R5A-SPIR-6 The Reproducibility of Interventional Radiology Randomized Controlled Trials

Participants
Assala Aslan, MD, Shreveport, LA (*Presenter*) Nothing to Disclose

PURPOSE

Numerous randomized controlled trials (RCTs) relevant to the Interventional Radiology field have been performed within the last decade. The fragility index was recently developed to complement the P value and measure the robustness and reproducibility of clinical findings of RCTs. Low fragility index indicates that the study hinges on only a few events for statistical significance. In this study we evaluate the fragility index for key Interventional Radiology RCTs.

METHODS AND MATERIALS

Interventional Radiology RCTs published between 2000 and 2021 were reviewed. Six key areas were specifically targeted in relation to transjugular intrahepatic portosystemic shunt, trans-arterial chemoembolization, preoperative embolization, needle biopsy, gastrostomy tube insertion, and nephrostomy tube insertion. RCTs related to cardiovascular or neurosurgical intervention were not included as they were reported in prior studies.

RESULTS

A total of 84 RCTs that reported significant differences between both study groups in terms of the primary outcome were included. The median fragility index of those studies was 4. Studies related to trans-arterial chemoembolization were associated with a higher fragility index compared to other fields.

CONCLUSION

s The median fragility index related to Intervention Radiology is low compared to other surgical fields. Therefore, one should exercise caution with interpreting the results of those RCTs, especially when the sample size and events numbers are small and there is a high number of patients who were lost to follow up.

CLINICAL RELEVANCE/APPLICATION

Fragility index is a reflex of the robustness and reproducibility of clinical trials. A fragility index of 1 means that if only 1 patient did not reach the primary outcome in the study group the results will not be statistically significant. Trials with low fragility index are less reproducible and, thus, should not be included in clinical guidelines.

R5A-SPIR-7 Short and Mid Term Follow-up of Sympathetic Chain Block with Botox in PAOD and CRPS Patients

Participants
Benjamin Reichardt, Hattingen, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To analyze the duration of therapeutic success in PAOD and CRPS patients in lumbar sympathetic chain block using botulinum toxin as an alternative to definitive sympathicolysis.

METHODS AND MATERIALS

We analyzed 126 Patients 66 with CRPS of the foot and 60 pat. with PAOD grade 3 4 from 2015 - 2022. 49 patients were treated bilaterally in the case of PAOD. Initial pain scale was between 7 and 10. PAOD patients with 67% had small dermal ulcerations. CRPS patients 40% with CRPS type 1; 60% type 2. PAOD patients were treated with medication, interventional or vascular surgery. Sympathicolysis was indicated to improve micro-vascular perfusion. CRPS patients suffered on average for more than 3 mo. from chronically maintained pain that could not be assigned to a nerve supply area. CT-guided lumbar sympathetic blocks. The target region was the ventrolateral ganglion at the level of the upper edge of the 4th lumbar vertebral body of the affected side. Temperature probes were applied to feootsoles before intervention . The injection is performed placing a 22G myelography needle into the target region with 100 mouse unitis botulinum toxin in 1ml NaCl. 1h, 24h, 1 week, 4 weeks, 3, 6 and 12 months the patients were evaluated by questionnaire about their symptoms, pain and walking distance.

RESULTS

CRPS patients showed a rapid increase in temperature and a significant reduction in pain. The improvement of symptoms in CRPS patients lasted up to 12 months and after follow up. PAOD patients showed a slight increase in temperature and delayed improvement in micro-vascular perfusion within the first hour after intervention. Pain improved from 7-10 to 1-4 in the first 24 h. Dermal ulcerations healed within the first week. The longer observation period between 6 and 12 months showed worsening of walking distance and pain as well as microvascularization. The median pain value: 7.

CONCLUSION

s Botox is a potent agent for lumbar sympathetic blocks. The results for the treatment of CRPS are promising and showed no risks.

There was no worsening of symptoms during the observation period. In contrast, botox showed only a medium-term improvement in microvascularization and pain reduction in PAOD. Symptom worsening was accompanied by physiological degradation of the product. Nevertheless, no clear distinction could be made whether there was worsening of the underlying PAOD, therapy changes etc..

CLINICAL RELEVANCE/APPLICATION

Botox can be used as a potent therapeutics in CRPS in sympathetic chain blocks. In PAOD it is a usefull and in a Dosis of 100MU a harmless therapeutic with effective improvement of mikrovasculature and pain reduction between 6 and 12 Months. It might also be used as bridging therapy for support of dermal ulcer healing or before definitive intervention or bypass surgery.

R5A-SPIR-8 Trends in Inferior Vena Cava Filter Placement, Repositioning, and Retrieval Rates in the Medicare Population

Participants
Nidhi Ramesh, (*Presenter*) Nothing to Disclose

PURPOSE

To analyze trends in the procedural volume of inferior vena cava (IVC) filter placements, retrievals, and repositionings in the Medicare beneficiary population between the years 2015 and 2019.

METHODS AND MATERIALS

The nationwide Medicare Physician/Supplier Procedure Summary Master Files were used to determine the volume of IVC filter placements, repositionings, and retrievals, which correspond to Current Procedural Terminology (CPT) codes 37191, 37192, and 37193, respectively. A regression analysis of each of these trends was additionally performed.

RESULTS

The total volume of Medicare IVC filter placement decreased from 44,378 in 2015 to 25,557 in 2019. The total volume of Medicare IVC filter repositionings in 2015 was 38 and increased to 46 in 2017, and then decreased to 35 in 2019. The total retrieval of IVC filters increased from 6,166 removals in 2015 to 7,490 in 2019. Placement rate per 100,000 Medicare beneficiaries decreased from 81.73 in 2015 to 42.42 in 2019. Retrieval rate per 100,000 Medicare beneficiaries increased from 11.36 in 2015 to 12.43 in 2019.

CONCLUSION

s In the Medicare population between 2015 and 2019, the number of IVC filter placements per 100,000 enrollees decreased by 48% while the number of IVC filter retrievals per 100,00 enrollees increased by 9.3%. The number of IVC repositionings remained relatively constant throughout this period. These data support the FDA’s 2014 recommendation to remove retrievable IVC filters once a patient’s risk for acute pulmonary embolism has passed, given that these types of filters are not always removed expeditiously.

CLINICAL RELEVANCE/APPLICATION

In analyzing IVC filter trends in the Medicare population, we are able to gain valuable insight into physician preferences for utilizing IVC filters as well as the success of efforts to improve filter retrievals.

R5A-SPIR-9 Emergency Trans-jugular Intrahepatic Portosystemic Shunt Creation (TIPS): Hybrid Intervention (tri-modal) and Image Fusion

Participants
Jonathan Nadjiri, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Emergency transjugular intrahepatic portosystemic shunt (TIPS) creation is associated with high peri-interventional mortality. It remains the only treatment in patients with portal hypertension and oesophageal bleedings and unsuccessful endoscopic treatment. The reasons for the high mortality are often post-interventional liver bleedings because of incorrect puncture. In the last years hybrid intervention suites are emerging. They combine CT-imaging with conventional angiography allowing to project 3D information into the conventional 2D imaging and further CT-fluoroscopic puncture of the portal vein.The purpose of this prospective study was to assess survival rate in emergency TIPS patients treated with a hybrid intervention using image fusion in comparison to outcome of TIPS using standard intervention.

METHODS AND MATERIALS

All emergency TIPS patients from 2021 and 2022 were included (n=11). Six patients were treated with the standard technique and 5 patients in the hybrid angiography suite. Jugular access was done with sonography guidance for both groups. For the hybrid intervention a contrast enhanced CT was performed on the angiography table. The 3D information was registered to the patient. Portal vein access point and preferred liver vein were marked. The lower liver capsule was marked. From the CT a 3D volume was created using virtual rendering technique (VRT). The VRT as well as the above-mentioned markings were blended into the conventional angiography image and used as guidance for the TIPS-needle.

RESULTS

Hybrid TIPS did lead to a significantly shorter fluoroscopy time ($p = 0.038$). Mean radiation exposure was significantly reduced be the factor 6 ($p = 0.014$). Furthermore, the mortality rate was lower in patients who underwent the hybrid intervention (0% vs 33%).

CONCLUSION

s Emergency TIPS using hybrid intervention technique improves survival for this high-risk procedure. Further, this technique the procedure is quicker and reduces radiation exposure for the patient and the interventionalist.

CLINICAL RELEVANCE/APPLICATION

In daily clinical practice hybrid TIPS creation using image fusion should be prefered over a conventional approach when ever possible.

Imaging Implications of Extracellular Matrix Stiffness on Liver Cancer Vascular Phenotypes

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - IR DPS

Participants
Ryosuke Taiji, MD, Kashihara, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Interplay between liver tumor stiffness and microvascular phenotypes has not been fully elucidated. The goal of this study is to characterize impact of matrix stiffness signatures on vascular histology and dynamic contrast-enhancement imaging in a rat HCC model.

METHODS AND MATERIALS

Buffalo-McA-RH7777 (n=12) and Sprague Dawley-N1S1 (n=8) tumor models were used to evaluate tumor stiffness by shear wave elastography (SWE), along with tumor perfusion by dynamic CEUS and CECT. Atomic force microscopy (AFM) was used to calculate tumor stiffness at a sub-micron scale. Computer-aided image analyses were performed using Aperio-microvessel and GENIE pattern-recognition algorithms. Arbitrary 2(au) and Hounsfield units (HU) were used for peak intensity or attenuation, respectively. Pearson product-moment correlation coefficient, linear mixed model, and Wilcoxon signed-rank were used to evaluate pairwise correlations and differences between models.

RESULTS

Results of linear mixed model showed distinct tissue signatures between models according to the distribution of the stiffness values ($P<0.05$). Higher stiffness values were attributed to SD-N1S1 tumors, with a positive coefficient for AFM ($P = 0.048$) and marginally significant for SWE ($P= 0.07$), using AFM as reference. The stiffer N1S1 model was associated with scant microvascular network and with mean % of CD34+microvessel coverage of 2.9±1.2 compared to 8.7±1.6 in McA-RH7777 ($P=0.001$). Moreover, a higher % of vessels were located on the tumor periphery compared to tumor center ($P=0.03$). Opposite results were observed in McA-RH7777 model, exhibiting richer tumor vasculature with predominantly central distribution ($P=0.02$). Consistently with these findings, tumor enhancement was significantly greater in McA-RH7777 tumors than N1S1 on both CEUS ($P=0.014$) and CECT (HU increase; $P=0.003$, AUCarterial; $P<0.001$; AUCtotal au*s; $P=0.02$ and HU*s; $P<0.001$). Significant positive correlation between tumor perfusion and % microvessel coverage was observed (CEUS;$P=0.043$ and CECT;$P=0.006$). Enhancement features were closely correlated with between CEUS and CECT; $P<0.05$

CONCLUSION

s Stiffness signatures translated into different tumor vascular phenotypes. These differences displayed unique imaging perfusion parameters with significantly greater contrast enhancement observed in softer McA-RH7777 tumors

CLINICAL RELEVANCE/APPLICATION

Matrix stiffness represents a barrier to effective drug delivery and can negatively impact the outcome of local treatments. Elastography can provide helpful information about the tumor microenvironment, particularly the matrix and its modification by stromal cells

Percutaneous Combined Chemical and Mechanical Necrosectomy for Walled-Off Pancreatic Necrosis: A Retrospective Analysis

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - IR DPS

Participants
Kamyar Ghabili, MD, New Haven, CT (*Presenter*) Nothing to Disclose

PURPOSE

The management of walled-off pancreatic necrosis (WOPN) as a complication of acute necrotic pancreatitis necessitates a multidisciplinary step-up approach. However, the current level of evidence for percutaneous necrosectomy by interventional radiology in treating WOPN is limited. We aimed to study the feasibility, safety, and efficacy of percutaneous combined chemical and mechanical necrosectomy using a Malecot anchor drain and Arrow-Trerotola Percutaneous Thrombolytic device in patients with WOPN by comparing the results with a historical control group.

METHODS AND MATERIALS

In a retrospective analysis, patients with pancreatitis complicated by WOPN not amenable to endoscopic-guided cystogastrostomy were studied in case and historical control groups. Patients in the case group underwent percutaneous combined chemical (using hydrogen peroxide) and mechanical necrosectomy using the Malecot anchor drain and/or Arrow-Trerotola percutaneous thrombolytic device from December 2020 through September 2021. The controls underwent mechanical necrosectomy alone without chemical necrosectomy. Clinical success was defined as complete resolution of the cavity on follow up sinogram or noncontract CT scans with subsequent drain removal.

RESULTS

Thirteen patients (median age, 40 years; 11 men) in the case group and 11 control patients (median age, 60 years; 10 men) underwent CT or US guided percutaneous drain placement followed by percutaneous combined chemical and mechanical necrosectomy (case group) or mechanical necrosectomy only (control group) for WOPN. Drain placement and necrosectomy were technically successful in all studied patients. One case patient developed bleeding from a small branch of the jejunal artery on post-necrosectomy day 9, which was successfully embolized by interventional radiology. No pancreaticocutaneous fistula was reported on 3-month follow-up of our patients. The clinical success rate in the case and control groups was 100% and 38.4%, respectively (p=0.002).

CONCLUSION

s Percutaneous combined chemical and mechanical necrosectomy performed by interventional radiology is a feasible, safe, and effective treatment approach of WOPN.

CLINICAL RELEVANCE/APPLICATION

Percutaneous chemical plus mechanical necrosectomy using Malecot catheter and Arrow-Trerotola thrombolytic device is a feasible, safe and effective treatment of walled-off pancreatic necrosis.

R5A-SPIR-3

The Bariatric Embolization of Arteries with Imaging Visible Embolics (BEATLES) Trial: Pilot Phase

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - IR DPS

Participants
Adham Khalil, MD, Baltimore, MD (*Presenter*) Research Grant, Siemens AG

PURPOSE

To evaluate the feasibility, safety and efficacy of bariatric artery embolization (BAE) in patients with obesity using customized tightly calibrated 100-200µm radiopaque embolic microspheres, "BTG-001933" (Biocompatibles UK Ltd).

