and outside stent among groups (108.41±51.76 vs 102.01± 49.64 vs 101.65±57.90)(F = 0.097, P = 0.908).In-stent noise decreased with the increase of reconstruction intensity (52.51±15.79 vs 42.11±15.42 vs 33.34±12.01) (P = 0.095, P < 0.001, P = 0.204).*Conclusions High level of deep learning reconstruction (DLIR-H) can significantly remove the hardening beam artifacts of small-diameter coronary stents and improve in-stent luminal visualization and image quality.*Clinical Relevance/Application Deep learning reconstruction algorithm is a better way to enhance the in-stent assessment while decreasing image noise and artifact.

RESULTS

Interobserver agreement was excellent regarding image quality (kappa=0.84). Image quality in DLIR-H group (4.47±0.61) was

interobserver agreement was excellent regarding image quality (kappa=0.84). Image quality in DLIR-H group (4.47±0.61) was significantly better than that in DLIR-M group (3.95±0.78) and DLIR-L group (3.16±0.60), (H=22.916, P<0.001).There was no significant difference in the CT attenuation difference inside stent and outside stent among groups (108.41±51.76 vs 102.01± 49.64 vs 101.65±57.90)(F = 0.097, P = 0.908).In-stent noise decreased with the increase of reconstruction intensity (52.51±15.79 vs 42.11±15.42 vs 33.34±12.01) (P = 0.095, P < 0.001, P = 0.204).

CLINICAL RELEVANCE/APPLICATION

Deep learning reconstruction algorithm is a better way to enhance the in-stent assessment while decreasing image noise and artifact.

PH04-A3   A Novel Deep Learning Pipeline For Simultaneous Segmentation Of Lung And COVID-19 Involvement In Thoracic CT Scans

Participants
Elise Katsnelson, Chicago, Illinois (*Presenter*) Nothing to Disclose

PURPOSE

To develop a fast and efficient deep learning model for segmenting total lung tissue and lung tissue diseased with COVID-19 on thoracic CT scans via a novel dual-headed U-Net architecture.*Methods and Materials A dataset of 31 thoracic CT scans (each with approximately 500 slices) from 18 patients were manually segmented for lung tissue and COVID-19 involvement by a trained expert radiologist. Features associated with COVID-19 disease were identified, including ground glass opacity, consolidation, linear/reticular opacities, crazy paving, nodules, and architectural distortions. Subsequently, a novel deep learning pipeline was developed by using a modified two-headed U-Net architecture for automatic, simultaneous segmentation of lung tissue and COVID-19 involvement for each input slice of the CT scan, and was trained and evaluated on this data set (split up into training, validation, and testing subsets). The Dice similarity coefficient from the testing subset was used as a measure of accuracy for this model. After training and evaluation, this model was then used to automatically segment the lungs and COVID-19 involvement on 865 thoracic CT scans, and quantitative features, such as shape, intensity, texture, and ratio of diseased to total tissue, were extracted to make clinically useful recommendations.*Results The Dice coefficients for the dual-segmentation U-Net model were 0.91 for the total lung tissue and 0.55 for COVID-19 involvement.*Conclusions Given the variation of COVID-19 segmentations amongst radiologists due to its many presentations, the novel U-Net architecture provides adequate and streamlined automatic simultaneous segmentations of the lungs and COVID-19 involvement for thoracic CT scans. This approach provides potential for faster and more efficient COVID-19 diagnostic performance without compromising cost.*Clinical Relevance/Application Due to the urgency and strained resources caused by the COVID-19 pandemic, there is a need to make efficient and rapid decisions to inform patient care and treatment based on the extent of COVID-19 severity and presentation to ensure hospital preparedness, minimize the length of hospital stay, and optimize care.

RESULTS

The Dice coefficients for the dual-segmentation U-Net model were 0.91 for the total lung tissue and 0.55 for COVID-19 involvement.

CLINICAL RELEVANCE/APPLICATION

Due to the urgency and strained resources caused by the COVID-19 pandemic, there is a need to make efficient and rapid decisions to inform patient care and treatment based on the extent of COVID-19 severity and presentation to ensure hospital preparedness, minimize the length of hospital stay, and optimize care.