METHODS AND MATERIALS

BEATLES is an IRB and FDA-approved physician-initiated investigational device exemption prospective clinical trial. The pilot phase of this study started in October 2020, with 10 participants currently enrolled. Key inclusion criteria include: age 21-70 years, BMI =35 kg/m2 and weight =400 lb. Absolute exclusion criteria include: taking hypoglycemic agents (except metformin), inability to undergo MRI, allergy to iodinated contrast and renal insufficiency. After initial screening, participants have a six-week "run-in" to complete pre-BAE screening for psychiatric disorders and dietary coaching. Eligible participants undergo a rapid whole-body MRI for volumetric measurement of body adiposity, and an upper endoscopy with gastric mucosal biopsy to rule out pathologies such as peptic ulcer disease or gastritis, which may exclude them from the study.Seven participants (6 women and 1 man; mean age 39.7±10.5 years) with obesity who underwent BAE were included in the preliminary analysis. Participants were followed up for 12 months after embolization. Changes in body weight and BMI at 1, 3, 6, and 12-months follow-up as well as the 30-day adverse events (AEs) were recorded. Feasibility was assessed based on ability to visualize the microspheres under fluoroscopy and extent of embolic fundal coverage on post-procedural MDCT.

RESULTS

In seven participants, the LGA (n=7), with or wiout the gastroepiploic artery (GEA; n=4), was embolized, with a 100% technical success rate. There were no major AEs. One minor AE (mucosal ulcer) was observed and healed at 5-month endoscopy. All participants were admitted for routine supportive care for <48 hours post-BAE. Pre-procedural mean weight was 124.6±21.2 kg and mean BMI 42.7±4.5 kg/m2. Table 1 shows the changes in body weight and BMI at different follow-ups.

CONCLUSION

s BAE using customized tightly calibrated radiopaque 100-200µm microspheres "BTG-001933" is feasible and appears to be well tolerated by participants with severe obesity. Preliminary analysis of weight loss outcomes demonstrates promising efficacy.

CLINICAL RELEVANCE/APPLICATION

BEATLES is the first clinical study to evaluate using "BTG-001933", a novel customized tightly caliberated radiopaque micropsheres of the 100-200µm size, for bariatric artery embolization.

Ethanol Embolization Combined or Not with Surgery and Close Clinical Follow-up Can Effectively Control Extracranial Arterio-venous Malformations (AVMS)

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - IR DPS

Participants
Ke Chen, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Arteriovenous malformations (AVM) are congenital high flow lesions that have a wide range of clinical manifestations, varying from asymptomatic to high-output heart failure. We looked at the long-term outcome of patients with extra-cranial AVMs following different types of treatment.

METHODS AND MATERIALS

A retrospective study was performed, collecting data on all cases of proven extracranial AVMs at two university hospitals from 1985 to 2021. We documented whether the patient received conservative, endovascular, surgical, or combined treatments. The clinical response of treatments was assessed using the Schobinger's classification. Our primary endpoint was to evaluate evolution of Schobinger class in patients of our cohort.

RESULTS

A total of 190 proven cases of extracranial AVMs were included in the study. Mean follow up time was 7.0 years [0.0-28.0 years]. The mean Schobinger stage was 2.11 at baseline and 1.32 at final follow-up ($p<0.001$). For the cohort, 52 patients were treated conservatively, 104 patients received endovascular treatment alone, 3 patients received surgical treatment alone, and 31 patients received combined therapy. Overall, 71 patients (37%) achieved complete remission of the disease, 34 patients (18%) achieved improvement of symptoms, 81 patients (42%) remained stable, and 4 patients (2%) worsened. No clinical worsening was observed in the 52 patients (Schobinger stage 1-2) that did not receive any endovascular or surgical treatment.

CONCLUSION

s Ethanol embolization with or without surgery is efficient for long term control of extracranial AVMs. We observed that not all patients evolve from Schobinger stage 1-2 to a further stage, and clinical observation without treatment can be suitable and appropriate for asymptomatic patients.

CLINICAL RELEVANCE/APPLICATION

Since extracranial AVMs are rare, there is a lack of empirical evidence in the literature to assess if ethanol embolization with or without surgery can successfully and safely achieve lifelong control of extracranial AVMs. It was also thought that all these lesions inevitably progress with time. Our study is demonstrates the effectiveness and safety of ethanol embolization to treat extracranial AVMs. We also show that not all patients with AVMs evolve to a further stage.

R5A-SPMK-1 Radiomic Nomogram for Predicting High-Risk Cytogenetic Status in Multiple Myeloma Based on Fat-Suppressed T2-Weighted Magnetic Resonance Imaging

Participants
Suwei Liu, (*Presenter*) Nothing to Disclose

PURPOSE

To establish and validate clinical fat-suppressed T2-weighted magnetic resonance imaging (FS-T2WI) radiomic nomograms of MM HRC status for pre-treatment decision making and prognostic assessment.

METHODS AND MATERIALS

A cohort of 159 patients with MM (71 HRC, 88 non-HRC),The region of interest of the largest tumor lesions on FS-T2WI images was manually outlined, and 1688 features were obtained. Fourteen radiomic features were selected by 10-fold cross-validation using feature selection variance thresholds, Student's t test, redundancy analysis, and least absolute shrinkage and selection operator methods. Logistic regression was used to establish a clinical prediction model (model 1), a FS-T2WI radiomic prediction model (model 2), and a clinical-radiomic prediction model (model 3). Receiver operating characteristic (ROC) curves were used to evaluate and compare their diagnostic performance. Kaplan-Meier survival analysis and logrank tests were used to assess the prognostic value of the radiomic nomograms.

RESULTS

Models 2 and 3 showed significantly higher diagnostic efficacy than model 1 (both p <0.05). The area under the ROC curve of models 1, 2, and 3 was (training set: 0.65, 0.83, and 0.85; validation set: 0.70, 0.73, and 0.76, respectively). Kaplan-Meier survival analysis showed similar prognostic values for the radiomic nomogram and MM cytogenetic status (logrank test, both p<0.05; C-index, 0.651 and 0.659, respectively; z-score test, p=0.153).

CONCLUSION

s Radiomic nomograms can predict the HRC status of MM, potentially contributing to pre-treatment clinical decision making and prognostic assessment.

CLINICAL RELEVANCE/APPLICATION

Radiomics has shown promise for predicting the cytogenetic status of multiple myeloma (MM). However, few studies have investigated the role of single sequence radiomic nomograms in predicting the high-risk cytogenetic (HRC) status of MM.

R5A-SPMK-2 Deep Learning-based Automated Compression Fracture Analysis Algorithm On Spine Radiography for Onsite Application

Participants
Hongjun Yoon, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To develop a deep-learning-based algorithm that conducts reliable measuring of compression ratio (CR) for compression fracture (CF) diagnosis in lateral X-rays.

METHODS AND MATERIALS

We, retrospectively, collected 7,650 spine X-ray images which has been sent to the government agency under ministry of health and welfare responsible for claims review and quality assessment of the Health Insurance. We used four classification models, view, body part, posture, and assistant device, to classify whether the input radiography is a subject for CF analysis. With U-Net model, trained with 1,040 lateral TL-spine X-rays and annotations, we segment vertebra body (VB) to calculate the compression ratio by each subject's front height over average of the two adjacent ones. We calculated CR by the subject VB's front height over average of the two adjacent VB's front heights.

RESULTS

For evaluating performance of our algorithm, we used 250 spine X-ray images, included 145 TL-Spine X-ray images suitable for CR measurment (44.18%±13.04%, min: 20%, max: 74.72%). The sequential CF subject classification model show an accuracy of

94.8% (95% CI: 0.912=p=0.972). Mean Absolute Error (MAE) between ground truth and the predicted CR was 6.04% with standard deviation of 8.86%. By evaluating the above performance by ground truth's severity, the mild, moderate, and, severe fracture performances were 6.54%±7.64%, 4%±3.78% and 7.2%±10.74% respectively.

CONCLUSION

s In practice, it is essential to check whether the input image is suitable for specific analysis algorithms. Unsuitable input could give false result, potentially misguide medical practitioner, and even slow down the process, which is the opposite of the purpose of automated system. Result of this study shows that our automatic algorithm could not only provide an efficient change in process of measuring CR with high performance, but also be an objective solution by selecting subject analysis images.

CLINICAL RELEVANCE/APPLICATION

To apply deep learning based automated analysis algorithm into actual practice, we propose a sequential classification model to select the subject image for analysis of CF, which is required to be plain lateral TL-spine x-ray image.

R5A-SPMK-3 A Study for Measuring Vertebral Bone Structure by Generated Micro-CT-like Images: An Approach Based on FUNIT Conditional Generative Adversarial Network Mapping

Participants
Dan Jin, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the quality of micro-CT-like images generated by FUNIT models based on conditional generative adversarial networks(CGAN) and their value in vertebral bone structure measurements.

METHODS AND MATERIALS

The same anatomical areas of 25 human lumbar spine specimens were scanned using MDCT and micro-CT for normalization, resulting in 6,250 MDCT images (slice thickness 0.6 mm, slice spacing 0.1 mm) and 12,500 micro-CT images (slice thickness 0.052 mm, slice spacing 0.052 mm). 80% of the MDCT and micro-CT images are randomly selected as the training set, and 20% image in the previous section are used as the test set in this part. Image mapping is performed by three unsupervised methods, where FUNIT is the experimental model and StarGAN and CycleGAN control models. Image quality evaluation of vertebral images was performed using Friedman test to compare the differences in SSIM and FID values between the original MDCT and three groups of unsupervised model-generated micro-CT-like images. The paired t-test and linear regression were used to compare the differences and correlations of bone structural indices (BV/TV, Tb.Th and Tb.Sp) between FUNIT-like micro-CT and micro-CT. ICCs were used to analyze the consistency between bone structure indexes between FUNIT micro-CT-like and micro-CT image.

RESULTS

The image quality scores (SSIM/FID) of original MDCT and micro-CT-like images generated by FUNIT,starGAN and cycleGAN models were 0.519±0.030/ 201.737±15.031,0.437±0.025/ 289.503±18.037,0.377±0.035/ 347.311±25.051,and 0.238±0.031/ 453.425±39.081 respectively. The bone structure measurements measured by FUNIT micro-CT-like and micro-CT were images as follows, BV/TV (%) 0.143±0.018 and 0.180±0.016, Tb.Th (mm) 0.158±0.021 and 0.218±0.015, Tb.Sp (mm) 1.144±0.166 and 0.934±0.126, respectively. The BV/TV and Tb.Th measured by FUNIT micro-CT-like images were smaller than that of micro-CT($P < 0.05$), while Tb.Sp was larger than that of micro-CT ($P < 0.05$). The correlations of bone structure indexes between FUNIT micro-CT-like and micro-CT were BV/TV (R2=0.667), Tb.Th (R2=0.613) and Tb.Sp (R2=0.603), respectively ($P<0.001$). The ICC of bone structure measurements between FUNIT micro-CT-like and the micro-CT images were BV/TV (0.809), Tb.Th (0.753) and Tb.Sp (0.753), respectively ($P < 0.001$).

CONCLUSION

s The CGAN-based unsupervised FUNIT-micro-CT-like images were highly similar to micro-CT, and the bone structure indexes measured by FUNIT-micro-CT-like images this image are highly correlated with those of micro-CT.

CLINICAL RELEVANCE/APPLICATION

The CGAN-based unsupervised FUNIT-micro-CT-like image may provides an in-vivo and non-invasive solution for bone structure measurement.

R5A-SPMK-4 A Deep Learning Model for Classification of Chondroid Tumors on CT-Images

Participants
Felix Gassert, MD, MBA, Munich, Germany (*Presenter*) Consultant, SmartReporting GmbH

PURPOSE

Differentiation between enchondromas, atypical cartilaginous tumors (ACT) and high-grade chondrosarcomas is crucial for adequate patient management. Although, several imaging features have been identified, differentiating enchondromas from ACTs radiologically remains challenging. Therefore, the goal of this study was to develop a deep learning model (DLM) for the classification of chondroid tumors based on CT images.

METHODS AND MATERIALS

Patients from two independent cohorts (n=344; age=50.3±14.3 years; 175 women) who were diagnosed with either an enchondroma (n=124), an ACT (n=92) or a high-grade chondrosarcoma (n=128) and had undergone CT imaging as well as clinical and histological assessment of the tumor, were included in this study. The final diagnosis was based on the consensus of an interdisciplinary tumor board. The tumors were segmented on the CT images. The major cohort was split into training and validation sets (n=168/76), and the smaller cohort was used for external testing (n=100). A 2D convolutional neural network (CNN) was trained for classification. The mean squared error loss was used for optimization. For comparison, blinded readings were performed on the external test-set by three radiologists (3, 4, 10 years of experience).

RESULTS

The DL model achieved an area under the curve (AUC) of 0.87 for the differentiation between benign, intermediate and malignant cartilaginous tumors on CT images. The AUC of the readers was at 0.77/0.81/0.83. For the differentiation between enchondromas

and ACTs performed by the DLM, the AUC was at 0.80, whereas the readings of the residents resulted in an AUC of 0.72 and 0.76 and the readings of the musculoskeletal fellowship-trained radiologist in an AUC of 0.79 for this analysis. The ROC of the DLM was significantly better than the ROC of resident 1 for the differentiation between benign and malignant lesions (P=0.012). Sensitivity, specificity and accuracy are displayed in the figure.

CONCLUSION

s Compared to resident radiologists, the DLM showed better results for the differentiation of benign, intermediate and malignant chondroid bone tumors, whereas there was no significant difference found compared to the musculoskeletal fellowship-trained radiologist. A DLM may therefore improve and standardize diagnosis of chondroid tumors especially for the differentiation between enchondromas and ACTs.

CLINICAL RELEVANCE/APPLICATION

Classification of chondroid tumors - especially the differentiation between enchondromas and ACTs is challenging on CT images and is crucial for proper patient management. A DLM assessing CT images of the tumor may therefore support the decision making of the radiologists and improve patient outcome.

Radiomic Nomogram for Predicting High-Risk Cytogenetic Status in Multiple Myeloma Based on Fat-Suppressed T2-Weighted Magnetic Resonance Imaging

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - MK DPS

Participants
Suwei Liu, (*Presenter*) Nothing to Disclose

PURPOSE

To establish and validate clinical fat-suppressed T2-weighted magnetic resonance imaging (FS-T2WI) radiomic nomograms of MM HRC status for pre-treatment decision making and prognostic assessment.

METHODS AND MATERIALS

A cohort of 159 patients with MM (71 HRC, 88 non-HRC),The region of interest of the largest tumor lesions on FS-T2WI images was manually outlined, and 1688 features were obtained. Fourteen radiomic features were selected by 10-fold cross-validation using feature selection variance thresholds, Student's t test, redundancy analysis, and least absolute shrinkage and selection operator methods. Logistic regression was used to establish a clinical prediction model (model 1), a FS-T2WI radiomic prediction model (model 2), and a clinical-radiomic prediction model (model 3). Receiver operating characteristic (ROC) curves were used to evaluate and compare their diagnostic performance. Kaplan-Meier survival analysis and logrank tests were used to assess the prognostic value of the radiomic nomograms.

RESULTS

Models 2 and 3 showed significantly higher diagnostic efficacy than model 1 (both p <0.05). The area under the ROC curve of models 1, 2, and 3 was (training set: 0.65, 0.83, and 0.85; validation set: 0.70, 0.73, and 0.76, respectively). Kaplan-Meier survival analysis showed similar prognostic values for the radiomic nomogram and MM cytogenetic status (logrank test, both p<0.05; C-index, 0.651 and 0.659, respectively; z-score test, p=0.153).

CONCLUSION

s Radiomic nomograms can predict the HRC status of MM, potentially contributing to pre-treatment clinical decision making and prognostic assessment.

CLINICAL RELEVANCE/APPLICATION

Radiomics has shown promise for predicting the cytogenetic status of multiple myeloma (MM). However, few studies have investigated the role of single sequence radiomic nomograms in predicting the high-risk cytogenetic (HRC) status of MM.

A Deep Learning Model for Classification of Chondroid Tumors on CT-Images

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - MK DPS

Participants
Felix Gassert, MD, MBA, Munich, Germany (*Presenter*) Consultant, SmartReporting GmbH

PURPOSE

Differentiation between enchondromas, atypical cartilaginous tumors (ACT) and high-grade chondrosarcomas is crucial for adequate patient management. Although, several imaging features have been identified, differentiating enchondromas from ACTs radiologically remains challenging. Therefore, the goal of this study was to develop a deep learning model (DLM) for the classification of chondroid tumors based on CT images.

METHODS AND MATERIALS

Patients from two independent cohorts (n=344; age=50.3±14.3 years; 175 women) who were diagnosed with either an enchondroma (n=124), an ACT (n=92) or a high-grade chondrosarcoma (n=128) and had undergone CT imaging as well as clinical and histological assessment of the tumor, were included in this study. The final diagnosis was based on the consensus of an interdisciplinary tumor board. The tumors were segmented on the CT images. The major cohort was split into training and validation sets (n=168/76), and the smaller cohort was used for external testing (n=100). A 2D convolutional neural network (CNN) was trained for classification. The mean squared error loss was used for optimization. For comparison, blinded readings were performed on the external test-set by three radiologists (3, 4, 10 years of experience).

RESULTS

The DL model achieved an area under the curve (AUC) of 0.87 for the differentiation between benign, intermediate and malignant cartilaginous tumors on CT images. The AUC of the readers was at 0.77/0.81/0.83. For the differentiation between enchondromas and ACTs performed by the DLM, the AUC was at 0.80, whereas the readings of the residents resulted in an AUC of 0.72 and 0.76 and the readings of the musculoskeletal fellowship-trained radiologist in an AUC of 0.79 for this analysis. The ROC of the DLM was significantly better than the ROC of resident 1 for the differentiation between benign and malignant lesions (P=0.012). Sensitivity, specificity and accuracy are displayed in the figure.

CONCLUSION

s Compared to resident radiologists, the DLM showed better results for the differentiation of benign, intermediate and malignant chondroid bone tumors, whereas there was no significant difference found compared to the musculoskeletal fellowship-trained radiologist. A DLM may therefore improve and standardize diagnosis of chondroid tumors especially for the differentiation between enchondromas and ACTs.

CLINICAL RELEVANCE/APPLICATION

Classification of chondroid tumors - especially the differentiation between enchondromas and ACTs is challenging on CT images and is crucial for proper patient management. A DLM assessing CT images of the tumor may therefore support the decision making of the radiologists and improve patient outcome.

Multisystem Thursday Poster Discussion - A

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - MS DPS

Sub-Events

R5A-SPMS-1 Inter-reader Reliability of Immune-specific Response Criteria (irRECIST iRECIST)

Participants
Kathleen Ruchalski, MD, Santa Monica, CA (*Presenter*) Nothing to Disclose

PURPOSE

RECIST 1.1 can underestimate treatment benefits of immunotherapy, with irRECIST and iRECIST accounting for atypical responses. Inter-reader discordances are known to occur in a dual reader paradigm. Our objective is to compare inter-reader reliability between RECIST 1.1, irRECIST, and iRECIST.

METHODS AND MATERIALS

This is a retrospective analysis of advanced Non-small cell lung cancer (NSCLC) patients treated with pembrolizumab at our institution as part of the KEYNOTE-001 study. All trial imaging was interpreted by two radiologists. RECIST 1.1, irRECIST, and iRECIST categorical responses and agreement for progressive disease (PD) was compared by kappa statistic. Time to progression (TTP) or time to censor was compared between readers by paired t test. Relationship to disease progression and overall survival (OS) was assessed by log rank.

RESULTS

Of 98 patients, 77 had baseline and subsequent imaging available for 5.8 mean timepoints with 42.9 weeks of follow up. From this group, 44 patients had imaging beyond iUPD (unconfirmed-PD) for confirmation and were analyzed. PD occurred by reader 1, reader 2 in 34, 33 patients by RECIST 1.1 (k = 0.562, CI = 0.275-0.850), 31, 29 patients by irRECIST (k = 0.477, CI = 0.201-0.754), and 27, 22 patients by iRECIST iCPD (confirmed-PD) (k = 0.682, CI = 0.471-0.892). There was no significant difference in reader agreement of time to PD by RECIST 1.1, irRECIST, iRECIST (p = 0.38, 0.60, 0.26). There was a significant difference in time to progression between RECIST 1.1, irRECIST and iRECIST, with median PFS 3.4 months (2.6-4.6), 4.7 (3.5-6.8) and 8.7 (6.9-14.5) (p < 0.0001). PD by any criteria was not significantly correlated with OS.

CONCLUSION

s PD confirmation by iRECIST resulted in substantial reader agreement compared to moderate reader agreement by RECIST 1.1 and irRECIST. There were significant differences in TTP between the criteria, with iRECIST having the longest TTP. PD by each criteria did not correlate with a significant difference in OS.

CLINICAL RELEVANCE/APPLICATION

While iRECIST provides improved reader agreement compared to irRECIST and RECIST 1.1, there were no significant differences in reader agreement of TTP for each criteria.

R5A-SPNMMI-1 Assessment of Bone Metastases Response to Lu177-PSMA in mCRPC Patients

Participants
Sarah Boughdad, (*Presenter*) Nothing to Disclose

PURPOSE

Prostate cancer (PC) is the most frequent cancer in males and progressive metastatic castrate-resistance PC (mCRPC) is defined as an incurable disease. Recently, Lu-177-PSMA has been validated as a valid therapeutic option by the Vision trial (Sartor et al. 2021). Most patients have a predominant bone disease, but to our knowledge there is no consensus for bone radiological response assessment. Thus, we investigated bone metastasis response using 68Ga-PSMA PET/CT, taking as a reference PSA changes.

METHODS AND MATERIALS

In our retrospective and single-center study, we included mCRPC patients eligible for Lu-177-PSMA after screening for 68Ga-PSMA PET/CT positivity and who received at least 4 Lu-177-PSMA cycles. Responders (PSA-R)/non-responders (PSA-NR) were defined as >50%/=50% decrease in PSA levels between baseline and at the 4th cycle. For each patient, 3 bone target lesions were assessed with SUVmax/SUVmean/Tumor lesion activity (TLA)/Metabolic tumor volume (MTV) evaluated by PET and the lesion biggest diameter and density (HU) by CT. Percent changes were compared between PSA-R and PSA-NR in a per-lesion analysis using Mann-Whitney test. We assessed the association between PET and CT response parameters using Spearman correlation. We also compared PSA changes as a function of the presence of visceral disease.

RESULTS

We included 18 mCRPC patients with a total of 55 bone lesions. Thirteen patients (72%) were classified as PSA-R. There was significantly drop in PSA-R in SUVmax (-64±45% vs. -42±24%; p=0.001), SUVmean (-64±45% vs. -43±25%; p<0.001) and TLA (-24±141% vs. 96%±281%; p=0.002). By contrast, changes in MTV, CT-size or -density were not significant (p=0.1, p=0.37 and p=0.19, respectively). There was no significant correlation between PET and CT response parameters. We found a trend for a negative correlation between SUVmax and CT density changes (p=0.095). There was a significant association between CT-size and -density variations (rho=0.29; p=0.03) and no difference in PSA variation as a function of the presence of visceral disease.

CONCLUSION

s In a small but homogenous population of mCRPC pts treated with Lu-177-PSMA, PSA response was associated with Ga-68-PSMA PET metabolic changes whereas changes in lesion size or density were not significant. Those findings suggest that metabolic changes better reflect tumor response in mCRPC patients and could help for the follow-up in this population. Indeed, mCRPC patients presenting with PSA increase after Lu-177-PSMA might benefit from additional cycles of Lu-177-PSMA in case of Ga-68-PSMA PET positive metastases.

CLINICAL RELEVANCE/APPLICATION

Most patients have a predominantly bone metastatic disease but to our knowledge there is few data on assessment of bone response.

R5A-SPNMMI-2 Validation of SSTR-RADS 1.0 for SSTR-PET/CT in the Diagnosis and Treatment Planning of NET Patients

Participants
Johannes Ruebenthaler, MD, Munich, Germany (*Presenter*) Nothing to Disclose

PURPOSE

The recently proposed standardized reporting and data system for somatostatin receptor (SSTR)-targeted PET/CT SSTR-RADS 1.0 showed promising first results in the assessment of diagnosis and treatment planning with peptide receptor radionuclide therapy (PRRT) in patients with neuroendocrine tumors (NET). This study aims to determine the intra- and interobserver agreement of SSTR-RADS 1.0 in the interpretation of SSTR-PET/CTs in NET patients.

METHODS AND MATERIALS

SSTR-PET/CT scans of 100 patients were independently evaluated by an experienced (E1, E2) and inexperienced (I1, I2) nuclear medicine physician and radiologist, respectively, according to SSTR-RADS 1.0 criteria at two time points with 6 weeks in between. For each scan, a maximum of five target lesions were freely chosen by the readers (not more than three lesions per organ) and

assigned to the SSTR-RADS 1.0 criteria. Moreover, an overall scan score and binary decision on PRRT was assessed. Intra- and interobserver agreement was assessed using the intraclass correlation coefficient (ICC).

RESULTS

The interobserver agreement using SSTR-RADS 1.0 for identical target lesions (ICC = 0.89) and for the overall scan score was excellent (ICC = 0.91). The decision to use PRRT also demonstrated excellent agreement (ICC = 0.80). No significant differences between E1/E2 and I1/I2 for overall scan impression were achieved (p = 0.11). All four readers showed excellent intraobserver agreement even among different experience levels (ICC 0.836 - 0.986) when comparing target lesion-based scores and decision for PRRT.

CONCLUSION

s SSTR-RADS 1.0 represents a highly reproducible and accurate system for stratifying SSTR-targeted PET imaging scans with high intra- and interobserver agreement. The system is a promising approach to standardize the diagnosis and treatment planning in NET patients.

CLINICAL RELEVANCE/APPLICATION

The reporting and data system SSTR-RADS 1.0 is a promising approach to standardize diagnosis and treatment planning of NET patients using hybrid imaging and can be a useful tool for simplifying and improving the management of NET patients in clinical practice.

R5A-SPNMMI-1

Assessment of Bone Metastases Response to Lu177-PSMA in mCRPC Patients

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - NMMI DPS

Participants
Sarah Boughdad, (*Presenter*) Nothing to Disclose

PURPOSE

Prostate cancer (PC) is the most frequent cancer in males and progressive metastatic castrate-resistance PC (mCRPC) is defined as an incurable disease. Recently, Lu-177-PSMA has been validated as a valid therapeutic option by the Vision trial (Sartor et al. 2021). Most patients have a predominant bone disease, but to our knowledge there is no consensus for bone radiological response assessment. Thus, we investigated bone metastasis response using 68Ga-PSMA PET/CT, taking as a reference PSA changes.

METHODS AND MATERIALS

In our retrospective and single-center study, we included mCRPC patients eligible for Lu-177-PSMA after screening for 68Ga-PSMA PET/CT positivity and who received at least 4 Lu-177-PSMA cycles. Responders (PSA-R)/non-responders (PSA-NR) were defined as >50%/=50% decrease in PSA levels between baseline and at the 4th cycle. For each patient, 3 bone target lesions were assessed with SUVmax/SUVmean/Tumor lesion activity (TLA)/Metabolic tumor volume (MTV) evaluated by PET and the lesion biggest diameter and density (HU) by CT. Percent changes were compared between PSA-R and PSA-NR in a per-lesion analysis using Mann-Whitney test. We assessed the association between PET and CT response parameters using Spearman correlation. We also compared PSA changes as a function of the presence of visceral disease.