PH04-A5   Effects Of Megavoltage Cross-scatter On Kilovoltage CBCT Image Quality In Image Guided Radiation Therapy

Participants
Farhang Bayat, Aurora, Colorado (*Presenter*) Nothing to Disclose

PURPOSE

Target tracking during image-guided radiation delivery is an active area of research to improve accuracy of radiation delivery. While 2D-3D kilovoltage (kV) imaging can be used for real-time target tracking during treatment delivery, the detrimental effects of megavoltage (MV) cross-scatter can degrade the quality of kV images and visualization of targets. Thus, in this work, we studied the effects of MV cross-scatter both in kV projections and CBCT reconstructions.*Methods and Materials A Varian TrueBeam linac was operated in Developer Mode to deliver MV beams during kV CBCT acquisitions in offset kV detector geometry. Using pelvis-sized phantoms, two sets of kV CBCT projections were acquired, one with and one without MV beam delivery during CBCT scans. To study MV cross-scatter, 200 cGy was delivered at isocenter using 3X3 and 15X15 cm2 field sizes. Experiments were repeated using 6 and 10 MV beams, and flattening filter free (FFF) modes. For evaluations, MV scatter to kV intensity ratio (MVkV-Ratio) was calculated in projections. In addition, contrast-to-noise (CNR) and Hounsfield Unit (HU) loss due to MV cross-scatter were calculated in CBCT images.*Results For 3X3 field size, MVkV-ratio varied between 0.1-1 for all MV beam energies. When field size was increased to 15X15, MVkV-ratio increased by a factor of 14-39, and it was in the range of 4-10. 6 MV beam yielded the highest scatter intensity in experiments using FFF. For 15X15 field, MV-cross scatter introduced severe cupping artifacts in CBCT images. CNR loss was in the range of 60- 88% and HU loss was in the range of 263-457.*Conclusions Our study indicates that MV cross-scatter has significant impact on kV image quality. Robust MV cross-scatter mitigation methods are needed to be able to perform real-time kV imaging during MV beam delivery. While our study employed static MV beams, effect of dynamic beam delivery in the context of stereotactic body radiation therapy will also be investigated in feature experiments.*Clinical Relevance/Application This work characterizes the detrimental effects of MV cross-scatter on kV CBCT image quality during intra-beam delivery kV CBCT scans in radiation therapy.

RESULTS

For 3X3 field size, MVkV-ratio varied between 0.1-1 for all MV beam energies. When field size was increased to 15X15, MVkV-ratio increased by a factor of 14-39, and it was in the range of 4-10. 6 MV beam yielded the highest scatter intensity in experiments using FFF. For 15X15 field, MV-cross scatter introduced severe cupping artifacts in CBCT images. CNR loss was in the range of 60- 88% and HU loss was in the range of 263-457.

CLINICAL RELEVANCE/APPLICATION

This work characterizes the detrimental effects of MV cross-scatter on kV CBCT image quality during intra-beam delivery kV CBCT

scans in radiation therapy.

PH04-A6 The Application Value Of Artificial Intelligence In Vessel Identification And Stenosis Diagnosis In Coronary CT Angiography

Participants
Shumeng Zhu, Xi'an, China (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the application value of artificial intelligence (AI) in automatically identifying coronary arteries and significant stenosis diagnosis in coronary CT angiography (CCTA).*Methods and Materials 60 patients (aged 54.90±10.81y, weight 61.39±11.90kg, and BMI 23.56±2.76 kg/m2) with suspected coronary heart disease for CCTA were enrolled. Patients underwent CCTA on a 256-row Revolution CT with 100kVp, automatic tube current. Images were reconstructed at 0.625mm with 70%ASIR-V and were transferred to a CAD AI Assisted Diagnosis System (CAD-AI-ADS). CAD-AI-ADS automatically processed the CCTA images to perform coronary artery segmentation and stenosis diagnosis. Meanwhile, manual image processing and stenosis diagnosis of coronary arteries were performed by 2 radiologists independently, and the results were used as reference standard for evaluating the ability of CAD-AI-ADS to recognize the right coronary artery (RCA), left anterior descending (LAD) and left circumflex (LCX), and the diagnostic ability of more than 50% stenosis in RCA (proximal, middle and distal), LAD (proximal, middle and distal) and LCX (proximal, mid-distal).*Results In total there were 480 vessel segments. CAD-AI-ADS performed significantly faster than radiologists in identifying coronary arteries (0.41±0.89 vs 7.35±2.64min, p < 0.001). The image processing accuracy of CAD-AI-ADS for identifying and segmenting RCA, LAD and LCX and their branches was 96.67%, 96.67% and 93.33%, respectively. The diagnostic accuracy, sensitivity and specificity of CAD-AI-ADS for coronary arteries with more than 50% stenosis were 85.21%, 57.76% and 93.96%, respectively. The positive predictive value and negative predictive value were 75.28% and 87.47%, respectively.*Conclusions Compared with image processing by radiologists, CAD-AI-ADS can significantly improve work efficiency on the basis of ensuring the same recognition accuracy. However, the sensitivity of CAD-AI-ADS for diagnosing coronary arteries with more than 50% stenosis is relatively low, and there is a certain rate of missed diagnosis, which still needs to be reviewed by doctors.*Clinical Relevance/Application CAD-AI-ADS can significantly improve work efficiency on the basis of ensuring the same recognition accuracy.