RESULTS

We included 18 mCRPC patients with a total of 55 bone lesions. Thirteen patients (72%) were classified as PSA-R. There was significantly drop in PSA-R in SUVmax (-64±45% vs. -42±24%; p=0.001), SUVmean (-64±45% vs. -43±25%; p<0.001) and TLA (-24±141% vs. 96%±281%; p=0.002). By contrast, changes in MTV, CT-size or -density were not significant (p=0.1, p=0.37 and p=0.19, respectively). There was no significant correlation between PET and CT response parameters. We found a trend for a negative correlation between SUVmax and CT density changes (p=0.095). There was a significant association between CT-size and -density variations (rho=0.29; p=0.03) and no difference in PSA variation as a function of the presence of visceral disease.

CONCLUSION

s In a small but homogenous population of mCRPC pts treated with Lu-177-PSMA, PSA response was associated with Ga-68-PSMA PET metabolic changes whereas changes in lesion size or density were not significant. Those findings suggest that metabolic changes better reflect tumor response in mCRPC patients and could help for the follow-up in this population. Indeed, mCRPC patients presenting with PSA increase after Lu-177-PSMA might benefit from additional cycles of Lu-177-PSMA in case of Ga-68-PSMA PET positive metastases.

CLINICAL RELEVANCE/APPLICATION

Most patients have a predominantly bone metastatic disease but to our knowledge there is few data on assessment of bone response.

R5A-SPNPM-1 Focused Assessment with Sonography for Trauma: Bridging the Resource Gap

Participants
Scott Rohren, Houston, TX (*Presenter*) Nothing to Disclose

PURPOSE

In resource-constrained regions, ultrasound serves as a portable and available diagnostic modality. Particularly in emergent cases such as trauma, ultrasound is often the only imaging available. There is limited evidence on the impact and cost benefits of ultrasound in resource-constrained settings. The purpose of this study is to identify the utility and applicability of ultrasound in trauma settings within low-and-middle-income countries (LMICs).

METHODS AND MATERIALS

Electronic databases were queried from 2012 to 2022, to identify stakeholders and trends in ultrasound use. Two categories were created, one for reported applications of ultrasound use in LMICs and another for novel ultrasound studies. Articles were characterized by (1) the geographic and specialty-specific use of ultrasound in LMICs, (2) the innovative applications and the accompanying research findings, and (3) the development of associated educational and training programs. Trend analysis was conducted based on grouping, noting temporal changes, similar uses in varying regions, and differential outcomes.

RESULTS

A total of 6,276 articles were identified with 287 studies describing original applications of ultrasound for trauma uses in LMICs. 72% of studies involved ultrasound usage originating from Southeast Asia and sub-Saharan Africa, the latter being the region with the highest number of innovative ultrasound use. Research about ultrasound use has increased by 70% and geographically expanded by 32% in the past decade, Overwhelmingly, ultrasounds have improved outcomes for trauma patients, with a 28% decrease in mortality. Additionally, there has been an 80% increase in sonographer training programs. The use of ultrasounds in sub-Saharan Africa has significantly increased at a rate faster than other LMICs.

CONCLUSION

s Ultrasound has growing utilization for its use as low-cost portable imaging technology. The increased interest in training and prehospital utilization has led to improved health outcomes in many resource-limited regions. Point-of-care ultrasound has particularly been useful for assessing patients in areas that would have otherwise lacked imaging capabilities. There is a growing use of ultrasound for diagnosing life-threatening conditions in trauma such as pneumothorax, vascular status, musculoskeletal injuries, and testicular injuries. While training programs have increased, there is still a deficit in formal education amongst sonographers in LMICs.

CLINICAL RELEVANCE/APPLICATION

The use of ultrasound in trauma settings within LMICs has not previously been quantified for overall usage or trends. This study provides new insights on how and where ultrasounds are being used while highlighting key areas for improvement.

R5A-SPNPM-2 Risk Factors for Acute Adverse Reactions to Gadolinium-Based Contrast Agents

Participants
Yasuhiro Fukushima, RT, PhD, (*Presenter*) Endowed Chair, Siemens AG

PURPOSE

Multiple gadolinium-based contrast agents (GBCAs) are classified according to the chelate structure (macrocyclic or linear, and ionic or nonionic). Macrocyclic GBCAs are recommended as possible for the prevention of nephrogenic systemic fibrosis (NSF), but it is also clinically important to consider acute adverse effects (AARs). The purpose of this study was to compare the incidence of AARs among the widely used five types of GBCAs and identify both the GBCA-related and patient-related risk factors.

METHODS AND MATERIALS

All intravenous GBCA injections in MRI studies (n=61 147) at a single institution between January 2008 and September 2019 were retrospectively evaluated. All AARs for the five types of GBCAs (gadoteridol, gadoterate meglumine, gadopentetate dimeglumine, gadobutrol, and gadoxetate disodium [hepatocyte specific GBCA]) were classified into allergic-like or physiologic reactions, and their severity was classified into mild, moderate and severe. GBCA-related and patient-related risk factors were evaluated by logistic regression models using generalized estimating equations.

RESULTS

AARs occurred in 238 GBCA injections (0.39%), with an incidence of 0.22% for allergic-like and 0.20% for physiologic reactions. The highest OR for allergic-like reactions with the reference of gadoterate meglumine was 4.5 for gadoteridol (95% confidence interval [CI]: 3.5, 8.1; p < .001), followed by 3.6 for gadobutrol (1.3, 10; p = .015) and 2.6 for gadopentetate dimeglumine (1.4, 4.8; p = .003). The OR for physiologic with the reference of gadoterate meglumine was 3.5 for gadoteridol (1.8, 6.9; p < .001). For allergic-like reactions, younger age (21-40 years) was the risk factor, and for physiologic reactions, men, inpatient, younger age (21-40 years), face/neck and breast MRI examinations were the risk factors.

CONCLUSION

s There was a significant difference in the AAR incidence between five types of GBCAs, particularly in the allergic-like reaction, and the incidence was also related to age. The incidence of physiologic reaction was related to age, gender, in/outpatient, and examination type.

CLINICAL RELEVANCE/APPLICATION

Not only the risk of NSF, but also the risk of AARs should be considered in selecting GBCA.

R5A-SPNPM-3 Reduced Body GD Exposure Over 5 Months After a Single Human Equivalent Dose of Gadopiclenol as Compared to Gadobutrol in Healthy Rats

Participants
Philippe Robert, Roissy CDG CEDEX, France (*Presenter*) Employee, Guerbet SA

PURPOSE

Gadopiclenol is a high relaxivity macrocyclic Gadolinium-Based Contrast Agent (GBCA) under review by health authorities. The phase 3 clinical trials demonstrated that gadopiclenol at 0.05 mmol/kg results in the same diagnostic performance as gadobutrol at 0.1 mmol/kg in CNS and body MRI. In this context, the aim of this study was to evaluate the body gadolinium (Gd) exposure over a period of 5 months in healthy rats after a single injection of gadopiclenol or gadobutrol both administered at the Human Equivalent Dose (HED).

METHODS AND MATERIALS

Healthy female rats (n=60) received a single injection at the HED of gadobutrol (0.6 mmol/kg) or gadopiclenol (0.3 mmol/kg), and were euthanized after 1, 4 or 20 weeks (W1, W4, W20) (n=10/group). Cerebellum, subcortical brain, liver, kidney medulla, kidney cortex and femur diaphysis were sampled at the time of sacrifice. In group W1, blood was sampled each day. Skin biopsies were performed at 1, 3 and 7 days and at 1, 2, 3, 4 and 5 months. Gd dosing was performed by Inductively Coupled Plasma-Mass Spectrometry (ICP-MS) and compared with a Mann-Whitney non-parametric t-test. Total Gd exposition in all organs between the first sampling point to the sacrifice was estimated by integrating the Area Under the concentration Curve (AUC) based on a mono-exponential fitting of the time-dependent Gd concentrations.

RESULTS

In all tissues except bone, Gd concentrations after gadopiclenol are lower than after gadobutrol administration during the first month after injection (see Figure, log scale). The higher Gd concentration is observed in the kidney cortex for both contrast agents with 1.5 to 1.8-fold lower levels for gadopiclenol (at 1 week, 194±65 nmol/g vs 109±32 nmol/g for gadobutrol and gadopiclenol respectively). A strong washout for both contrast agents is observed in all tissues during the period of follow-up. In femur, residual gadolinium concentration is higher or equal after gadopiclenol as compared to gadobutrol, and no washout is observed for both GBCAs, making mono-exponential fitting not possible. The global Gd exposition (AUC) over 5 months is 1.2 to 2.6-times lower after gadopiclenol as compared to gadobutrol.

CONCLUSION

s For the same diagnostic efficacy (demonstrated by phase 3 clinical trials), the exposition of Gd after gadopiclenol is lower than that of gadobutrol, thanks to the half dose injected.

CLINICAL RELEVANCE/APPLICATION

Gadopiclenol, a high relaxivity GBCA (2 to 2.5-fold higher than gadobutrol), allows to reduce the Gd exposure by injecting half dose.

R5A-SPNR-1 A Fully Automated and Quantifiable Visual Grading System for WMH Utilizing a Rule-Based Algorithm: The Modified Fazekas Scale Using T2-Fluid Attenuated Inversion Recovery Magnetic Resonance Imaging

Participants
ZunHyan Rieu, BS, Seoul, Korea, Republic Of (*Presenter*) Employee, NEUROPHET, Inc

PURPOSE

White matter hyperintensities (WMH) have become the primary biomarker for small-vessel cerebrovascular diseases and brain atrophy. The Fazekas and Scheltens scales are the most conventional visual grading system for WMH and have been practiced by radiologists worldwide. However, in clinical practice, it is still challenged by the labor-intensive process and non-standardized criteria for measuring the irregular shapes of WMHs, which tend to be evaluated with one's subjective opinion. Therefore, we aim to fully automate the visual grading system for WMH with only the numerically quantifiable measurement using the modified Fazekas scale, Clinical Research Center for Dementia of South Korea (CREDOS) criteria, which suggests the visual grading system for WMH with the combination of diameter measurements between deep white matter hyperintensity (DWMH) and periventricular hyperintensity (PWMH).

METHODS AND MATERIALS

Our approach involves four stages, including brain tissue and WMH segmentation using the deep learning algorithm, WMH separation into periventricular hyperintensity and deep white matter hyperintensity using a rule-based algorithm, diameter measurement of WMH, and Fazekas scale prediction. For validation, we compared the performances of our proposed method and that of the CREDOS criteria-based visual grading system for WMH done by three certified radiologists using a total of 404 subjects with T2-fluid attenuated inversion recovery magnetic resonance imaging (T2-FLAIR) utilized from a clinical site in Korea.

RESULTS

The inter-rater agreements using Krippendorff's alpha were comparable between the radiologists (R) and all methods (A), including our approach. The agreements were substantial (R, 0.732 vs. A, 0.694), substantial (R, 0.671 vs. A, 0.658), and moderate (R, 0.586 vs. A, 0.579) for the modified Fazekas scale, the DWMH scale, and the PWMH scale, respectively. In addition, the total mean of areas under the receiver operating characteristic curve between radiologists (G) and radiologists against our approach (P) showed comparable performance (G, 0.80±0.09 vs. P, 0.80±0.03).

CONCLUSION

s Our approach, a fully automated and quantifiable visual grading system for WMH, demonstrated comparable results against the radiologists.

CLINICAL RELEVANCE/APPLICATION

We believe our approach has a great potential to assist the radiologist in clinical findings.

R5A-SPNR-10 Optimization of 3D Head SNAP Angiography Based on Compression Sensing Technology

Participants
Yukun Zhang, Dalian, China (*Presenter*) Nothing to Disclose

PURPOSE

To optimize simultaneous non-contrast angiography and intraplaque hemorrhage (SNAP), we combined SNAP and compressed sensing (CS SNAP) and identified the optimal acceleration factors (AFs) for clinical use to obtain high-quality MRA and vascular wall images capable of whole brain coverage in a short time.

METHODS AND MATERIALS

30 healthy volunteers (13 males, 17 females, mean age 43.33 ±18.76 years) were prospectively recruited in this study. Among them, 10 volunteers performed the pre-scan for selecting a precise head 3D SNAP parameters(Table.1) at 3.0 Tesla (Philips Ingenia CX 3.0T MRI); The remaining 20 volunteers scanned with different CS AFs of 2,2.5,3,4,5 on the basis of the optimized pre-scan sequence(Table.2). Two radiologists delineated the region of interest (ROI) on all of the original images, measured the signal intensity (SI) and standard deviation (SD) for the vascular lumen, vascular wall and white matter (Fig.1). Signal to noise ratio (SNR) and contrast to noise ratio (CNR) of vascular lumen, contrast-to-tissue ratio (CTR) and CTR efficiency (CTReff) of the

vascular wall were further calculated; at the same time, The image quality of each dataset was scored subjectively by two radiologists (Table.3). The consistency of measurements and subjective scores of the two observers was analyzed using Kappa and intraclass correlation coefficient (ICC) test. Compare and analyze the differences in measurement parameters and subjective scores between different AFs.

RESULTS

The measured data and subjective scores of the two observers were in good agreement (Kappa: 0.568-0.884, ICC: 0.602-0.968). when CS AF=4, the SNR and CNR of vascular lumen, and subjective score were significantly different from SNAP without CS($p<0.05$). When CS AF =2.5, 3, 4, 5, the CTReff of vascular wall were significantly different compared with SNAP without CS ($p<0.05$) (Table.4, Fig.2).

CONCLUSION

s 3D CS SNAP can obtain whole cerebrovascular MRA and vascular wall images in a relatively short period of time, and AF of 3 is recommended as its optimized sequence (Fig.5).

CLINICAL RELEVANCE/APPLICATION

3D CS SNAP technology has the potential to apply to multi-contrast blood imaging protocols, allowing for the acquisition of whole cerebral angiography and vascular wall images in relatively short periods of time.

R5A-SPNR-11 Pharmacokinetics, Safety and Tolerability of the Novel Tetrameric, High Relaxivity, Macrocyclic Gadolinium-based Contrast Agent Gadoquatrane for CE-MRI

Participants
Birte Hofmann, DVM, PhD, Berlin, Germany (*Presenter*) Employee, Bayer AG

PURPOSE

Gadoquatrane (BAY 1747846) is a novel tetrameric, macrocyclic gadolinium (Gd)-based contrast agent (GBCA) featuring a unique tetrameric structure and high relaxivity. The present study investigated its pharmacokinetics (PK) including excretion pathways, safety and tolerability in healthy volunteers.

METHODS AND MATERIALS

This first-in-human study was conducted as a randomized, single-blind, placebo-controlled, single dose study with 6 consecutive dose cohorts consisting of 8 to 9 healthy young women and men (N=49 total). Gadoquatrane or matching placebo (NaCl 0.9%) were intravenously administered by either infusion (doses of 0.025, 0.05, or 0.1 mmol Gd/kg bw) or bolus injection (doses of 0.03, 0.1 or 0.2 mmol Gd/kg bw). Safety and tolerability were assessed over 7 days post injection (p.i.) including adverse events, cardiac and respiratory function and safety laboratory analyses. Plasma PK and excretion in urine and feces were investigated over 72 h p.i. by ICP-MS as well as HPLC-ICP-MS.

RESULTS

Demographics were well balanced, with no notable differences between cohorts (24 ?, 25 ?; mean age (±SD) of 34.6±6.3 years; mean BMI (±SD) of 23.4±2.57 kg/m2). Plasma concentrations declined rapidly due to fast extracellular distribution and elimination, with no relevant gender differences. AUC and Cmax increased dose proportionally, volume of distribution (0.21-0.24 L/kg) and plasma clearance (0.09-0.1 L/h/kg) remained constant. Excretion via the kidneys was essentially complete (80-100%) within 12 h p.i.. No metabolites were detected in plasma or urine. Incidence and severity of treatment emergent adverse events (TEAEs) were similar in all dose groups incl. placebo. Intensity of most study drug related TEAE was mild, few were of moderate intensity, and none severe; all were recovered or recovering at 7 days p.i..

CONCLUSION

s The novel high relaxivity, tetrameric, macrocyclic GBCA gadoquatrane was very well tolerated at all doses. The PK profile is essentially the same as for other extracellular macrocyclic GBCAs (like gadobutrol or gadoterate meglumine). Gadoquatrane has the potential to be used at substantially lower Gd doses in clinical routine compared to currently marketed extracellular GBCAs.

CLINICAL RELEVANCE/APPLICATION

The novel, tetrameric gadoquatrane is a promising GBCA in development for MRI and its profile incl PK, safety, high relaxivity and stability meets the clinical demand to reduce the gadolinium dose.

R5A-SPNR-13 Investigation of Image Quality of Different Monochromatic Energy Images in Spectral CT Scan: A Phantom Study

Participants
Yaoxing Ma, (*Presenter*) Nothing to Disclose

PURPOSE

Objective to explore the influence of different monochromatic energy images on the quality of energy spectrum images.

METHODS AND MATERIALS

A polypropylene cylindrical phantom (QSP Phantom dimension) with five tubes containing different concentrations of iodine (0, 2.5, 5, 10, 20 mg/ml) was scanned using a spectral CT (Revolution CT, GE Healthcare) in gemstone spectral imaging (GSI) mode using fast kV switch (80/140 kV) ,the tube current was 485mA, the layer thickness was 1.25mm, the collimation width was 80mm, noise index (NI) 9, pitch 0.992:1.The CT and SD values were measured at 11 different central planes.,the region of interest (ROI) of the phantom tube with iodine concentration of 20% was delineated, The area of ROI was 1 / 2-1 / 3 of the cross-sectional area of the phantom tube.The CT values and noise of 40 keV, 70 keV, 100 keV and 130 keV groups were measured and recorded by GSI viewer. One way ANOVA was used to compare the CT value and noise of iodine 20 phantom tube under different keV. LSD-t test was used to compare the two groups.

RESULTS

With the increase of monochromatic energy level the CT value and noise of the images gradually decreased. The CT value of 40

With the increase of monochromatic energy level,the CT value and noise of the images gradually decreased. The CT value of 40 keV, 70 keV, 100 keV and 130 keV groups were 1546.34±3.13HU, 490.13±1.60HU, 215.71±1.28HU, 121.52±18HU, the difference was statistically significant (P < 0.05); The noise of 40 keV, 70 keV, 100 keV and 130 keV groups was 25.46±2.89HU, 11.44±1.3HU, 7.83±0.92HU, 6.62±0.75HU, the difference was statistically significant (P < 0.05).

CONCLUSION

s With the increase of monochromatic energy level, the CT value and noise of the images gradually decrease, and monochromatic energy images in spectral CT scan can optimize the image quality.

CLINICAL RELEVANCE/APPLICATION

Through the basic research of phantom, compared with conventional kVp scanning, energy spectrum CT scanning can provide the same image quality scanning radiation dose. At the same time, compared with conventional kVp scanning, energy spectrum CT scanning can provide different levels (40-140kev) of single energy and effective atomic coefficient, and more energy spectrum information of base material. This study has guiding significance for the application of energy spectrum scanning in different clinical scenes.

R5A-SPNR-15 Study on the Image Quality of Head and Neck CTA With Energy Spectrum Combined With Iterative Reconstruction Method

Participants
Deng Jie, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the influence and application value of spectral CT single-energy imaging combined with adaptive iterative reconstruction (ASIR) technology on head and neck CT angiography (CTA).

METHODS AND MATERIALS

88 patients undergoing head and neck CTA examination were compared using energy spectrum combined with adaptive iterative 40% ASIR scanning, and reconstructed single-energy 40keV, 60 keV, 80 keV, and performed vascular surface reconstruction (CPR) and maximum density projection on the three groups of images. Processing (MIP). The effects of different reconstruction methods on the image quality of head and neck CTA were evaluated from the two aspects of objective measurement and subjective score.

RESULTS

Objective evaluation: The CT values, SD values, SNR values, and CNR values of the aortic arch, common carotid artery, middle cerebral artery, vertebral artery, and basilar artery measured under the three reconstruction methods were all statistically different (P<0.05). Subjective evaluation: The Kappa value of the subjective evaluation of the image reconstruction quality by the physicians of the two diagnosis groups in each group was 0.75, showing strong consistency. There was no statistical difference in the scores of MIP reconstruction images among the groups (P=0.467). There was a statistically significant difference in the scores of CPR reconstruction images among the groups (P<0.05).

CONCLUSION

s In the image quality of head and neck CTA examination, the single energy spectrum of 60keV combined with adaptive iterative 40% ASIR scanning can reduce image noise and improve the image signal-to-noise ratio. be applied.

CLINICAL RELEVANCE/APPLICATION

When applied to head and neck CTA, the single energy spectrum of 60keV combined with adaptive iterative 40% ASIR scan has the best image quality, which can be used in clinical practice.

R5A-SPNR-16 Predicting Early Glioma Recurrence With Peritumoral Radiomic Features From Amide Proton Transfer Weighted MR Images

Participants
Shanshan Jiang, MD, PhD, Baltimore, MD (*Presenter*) Nothing to Disclose

PURPOSE

Because of the basement membrane barrier effect, diffuse infiltration of tumor cells into surrounding brain tissue has been proved a significant factor for migration/invasion of malignant gliomas. However, the peritumoral areas have been rarely studied for post-surgery/chemoradiation malignant gliomas. Amide proton transfer-weighted (APTw) MRI, a method generating the MRI contrast dominated by endogenous cellular proteins, has showed an encouraging diagnostic performance for gliomas. The goal was to evaluate the power of APTw-based peritumoral radiomics for classification of treatment effects and tumor recurrence.

METHODS AND MATERIALS

A total of 90 patients with post-treatment malignant gliomas were retrospectively re-assessed. Diagnosis of tumor recurrence vs. treatment effects was based on the integrated clinical pathologic results or the updated RANO criteria. The sequences included T1w, T2w, FLAIR, APTw, and gadolinium contrast-enhanced T1w (T1w-Gd). After imaging preprocessing, radiomic features were extracted from the peritumoral regions, which were segmented manually covering abnormal FALIR/T2w signal intensities outside the gadolinium-enhancing tumor core. A current reality tree (CRT) model was constructed to identify the most critical features when differentiating tumor recurrence from treatment effects. The alpha level of all tests was set at P < 0.05.

RESULTS

29 vs. 61 patients were confirmed, respectively, as treatment effect or tumor recurrence. The CRT model achieved accuracies of 83.3% with radiomic features extracted from FLAIR, 90.0% with those from APTw, and 91.1% with those from both FLAIR and APTw. The 90 percentile APTw value was listed as the most important feature to distinguish these two entities in both decision trees based on APTw and FLAIRAPTw MRI models.

CONCLUSION

s APTw-derived radiomic features are capable of capturing the progressive pattern in peritumoral areas, aiding in the accurate

treatment response assessment in post-treatment malignant gliomas by increasing detection specificity.

CLINICAL RELEVANCE/APPLICATION

Our results suggest that the use of APTw MR images radiomic features from peritumoral area can add important value to structural MRI to assess the early treatment response.

R5A-SPNR-18 Newly Developed Iterative Motion Correction (IMC) for Brain MRI: Utility for Reducing Motion Artifacts and Improving Image Quality without Any Affection to Examination Time in Uncooperative Patients

Participants
Kazuhiro Murayama, MD, Toyoake, Japan (*Presenter*) Research Grant, Canon Medical Systems Corporation

PURPOSE

To determine the utility of newly developed iterative motion correction (IMC) method for reducing motion artifact and improve image quality without any affection to examination time in uncooperative patients.

METHODS AND MATERIALS

65 patients suspected of cerebrovascular disease obtained fluid attenuated inversion recovery (FLAIR) images with and without IMC at 3T systems. Based on FLAIR image without IMC results, all patients were divided into cooperative (n=19) and uncooperative (n=46) patient groups. To compare examination and reconstruction time differences, these times were recorded in all patients. To assess the capability for image quality improvement between FLAIR images with and without IMC, SNR of normal appearance white matter (NAWM), CNR between gray matter and NAWM, and CNR between NAWM and deep and subcortical white matter hyper intensity (DSWMH) abnormalities were determined by ROI measurements on each FLAIR. Moreover, overall image quality, artifact and lesion conspicuity in each group were assessed by 5-point scales by two board-certified radiologists. To compare examination and reconstruction time between two methods, Wilcoxon signed-rank test was performed. For image quality comparisons, SNR and CNRs were compared between FLAIRs with and without IMC in cooperative and uncooperative groups by Student's t-test. To determine interobserver agreements for all indexes, kappa statistics with ?2 test were performed. Then, each qualitative score was also compared between FLAIRs with and without IMC by Wilcoxon's signed sum test.

RESULTS

Mean examination and reconstruction times of FLAIR with IMC (256.3±2.7 sec) were significantly longer than those of FLAIR without IMC (217.0±0.59 sec, $p<0.0001$). SNR and CNRs of FLAIRs with IMC was significantly higher than that without IMC in uncooperative group ($p<0.05$). Interobserver agreements for each qualitative image quality score were assessed as substantial or excellent in each group ($0.74=?=0.91$, $p<0.001$). Each qualitative image quality score of FLAIR with IMC was significantly higher than that without IMC in uncooperative group ($p<0.05$).

CONCLUSION

s The IMC technique has a potential for reducing motion artifacts and improving image quality on brain MRI with less than 1 minute prolongation of examination and reconstruction times in uncooperative patients.

CLINICAL RELEVANCE/APPLICATION

The IMC technique has a potential for reducing motion artifacts and improving image quality on brain MRI in uncooperative patients.

R5A-SPNR-19 Natural Language Processing for Extraction of Glioblastoma and Patient Characteristics from Radiology Reports

Participants
Ahmad Amer, BS, North Chicago, IL (*Presenter*) Nothing to Disclose

PURPOSE

Glioblastoma (GBM) is an aggressive primary brain tumor with a median survival of 15 months. To assist with data extraction and evaluation of potential prognostic factors, natural language processing (NLP) was applied to automate extraction of patient and tumor data from one of the largest GBM patient populations at MD Anderson Cancer Center (MDACC).

METHODS AND MATERIALS

The radiology information system (RIS) was used to identify 4511 patients with a pathology-confirmed GBM diagnosis presenting to MDACC from 2006-2021. 50,202 corresponding radiology reports were identified, and Python was used for report processing. Identification of specific strings and aggregation by MRN allowed for determination of tumor multicentrality, extent of resection, and patient handedness. A similar approach was applied to extract tumor location, with separate strings used for lobe and laterality. Primary and secondary lobe were determined based on occurrence frequency of lobe-specific strings. Patient survival was estimated by determining the time difference between patients' first report mentioning GBM and last report. Extraction of pre-op tumor volume first required isolation of pre-op reports. A subset of such reports were extracted by selecting reports with pre-op-specific phrases in the examination section. Next, reports nearest to and within a week prior to intra-op dates were extracted. Intra-op dates were determined by searching reports' examination sections for intra-op-specific strings and extracting surgery dates with Regex. Reports occurring prior to suspicion or diagnosis of GBM were excluded. The syntax of remaining reports were then analyzed using a pre-trained SciSpacy model, and sentences without tumor-related strings were excluded. Tumor dimensions were extracted using Regex and used to calculate tumor volume. Manual validation was performed for OS, volume, and location.

RESULTS

NLP characterized patients as long-term survivors with 94.7% sensitivity, 97.6% specificity, and an ROC-AUC of .953. Quantitative analysis yielded a mean absolute error of 19.40%. Lobe and laterality were 98% and 90% accurate respectively. Successful extraction of all tumor dimensions for volume calculation was achieved in 72.5% of cases.