RESULTS

In total there were 480 vessel segments. CAD-AI-ADS performed significantly faster than radiologists in identifying coronary arteries (0.41±0.89 vs 7.35±2.64min, p < 0.001). The image processing accuracy of CAD-AI-ADS for identifying and segmenting RCA, LAD and LCX and their branches was 96.67%, 96.67% and 93.33%, respectively. The diagnostic accuracy, sensitivity and specificity of CAD-AI-ADS for coronary arteries with more than 50% stenosis were 85.21%, 57.76% and 93.96%, respectively. The positive predictive value and negative predictive value were 75.28% and 87.47%, respectively.

CLINICAL RELEVANCE/APPLICATION

CAD-AI-ADS can significantly improve work efficiency on the basis of ensuring the same recognition accuracy.

PH04-A8 Personalized Quantitative Perfusion MRI Parametric Mapping Using High Spatiotemporal Resolution Grasp And Patient-specific Estimation Of The Arterial Input Function In Gynecologic Tumors

Participants
Yousef Mazaheri, PhD, New York, New York (*Presenter*) Nothing to Disclose

PURPOSE

To develop a personalized quantitative dynamic contrast enhanced MRI (DCE-MRI) technique using golden-angle radial sparse parallel MRI (GRASP) with high spatial and temporal resolution and estimation of arterial input function (AIF) directly from the data in each patient.*Methods and Materials Six patients referred for pelvic MRI to assess gynecologic cancer were included in this IRB approved single institution prospective study. DCE-MRI was performed with a 3T MRI scanner (MR750w, GE Healthcare) using the GRASP technique and retrospective image reconstruction of image series at dual temporal resolution (1 s/frame and 5 s/frame). A 4D (3D+time) supervoxel method was used to cluster voxels within the tumor volume based on both contrast enhancement patterns and spatial distance. Joint estimation of AIF and pharmacokinetic parameters was achieved with an algorithm that iteratively alternates between estimation of AIF and pharmacokinetic parameters constructed based on images reconstructed at 1 s/frame. Voxelwise pharmacokinetic analysis using extended Tofts model was performed with images reconstructed at 5 s/frame using cluster-specific AIF. Maps of volume transfer constant (Ktrans), extravascular extracellular fractional volume (ve), and blood plasma volume fraction (vp) were generated.*Results The use of dual temporal resolution of 1-5 s/frame yield less than 5% error in the estimation of pharmacokinetic parameters. Using personalized AIF, the normalized root-mean-square error (mean ± std. dev.) was 0.16±0.04 as compared to 0.22±0.05 using population-averaged AIF. The figure demonstrates the ability of patient specific AIF to 1) better account for tumor heterogeneity as demonstrated by the higher dynamic range of Ktrans and kep maps and higher count of non-zero vp voxels and 2) improved goodness of fit as demonstrated by near zero nRMSE values for most voxels for patient-specific AIF.*Conclusions The proposed patient-specific GRASP results in pharmacokinetic model parameter estimates which are less biased as compared to population-averaged AIF. The spatial-temporal characteristics of localized AIF could provide information regarding the network organization of the tumor microvasculature that leads to contrast agent transport.*Clinical Relevance/Application This work represents a step toward promoting GRASP as a one-stop-shop approach for quantitative DCE-MRI and alleviating the need for population-based AIF, the highest sources of quantitative DCE-MRI bias.

RESULTS

The use of dual temporal resolution of 1-5 s/frame yield less than 5% error in the estimation of pharmacokinetic parameters. Using personalized AIF, the normalized root-mean-square error (mean ± std. dev.) was 0.16±0.04 as compared to 0.22±0.05 using population-averaged AIF. The figure demonstrates the ability of patient specific AIF to 1) better account for tumor heterogeneity as demonstrated by the higher dynamic range of Ktrans and kep maps and higher count of non-zero vp voxels and 2) improved goodness of fit as demonstrated by near zero nRMSE values for most voxels for patient-specific AIF.

CLINICAL RELEVANCE/APPLICATION

This work represents a step toward promoting GRASP as a one-stop-shop approach for quantitative DCE-MRI and alleviating the need for population-based AIF, the highest sources of quantitative DCE-MRI bias.