CONCLUSION

s Automated extraction of tumor lobe, laterality, multicentrality, extent of resection, volume, and OS and handedness was

accomplished. OS and location data were highly accurate.

CLINICAL RELEVANCE/APPLICATION

NLP was successfully applied to extract data for the investigation of prognostic factors of GBM, which could lead to improvements in patient management and inform expectations of care.

R5A-SPNR-2 A Novel Connectomic Analysis Framework for Personalised Presurgical Planning using Multimodal Neuroimaging

Participants
Ruchi Sharma, MS,BS, Bhopal, madhya Pradesh, India (*Presenter*) Nothing to Disclose

PURPOSE

The traditional method of surgical selection and planning in brain tumours was based mostly on the topography of the tumour. With recent advances, connectomics promises to provide comprehensive information by integrating the inferences from network mapping, tractography, and tumour segmentation. This information helps neurosurgeons develop new insights and an optimal strategy for tumour resection. We present a novel, automated connectomic analysis framework that integrates rs-fMRI, DWI and sMRI (T1w, FLAIR, and T1CE) modalities to determine the effect of a tumor on the individual's structural and functional connectivity, assisting in presurgical planning.

METHODS AND MATERIALS

A study was conducted on 15 tumor subjects who underwent the above mentioned MR modalities prior to surgery. Three groups of five subjects underwent tb-fMRI for Motor, Visual, and Language tasks. For each subject, our framework analysed the multiple modalities using the following techniques - multivariate statistical analysis on rs-fMR images to generate major functional networks, deep learning-based segmentation strategy on sMR images for tumour demarcation, and whole-brain probabilistic tractography on DWI for generation of major fibre tracts.Additionally, the framework reports the tumor's proximity to the generated functional network and white matter tracts using a heuristic algorithm.

RESULTS

Connectomic profiles were generated for all the subjects. For the five subjects that underwent tb-fMRI, all the network maps produced by rs-fMRI and tb-fMRI yielded similar activations in the corresponding network regions. The heuristic algorithm used to report the distance between the tumours, network maps, and tracts were highly useful in deciding the trajectory of operation.

CONCLUSION

s The connectomic profile for the clinical cases using network maps, fibre tracts, and tumor demarcation proved to be highly beneficial in the personalised presurgical planning. The validation of rs-fMRI against tb-fMRI also helped to mindfully perform the surgery to avoid functional loss of major networks.

CLINICAL RELEVANCE/APPLICATION

This study proposes a multimodal connectomic analysis method to produce personalised presurgical insights for tumor patients which helps in taking critical decisions for operating the tumor with a better understanding of the anatomical, functional and surgical complexities which is highly beneficial.

R5A-SPNR-20 Perfusion-Based Radiomics Enable to Predict Thrombolysis/Thrombectomy Related Hemorrhagic Transformation in Patients With Acute Stroke: Development and Validation

Participants
Yunhwa Roh, (*Presenter*) Nothing to Disclose

PURPOSE

Prompt diagnosis and early detection of hemorrhagic transformation (HT) may prevent dismal prognosis in acute stroke patients. We aimed to develop and validate a radiomics-based model for predicting thrombolysis/thrombectomy-related HT in patients with acute ischemic stroke using multiparametric MRI of conventional, diffusion-, and perfusion-weighted imaging.

METHODS AND MATERIALS

In this retrospective study, a radiomics model was developed in a consecutive 462 patients diagnosed with acute ischemic stroke and who underwent multiparametric MRI between 2017 to 2018 and tested in an independent validation set of 276 patients between 2019 to 2021. For each patient, 140 radiomics features were extracted from FLAIR and GRE image, DWI, and perfusion-weighted imaging including CBF, CBV, K2, MTT, Tmax, and TTP maps. HT was classified as either presence of HT (HT) or the presence of parenchymal hemorrhage (PH). Radiomics features for predicting outcomes were selected using random forest, and the model was developed by using logistic regression classifier. The diagnostic performance was calculated and compared among imaging sequences in the independent validation set using the area under the curve (AUC) from a receiver operating characteristic curve analysis, sensitivity, specificity, and accuracy.

RESULTS

For predicting HT, 8 out of 10 top features were from perfusion-weighted imaging using variable importance including TTP, CBF, and Tmax. For predicting PH, 8 out of 10 top features were from perfusion-weighted imaging including CBV, CBF, MTT, and K2. Volume and compactness of DWI and FLAIR also become significant predictors. In the test cohort, the perfusion-based radiomics model significantly improved performance (AUC 0.725) compared with DWI or FLAIR alone (AUC 0.665 and 0.679, respectively) for predicting HT. For predicting PH, the perfusion-based radiomics model also significantly improved performance (AUC 0.732) compared with DWI or FLAIR alone (AUC, 0.693 and 0.702, respectively).

CONCLUSION

s Utilizing perfusion-weighted imaging for the radiomics model significantly improved the prediction of hemorrhagic transformation as well as parenchymal hemorrhage in patients with acute stroke.

CLINICAL RELEVANCE/APPLICATION

HT following cerebral ischemia has been postulated to result in a negative impact on the clinical course. A radiomics model that utilized perfusion-weighted imaging showed improved diagnostic performance for predicting hemorrhagic transformation than conventional imaging or diffusion-weighted imaging alone. These findings support the role of perfusion MRI in identifying patients who are at increased risk for secondary HT following acute ischemic stroke and may assist patient management for clinicians.

R5A-SPNR-3 Disorganized Subcortical Functional Gradients in Schizophrenia and the Treatment Effects After Administration of Antipsychotics

Participants
Chengmin Yang, (*Presenter*) Nothing to Disclose

PURPOSE

Growing evidence indicates that subcortex is pivotal in the pathophysiology of schizophrenia, and changes in subcortical regions were also sensitive indicators of pharmacological treatments. However, how the subcortex embeds within the macroscale cortical system, and the structural constraints and functional emergences of spatial arrangements, remain unclear. The new concept of gradients focused on spatial relationships, which revealed that macroscale gradients integrated systematic information into more abstract representations. Exploring the subcortex in the broader cortical landscape as well as investigating its feature as treatment target in schizophrenia is promising for its extensive connections with the entire cerebral cortex.

METHODS AND MATERIALS

Leveraging connectome gradients, we systematically scrutinized abnormalities of functional connectome gradient in antipsychotic-naïve first-episode schizophrenia patients (FES0W, n = 57) at baseline, comparing to healthy controls (HCs, n = 64), as well as longitudinal comparisons of baseline with 6-week (FES6W, n = 19) and 12-month (FES12M, n = 57) follow-up, respectively. And further examined the reproducibility in an independent validation sample (vFES0W, n = 22; HCs, n = 25), and the patients with 6-week (vFES6W, n = 22) follow-up. Correlational analyses were conducted between the longitudinal functional gradient alterations and the psychopathological ratings, including Positive and Negative Syndrome Scale (PANSS) and Global Assessment of Functioning (GAF) scores.

RESULTS

In both primary and validation datasets, patients at baseline showed the higher gradients mainly in limbic system and lower gradients in thalamus and caudate , and the longitudinal functional gradients alterations showed the improved trend over time (all $p < 0.001$, Bonferroni corrected, Figure 1 and 2). Namely, in the period of antipsychotic treatment, the increased gradients were positively while the decreased gradients were negatively correlated with symptom improvement.

CONCLUSION

s Our findings provided a novel insight into the functional system hierarchy alterations of subcortical organization, which were sensitive to illness and treatment effects. This might extend our understanding of the functional connectome organization of subcortex in schizophrenia, and this measure makes a promising indicator of treatment response.

CLINICAL RELEVANCE/APPLICATION

This study provided the new perspective on the abnormal subcortical hierarchy organization in schizophrenia and its longitudinal gradient changes could be sensitive to reflect the antipsychotic treatment effect.

R5A-SPNR-5 Use of Real Life Safety Data From International Pharmacovigilance Databases to Assess the Importance of Symptoms Associated With Gadolinium Exposure

Participants
Imran Shahid, (*Presenter*) Nothing to Disclose

PURPOSE

Recent scientific publications have reported cases of patients who complained from a variety of symptoms after they received a gadolinium-based contrast agent (GBCA). The aim of this study was to appreciate the importance of these clinical manifestations in the overall population by assessing the weight of "symptoms associated with gadolinium exposure" (SAGE) among the bulk of safety experiences reported to major health authorities.

METHODS AND MATERIALS

SAGE symptoms were identified from a review of the scientific literature, and the corresponding preferred terms (PTs) were searched in each system organ class (SOC) category recorded in the European and North American pharmacovigilance databases, EudraVigilance (EV) and FDA Adverse Event Reporting System (FAERS), respectively. The numbers of SAGE symptoms per PT, and cumulatively per SOC, were recorded and their weights in the overall spectrum of AEs was determined for each GBCA.

RESULTS

The literature search led to identify 11 articles from which the most prevalent SAGE symptoms were selected. The extraction and analysis of such AEs in EV and FAERS revealed a significantly higher SAGE weight for gadobenate dimeglumine (EV: 25.83%, FAERS: 32.24%) than for gadoteridol (EV: 15.51%; FAERS: 21.13%), and significantly lower SAGE weights for gadobutrol (EV: 7.75%; FAERS: 13.31%) and gadoterate meglumine (EV: 8.66%; FAERS: 12.99%). The SOCs "skin and subcutaneous tissue disorders", "musculoskeletal and connective tissue disorders", "general disorders and administration site conditions" and "psychiatric disorders" were consistent with this ranking, with gadoteridol showing alternately a SAGE profile aligned on the linear GBCA or on the other macrocyclic GBCAs.

CONCLUSION

s This study showed that SAGE symptoms represent a significant percentage of the bulk of adverse events reported to the health authorities for each GBCA. It provided real-life arguments suggesting that SAGE symptoms may be more prevalent with linear than macrocyclic GBCAs, and that gadoteridol may present a higher SAGE risk than the other macrocyclic contrast agents.

CLINICAL RELEVANCE/APPLICATION

This study investigates, in EMA and FDA pharmacovigilance databases, the proclivity of symptoms associated with gadolinium

This study investigates, in EMA and FDA pharmacovigilance databases, the prevalence of symptoms associated with gadolinium exposure (SAGE) in patients exposed to gadolinium-based MRI contrast agents.

R5A-SPNR-6 Variation in Prices for Outpatient Brain MRI in the US

Participants
Kinpritma Sangha, PhD, MPH, (*Presenter*) Employee, Siemens AG

PURPOSE

The 2021 Hospital Price Transparency Rule was implemented to require hospitals to publish payer-specific negotiated commercial prices for medical services. Payer-negotiated prices vary across the country and are based on hospital and state characteristics, with the greatest markup from mean negotiated prices compared with Medicare reimbursement to be for magnetic resonance imaging (MRI). The objective of this study was to analyze the variation in MRI brain exam prices and to estimate the association between state characteristics and the median MRI brain exam price in the US.

METHODS AND MATERIALS

This cross-sectional study examined MRI brain exam prices in the hospitals across US using payer-negotiated prices from the Turquoise Health dataset. MRI brain exam, as a billable service, was identified using the Current Procedural Terminology (CPT) code of 70551. Price variance analysis was performed for all states and characteristics including Herfindahl-Hirschman Index (HHI) and certificate of need (CON) program in the state. Multivariable regression analyses were conducted to determine factors that impact brain MRI exam price among the states.

RESULTS

A total of 2504 hospitals disclosed the payer-negotiated prices in 2021 Turquoise Health dataset for brain MRI exams. The greatest price variation in brain MRI exams was for commercial payers with median price of $1531, ranging from $3230 to $611.57. Alaska, with the least number of hospitals, has the highest median price of $3230, while New York, with 84 hospitals has the lowest median price of $611.57. States with the CON program had a higher median price (by $164) than states without the CON program and states with a high HHI index (HHI>6000), indicating a less competitive market, have a higher median price (by $412) than states with a more competitive market. Both the number of health systems in the state (p=0.001) and having commercial payers (p=0.000) were found to be statistically significant in affecting impact the median MRI brain exam prices.

CONCLUSION

s While MRI brain exam prices vary throughout the US, more health systems and commercial payers in the state drive the prices higher.

CLINICAL RELEVANCE/APPLICATION

This study helps to understand the factors affecting price variation in brain MRIs in the US.

R5A-SPNR-7 Clinical Evaluation of Scout Accelerated Motion Estimation and Reduction (SAMER) For Brain MRI in an Emergency and Inpatient Setting

Participants
Azadeh Tabari, MD, Boston, MA (*Presenter*) Nothing to Disclose

PURPOSE

A navigation-free retrospective motion-correction method (SAMER) has been developed to achieve rapid motion estimation and correction. In this work, we performed an initial evaluation of SAMER in a clinical setting

METHODS AND MATERIALS

In this prospective IRB approved and HIPAA compliant study, 97 patients from emergency and inpatient care settings were scanned on a 3T system (MAGNETOM Skyra, Siemens) using a 20-channel head-neck coil, between August 2021 and January 2022. The imaging protocol included a 4-fold accelerated T1-weighted MPRAGE sequence, which was acquired using a custom linear+checkered sequence reordering. This sequence was incorporated into routine brain MRI to assess the performance of motion correction on non-contrast and contrast-enhanced exams. Retrospective reconstructions of the MPRAGE data were performed with and without SAMER motion correction. All 97 cases were reviewed by two neuroradiologists in a blinded manner to rate the impact of motion artifacts on diagnostic image quality using a previously published 5-tier scale (None, minimal, mild, moderate, severe). Discrepancies in the two neuroradiologists' scores were adjudicated by a third neuroradiologist

RESULTS

There was no significant difference in the performance of motion correction between the contrast-enhanced (n=58) and non-contrast (n=42) exams (p>0.05). Six (6.1%) of cases showed no motion, 46 (47.4%) showed minimal motion, 30 (31%) showed mild motion, 8 (8.2%) showed moderate motion, and 10 (10.3%) showed severe motion. The prevalence of repeat sequences was 3% of total MRI examinations. Following motion correction with SAMER, there was a significant improvement in motion score (P<0.005 for both raters). The motion score improvement was defined as the pre-correction motion score minus the post-correction score. For cases with motion scores of "none" or "minimal", SAMER had negligible impact on the motion score. For cases with "mild", "moderate", and "severe" motion, SAMER improved the motion score by an average score of 0.36, 1.1, and 1.2 points, respectively

CONCLUSION

s SAMER improves diagnostic image quality of clinical brain MR exams in the presence of motion, and the improvement is most pronounced when motion is moderate or severe

CLINICAL RELEVANCE/APPLICATION

Motion artifacts are common in emergency and inpatient brain MRI exams. SAMER demonstrates utility in a clinical setting to reduce motion artifacts in these studies, which may facilitate timely diagnosis and require fewer repeat sequences and callbacks for critically ill patients

R5A-SPNR-8 Preoperative Visualization of the Transverse and Sigmoid Sinuses Using Non-contrast Virtual

Monochromatic CT Images for the Lateral Suboccipital Retrosigmoid Approach

Participants
Tomomi Omura, Akita, Japan (*Presenter*) Nothing to Disclose

PURPOSE

In the surgical planning of suboccipital retrosigmoid craniotomy, it is important for neurosurgeons to recognize tortuosity of the transverse and sigmoid sinuses and their relationship to superficial landmarks including asterion. This study aimed to improve the depiction of those venous sinuses in preoperative non-contrast (NC) virtual monochromatic images (VMIs).

METHODS AND MATERIALS

Thirty-one patients (24 women and 7 men; mean age, 63 ± 19 years) who underwent NCCT retrosigmoid craniotomy were included. The NCCT was scanned using dual-source CT (SOMATOM Drive, Siemens Healthineers, Forchheim, Germany). The NC-DECT images were acquired at a kV-pair of 80 kV and 140 kV with tin-filtration at about 70 mGy using automatic exposure control. Mixed-120 kV images were synthesized by compositing both kV images. The native VMIs were generated at 40, 70, 100, 130, 160, and 190 keV using a CT vendor's workstation. In the reconstructed sagittal section of each image, a circular region of interest (ROI) was set in the transverse sinus and cerebral cortex as a reference. Standard deviation (SD) and attenuation value (HU) were measured in each ROI to obtain the difference in HU values between the transverse sinus and cerebral cortex (?HU) and contrast-to-noise ratio (CNR).

RESULTS

The median ?HU for each VMI was increased with higher keV, and each ?HU for 100, 130, 160, and 190 keV was significantly higher than that for Mixed-120 kV (9.6, 10.3, 10.5, and 11.0 HU for 100, 130, 160, and 190 keV respectively, and 8.8 HU for Mixed-120 kV, $P<0.001$ for each). The median CNR for each VMI was also increased with higher keV, and each CNR for 100, 130, 160, and 190 keV was significantly higher than that for Mixed-120 kV (6.8, 6.8, 6.7, and 7.3 for 100, 130, 160, and 190 keV respectively, and 3.2 for Mixed-120 kV, $P<0.001$ for each).

CONCLUSION

s Both ?HU and CNR of transverse sinuses were improved at VMIs above 100 keV. The results suggest that high keV VMIs improve visualization of the transverse sinus and are useful in surgical planning for suboccipital retrosigmoid craniotomy.

CLINICAL RELEVANCE/APPLICATION

High keV VMI is less susceptible to beam hardening, so structures and findings adjacent to bone are clearly delineated.

R5A-SPNR-9 Blood-Brain Barrier Dysfunction in Patients with Heart Failure

Participants
Kamlesh Jobanputra, MD, Birmingham, AL (*Presenter*) Nothing to Disclose

PURPOSE

Heart failure (HF) patients show brain tissue injury in sites that mediate autonomic, cognitive, and mood functions, which are deficient in HF and are linked with increased morbidity and mortality and poor quality of life in the condition. However, the pathological mechanisms that may contribute to brain tissue injury in HF are unclear, but blood brain barrier (BBB) disruption might be one of the processes that contribute to brain injury. Our aim was to examine BBB function, based on diffusion-weighted pseudo-continuous arterial spin labeling (DW-pCASL) procedures, in HF and healthy control subjects.

METHODS AND MATERIALS

We performed DW-pCASL imaging in 25 HF [age, 55.4±7.4 years; body-mass-index (BMI), 27.2±4.3 kg/m2; 18 male; NYHA functional class II/III, LVEF <40%] and 56 healthy controls (age, 51.7±9.0 years; BMI, 26.8±3.7 kg/m2; 31 male) using a 3.0-Tesla MRI scanner (Siemens, Magnetom, Prisma Fit). Using DW-pCASL data, arterial transit time (ATT, an index of large artery integrity) and water exchange rate across the BBB (Kw, BBB function) were quantified and whole-brain ATT and Kw maps were generated. Whole-brain ATT and Kw maps were normalized to Montreal neurological institute space, smoothed, and compared voxel-by-voxel between HF and control groups using analysis of covariance (ANCOVA; covariates: age, sex; SPM12, uncorrected $p<0.005$). Brain clusters with significant differences between groups were overlaid onto background images for structural identification.

RESULTS

No significant differences in age ($p=0.08$), sex ($p=0.16$), or BMI ($p=0.65$) appeared between groups. Multiple brain areas, which are involved in cognitive, mood, autonomic functions, showed altered Kw and ATT values in HF over health controls. Increased Kw values were observed in the insular cortices, hippocampus, thalamus, occipital cortices, cerebellar vermis, and other cortices and white matters regions. ATT values were decreased in the prefrontal, temporal, and occipital cortices, and mid brain, and increased in few areas, including the insular cortices and cerebellum in HF patients.

CONCLUSION

s HF patients show compromised BBB function and altered large artery integrity. BBB alterations may introduce neural damage in autonomic, mood, and cognitive regulatory areas, contributing to abnormal functions in HF. The findings suggest a need to repair BBB function in HF with strategies commonly used in other acute and chronic conditions.

CLINICAL RELEVANCE/APPLICATION

Management of neurologic symptoms in patients with heart failure is complex. Translational research focused on need for blood brain barrier repairing strategies in HF patients with brain injury may open new avenues of disease prevention and limiting progression.

A Fully Automated and Quantifiable Visual Grading System for WMH Utilizing a Rule-Based Algorithm: The Modified Fazekas Scale Using T2-Fluid Attenuated Inversion Recovery Magnetic Resonance Imaging

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
ZunHyan Rieu, BS, Seoul, Korea, Republic Of (*Presenter*) Employee, NEUROPHET, Inc

PURPOSE

White matter hyperintensities (WMH) have become the primary biomarker for small-vessel cerebrovascular diseases and brain atrophy. The Fazekas and Scheltens scales are the most conventional visual grading system for WMH and have been practiced by radiologists worldwide. However, in clinical practice, it is still challenged by the labor-intensive process and non-standardized criteria for measuring the irregular shapes of WMHs, which tend to be evaluated with one's subjective opinion. Therefore, we aim to fully automate the visual grading system for WMH with only the numerically quantifiable measurement using the modified Fazekas scale, Clinical Research Center for Dementia of South Korea (CREDOS) criteria, which suggests the visual grading system for WMH with the combination of diameter measurements between deep white matter hyperintensity (DWMH) and periventricular hyperintensity (PWMH).

METHODS AND MATERIALS

Our approach involves four stages, including brain tissue and WMH segmentation using the deep learning algorithm, WMH separation into periventricular hyperintensity and deep white matter hyperintensity using a rule-based algorithm, diameter measurement of WMH, and Fazekas scale prediction. For validation, we compared the performances of our proposed method and that of the CREDOS criteria-based visual grading system for WMH done by three certified radiologists using a total of 404 subjects with T2-fluid attenuated inversion recovery magnetic resonance imaging (T2-FLAIR) utilized from a clinical site in Korea.

RESULTS

The inter-rater agreements using Krippendorff's alpha were comparable between the radiologists (R) and all methods (A), including our approach. The agreements were substantial (R, 0.732 vs. A, 0.694), substantial (R, 0.671 vs. A, 0.658), and moderate (R, 0.586 vs. A, 0.579) for the modified Fazekas scale, the DWMH scale, and the PWMH scale, respectively. In addition, the total mean of areas under the receiver operating characteristic curve between radiologists (G) and radiologists against our approach (P) showed comparable performance (G, 0.80±0.09 vs. P, 0.80±0.03).

CONCLUSION

s Our approach, a fully automated and quantifiable visual grading system for WMH, demonstrated comparable results against the radiologists.

CLINICAL RELEVANCE/APPLICATION

We believe our approach has a great potential to assist the radiologist in clinical findings.

Optimization of 3D Head SNAP Angiography Based on Compression Sensing Technology

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Yukun Zhang, Dalian, China (*Presenter*) Nothing to Disclose

PURPOSE

To optimize simultaneous non-contrast angiography and intraplaque hemorrhage (SNAP), we combined SNAP and compressed sensing (CS SNAP) and identified the optimal acceleration factors (AFs) for clinical use to obtain high-quality MRA and vascular wall images capable of whole brain coverage in a short time.

METHODS AND MATERIALS

30 healthy volunteers (13 males, 17 females, mean age 43.33 ±18.76 years) were prospectively recruited in this study. Among them, 10 volunteers performed the pre-scan for selecting a precise head 3D SNAP parameters(Table.1) at 3.0 Tesla (Philips Ingenia CX 3.0T MRI); The remaining 20 volunteers scanned with different CS AFs of 2,2.5,3,4,5 on the basis of the optimized pre-scan sequence(Table.2). Two radiologists delineated the region of interest (ROI) on all of the original images, measured the signal intensity (SI) and standard deviation (SD) for the vascular lumen, vascular wall and white matter (Fig.1). Signal to noise ratio (SNR) and contrast to noise ratio (CNR) of vascular lumen, contrast-to-tissue ratio (CTR) and CTR efficiency (CTReff) of the vascular wall were further calculated; at the same time, The image quality of each dataset was scored subjectively by two radiologists (Table.3). The consistency of measurements and subjective scores of the two observers was analyzed using Kappa and intraclass correlation coefficient (ICC) test. Compare and analyze the differences in measurement parameters and subjective scores between different AFs.

RESULTS

The measured data and subjective scores of the two observers were in good agreement (Kappa: 0.568-0.884, ICC: 0.602-0.968). when CS AF=4, the SNR and CNR of vascular lumen, and subjective score were significantly different from SNAP without CS($p<0.05$). When CS AF =2.5, 3, 4, 5, the CTReff of vascular wall were significantly different compared with SNAP without CS ($p<0.05$) (Table.4, Fig.2).

CONCLUSION

s 3D CS SNAP can obtain whole cerebrovascular MRA and vascular wall images in a relatively short period of time, and AF of 3 is recommended as its optimized sequence (Fig.5).

CLINICAL RELEVANCE/APPLICATION

3D CS SNAP technology has the potential to apply to multi-contrast blood imaging protocols, allowing for the acquisition of whole cerebral angiography and vascular wall images in relatively short periods of time.

Pharmacokinetics, Safety and Tolerability of the Novel Tetrameric, High Relaxivity, Macrocyclic Gadolinium-based Contrast Agent Gadoquatrane for CE-MRI

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Birte Hofmann, DVM, PhD, Berlin, Germany (*Presenter*) Employee, Bayer AG

PURPOSE

Gadoquatrane (BAY 1747846) is a novel tetrameric, macrocyclic gadolinium (Gd)-based contrast agent (GBCA) featuring a unique tetrameric structure and high relaxivity. The present study investigated its pharmacokinetics (PK) including excretion pathways, safety and tolerability in healthy volunteers.

METHODS AND MATERIALS

This first-in-human study was conducted as a randomized, single-blind, placebo-controlled, single dose study with 6 consecutive dose cohorts consisting of 8 to 9 healthy young women and men (N=49 total). Gadoquatrane or matching placebo (NaCl 0.9%) were intravenously administered by either infusion (doses of 0.025, 0.05, or 0.1 mmol Gd/kg bw) or bolus injection (doses of 0.03, 0.1 or 0.2 mmol Gd/kg bw). Safety and tolerability were assessed over 7 days post injection (p.i.) including adverse events, cardiac and respiratory function and safety laboratory analyses. Plasma PK and excretion in urine and feces were investigated over 72 h p.i. by ICP-MS as well as HPLC-ICP-MS.

RESULTS

Demographics were well balanced, with no notable differences between cohorts (24 ?, 25 ?; mean age (±SD) of 34.6±6.3 years; mean BMI (±SD) of 23.4±2.57 kg/m2). Plasma concentrations declined rapidly due to fast extracellular distribution and elimination, with no relevant gender differences. AUC and Cmax increased dose proportionally, volume of distribution (0.21-0.24 L/kg) and plasma clearance (0.09-0.1 L/h/kg) remained constant. Excretion via the kidneys was essentially complete (80-100%) within 12 h p.i.. No metabolites were detected in plasma or urine. Incidence and severity of treatment emergent adverse events (TEAEs) were similar in all dose groups incl. placebo. Intensity of most study drug related TEAE was mild, few were of moderate intensity, and none severe; all were recovered or recovering at 7 days p.i..

CONCLUSION

s The novel high relaxivity, tetrameric, macrocyclic GBCA gadoquatrane was very well tolerated at all doses. The PK profile is essentially the same as for other extracellular macrocyclic GBCAs (like gadobutrol or gadoterate meglumine). Gadoquatrane has the potential to be used at substantially lower Gd doses in clinical routine compared to currently marketed extracellular GBCAs.

CLINICAL RELEVANCE/APPLICATION

The novel, tetrameric gadoquatrane is a promising GBCA in development for MRI and its profile incl PK, safety, high relaxivity and stability meets the clinical demand to reduce the gadolinium dose.

Investigation of Image Quality of Different Monochromatic Energy Images in Spectral CT Scan: A Phantom Study

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Yaoxing Ma, (*Presenter*) Nothing to Disclose

PURPOSE

Objective to explore the influence of different monochromatic energy images on the quality of energy spectrum images.

METHODS AND MATERIALS

A polypropylene cylindrical phantom (QSP Phantom dimension) with five tubes containing different concentrations of iodine (0, 2.5, 5, 10, 20 mg/ml) was scanned using a spectral CT (Revolution CT, GE Healthcare) in gemstone spectral imaging (GSI) mode using fast kV switch (80/140 kV) ,the tube current was 485mA, the layer thickness was 1.25mm, the collimation width was 80mm, noise index (NI) 9, pitch 0.992:1.The CT and SD values were measured at 11 different central planes.,the region of interest (ROI) of the phantom tube with iodine concentration of 20% was delineated, The area of ROI was 1 / 2-1 / 3 of the cross-sectional area of the phantom tube.The CT values and noise of 40 keV, 70 keV, 100 keV and 130 keV groups were measured and recorded by GSI viewer. One way ANOVA was used to compare the CT value and noise of iodine 20 phantom tube under different keV. LSD-t test was used to compare the two groups.

RESULTS

With the increase of monochromatic energy level,the CT value and noise of the images gradually decreased. The CT value of 40 keV, 70 keV, 100 keV and 130 keV groups were 1546.34±3.13HU, 490.13±1.60HU, 215.71±1.28HU, 121.52±18HU, the difference was statistically significant ($P < 0.05$); The noise of 40 keV, 70 keV, 100 keV and 130 keV groups was 25.46±2.89HU, 11.44±1.3HU, 7.83±0.92HU, 6.62±0.75HU, the difference was statistically significant ($P < 0.05$).

CONCLUSION

s With the increase of monochromatic energy level, the CT value and noise of the images gradually decrease, and monochromatic energy images in spectral CT scan can optimize the image quality.

CLINICAL RELEVANCE/APPLICATION

Through the basic research of phantom, compared with conventional kVp scanning, energy spectrum CT scanning can provide the same image quality scanning radiation dose. At the same time, compared with conventional kVp scanning, energy spectrum CT scanning can provide different levels (40-140kev) of single energy and effective atomic coefficient, and more energy spectrum information of base material. This study has guiding significance for the application of energy spectrum scanning in different clinical scenes.

Study on the Image Quality of Head and Neck CTA With Energy Spectrum Combined With Iterative Reconstruction Method

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Deng Jie, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the influence and application value of spectral CT single-energy imaging combined with adaptive iterative reconstruction (ASIR) technology on head and neck CT angiography (CTA).

METHODS AND MATERIALS

88 patients undergoing head and neck CTA examination were compared using energy spectrum combined with adaptive iterative 40% ASIR scanning, and reconstructed single-energy 40keV, 60 keV, 80 keV, and performed vascular surface reconstruction (CPR) and maximum density projection on the three groups of images. Processing (MIP). The effects of different reconstruction methods on the image quality of head and neck CTA were evaluated from the two aspects of objective measurement and subjective score.

RESULTS

Objective evaluation: The CT values, SD values, SNR values, and CNR values of the aortic arch, common carotid artery, middle cerebral artery, vertebral artery, and basilar artery measured under the three reconstruction methods were all statistically different ($P<0.05$). Subjective evaluation: The Kappa value of the subjective evaluation of the image reconstruction quality by the physicians of the two diagnosis groups in each group was 0.75, showing strong consistency. There was no statistical difference in the scores of MIP reconstruction images among the groups ($P=0.467$). There was a statistically significant difference in the scores of CPR reconstruction images among the groups ($P<0.05$).

CONCLUSION

s In the image quality of head and neck CTA examination, the single energy spectrum of 60keV combined with adaptive iterative 40% ASIR scanning can reduce image noise and improve the image signal-to-noise ratio. be applied.

CLINICAL RELEVANCE/APPLICATION

When applied to head and neck CTA, the single energy spectrum of 60keV combined with adaptive iterative 40% ASIR scan has the best image quality, which can be used in clinical practice.

Predicting Early Glioma Recurrence With Peritumoral Radiomic Features From Amide Proton Transfer Weighted MR Images

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Shanshan Jiang, MD, PhD, Baltimore, MD (*Presenter*) Nothing to Disclose

PURPOSE

Because of the basement membrane barrier effect, diffuse infiltration of tumor cells into surrounding brain tissue has been proved a significant factor for migration/invasion of malignant gliomas. However, the peritumoral areas have been rarely studied for post-surgery/chemoradiation malignant gliomas. Amide proton transfer-weighted (APTw) MRI, a method generating the MRI contrast dominated by endogenous cellular proteins, has showed an encouraging diagnostic performance for gliomas. The goal was to evaluate the power of APTw-based peritumoral radiomics for classification of treatment effects and tumor recurrence.

METHODS AND MATERIALS

A total of 90 patients with post-treatment malignant gliomas were retrospectively re-assessed. Diagnosis of tumor recurrence vs. treatment effects was based on the integrated clinical pathologic results or the updated RANO criteria. The sequences included T1w, T2w, FLAIR, APTw, and gadolinium contrast-enhanced T1w (T1w-Gd). After imaging preprocessing, radiomic features were extracted from the peritumoral regions, which were segmented manually covering abnormal FALIR/T2w signal intensities outside the gadolinium-enhancing tumor core. A current reality tree (CRT) model was constructed to identify the most critical features when differentiating tumor recurrence from treatment effects. The alpha level of all tests was set at $P < 0.05$.

RESULTS

29 vs. 61 patients were confirmed, respectively, as treatment effect or tumor recurrence. The CRT model achieved accuracies of 83.3% with radiomic features extracted from FLAIR, 90.0% with those from APTw, and 91.1% with those from both FLAIR and APTw. The 90 percentile APTw value was listed as the most important feature to distinguish these two entities in both decision trees based on APTw and FLAIRAPTw MRI models.

CONCLUSION

s APTw-derived radiomic features are capable of capturing the progressive pattern in peritumoral areas, aiding in the accurate treatment response assessment in post-treatment malignant gliomas by increasing detection specificity.

CLINICAL RELEVANCE/APPLICATION

Our results suggest that the use of APTw MR images radiomic features from peritumoral area can add important value to structural MRI to assess the early treatment response.

Newly Developed Iterative Motion Correction (IMC) for Brain MRI: Utility for Reducing Motion Artifacts and Improving Image Quality without Any Affection to Examination Time in Uncooperative Patients

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Kazuhiro Murayama, MD, Toyoake, Japan (*Presenter*) Research Grant, Canon Medical Systems Corporation

PURPOSE

To determine the utility of newly developed iterative motion correction (IMC) method for reducing motion artifact and improve image quality without any affection to examination time in uncooperative patients.

METHODS AND MATERIALS

65 patients suspected of cerebrovascular disease obtained fluid attenuated inversion recovery (FLAIR) images with and without IMC at 3T systems. Based on FLAIR image without IMC results, all patients were divided into cooperative (n=19) and uncooperative (n=46) patient groups. To compare examination and reconstruction time differences, these times were recorded in all patients. To assess the capability for image quality improvement between FLAIR images with and without IMC, SNR of normal appearance white matter (NAWM), CNR between gray matter and NAWM, and CNR between NAWM and deep and subcortical white matter hyper intensity (DSWMH) abnormalities were determined by ROI measurements on each FLAIR. Moreover, overall image quality, artifact and lesion conspicuity in each group were assessed by 5-point scales by two board-certified radiologists. To compare examination and reconstruction time between two methods, Wilcoxon signed-rank test was performed. For image quality comparisons, SNR and CNRs were compared between FLAIRs with and without IMC in cooperative and uncooperative groups by Student's t-test. To determine interobserver agreements for all indexes, kappa statistics with ?2 test were performed. Then, each qualitative score was also compared between FLAIRs with and without IMC by Wilcoxon's signed sum test.

RESULTS

Mean examination and reconstruction times of FLAIR with IMC (256.3±2.7 sec) were significantly longer than those of FLAIR without IMC (217.0±0.59 sec, $p<0.0001$). SNR and CNRs of FLAIRs with IMC was significantly higher than that without IMC in uncooperative group ($p<0.05$). Interobserver agreements for each qualitative image quality score were assessed as substantial or excellent in each group ($0.74=?=0.91$, $p<0.001$). Each qualitative image quality score of FLAIR with IMC was significantly higher than that without IMC in uncooperative group ($p<0.05$).

CONCLUSION

s The IMC technique has a potential for reducing motion artifacts and improving image quality on brain MRI with less than 1 minute prolongation of examination and reconstruction times in uncooperative patients.

CLINICAL RELEVANCE/APPLICATION

The IMC technique has a potential for reducing motion artifacts and improving image quality on brain MRI in uncooperative patients.

Natural Language Processing for Extraction of Glioblastoma and Patient Characteristics from Radiology Reports

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Ahmad Amer, BS, North Chicago, IL (*Presenter*) Nothing to Disclose

PURPOSE

Glioblastoma (GBM) is an aggressive primary brain tumor with a median survival of 15 months. To assist with data extraction and evaluation of potential prognostic factors, natural language processing (NLP) was applied to automate extraction of patient and tumor data from one of the largest GBM patient populations at MD Anderson Cancer Center (MDACC).

METHODS AND MATERIALS

The radiology information system (RIS) was used to identify 4511 patients with a pathology-confirmed GBM diagnosis presenting to MDACC from 2006-2021. 50,202 corresponding radiology reports were identified, and Python was used for report processing. Identification of specific strings and aggregation by MRN allowed for determination of tumor multicentrality, extent of resection, and patient handedness. A similar approach was applied to extract tumor location, with separate strings used for lobe and laterality. Primary and secondary lobe were determined based on occurrence frequency of lobe-specific strings. Patient survival was estimated by determining the time difference between patients' first report mentioning GBM and last report. Extraction of pre-op tumor volume first required isolation of pre-op reports. A subset of such reports were extracted by selecting reports with pre-op-specific phrases in the examination section. Next, reports nearest to and within a week prior to intra-op dates were extracted. Intra-op dates were determined by searching reports' examination sections for intra-op-specific strings and extracting surgery dates with Regex. Reports occurring prior to suspicion or diagnosis of GBM were excluded. The syntax of remaining reports were then analyzed using a pre-trained SciSpacy model, and sentences without tumor-related strings were excluded. Tumor dimensions were extracted using Regex and used to calculate tumor volume. Manual validation was performed for OS, volume, and location.

RESULTS

NLP characterized patients as long-term survivors with 94.7% sensitivity, 97.6% specificity, and an ROC-AUC of .953. Quantitative analysis yielded a mean absolute error of 19.40%. Lobe and laterality were 98% and 90% accurate respectively. Successful extraction of all tumor dimensions for volume calculation was achieved in 72.5% of cases.

CONCLUSION

s Automated extraction of tumor lobe, laterality, multicentrality, extent of resection, volume, and OS and handedness was accomplished. OS and location data were highly accurate.

CLINICAL RELEVANCE/APPLICATION

NLP was successfully applied to extract data for the investigation of prognostic factors of GBM, which could lead to improvements in patient management and inform expectations of care.

A Novel Connectomic Analysis Framework for Personalised Presurgical Planning using Multimodal Neuroimaging

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Ruchi Sharma, MS,BS, Bhopal, madhya Pradesh, India (*Presenter*) Nothing to Disclose

PURPOSE

The traditional method of surgical selection and planning in brain tumours was based mostly on the topography of the tumour. With recent advances, connectomics promises to provide comprehensive information by integrating the inferences from network mapping, tractography, and tumour segmentation. This information helps neurosurgeons develop new insights and an optimal strategy for tumour resection. We present a novel, automated connectomic analysis framework that integrates rs-fMRI, DWI and sMRI (T1w, FLAIR, and T1CE) modalities to determine the effect of a tumor on the individual’s structural and functional connectivity, assisting in presurgical planning.

METHODS AND MATERIALS

A study was conducted on 15 tumor subjects who underwent the above mentioned MR modalities prior to surgery. Three groups of five subjects underwent tb-fMRI for Motor, Visual, and Language tasks. For each subject, our framework analysed the multiple modalities using the following techniques - multivariate statistical analysis on rs-fMR images to generate major functional networks, deep learning-based segmentation strategy on sMR images for tumour demarcation, and whole-brain probabilistic tractography on DWI for generation of major fibre tracts.Additionally, the framework reports the tumor's proximity to the generated functional network and white matter tracts using a heuristic algorithm.

RESULTS

Connectomic profiles were generated for all the subjects. For the five subjects that underwent tb-fMRI, all the network maps produced by rs-fMRI and tb-fMRI yielded similar activations in the corresponding network regions. The heuristic algorithm used to report the distance between the tumours, network maps, and tracts were highly useful in deciding the trajectory of operation.

CONCLUSION

s The connectomic profile for the clinical cases using network maps, fibre tracts, and tumor demarcation proved to be highly beneficial in the personalised presurgical planning. The validation of rs-fMRI against tb-fMRI also helped to mindfully perform the surgery to avoid functional loss of major networks.

CLINICAL RELEVANCE/APPLICATION

This study proposes a multimodal connectomic analysis method to produce personalised presurgical insights for tumor patients which helps in taking critical decisions for operating the tumor with a better understanding of the anatomical, functional and surgical complexities which is highly beneficial.

Perfusion-Based Radiomics Enable to Predict Thrombolysis/Thrombectomy Related Hemorrhagic Transformation in Patients With Acute Stroke: Development and Validation

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Yunhwa Roh, (*Presenter*) Nothing to Disclose

PURPOSE

Prompt diagnosis and early detection of hemorrhagic transformation (HT) may prevent dismal prognosis in acute stroke patients. We aimed to develop and validate a radiomics-based model for predicting thrombolysis/thrombectomy-related HT in patients with acute ischemic stroke using multiparametric MRI of conventional, diffusion-, and perfusion-weighted imaging.

METHODS AND MATERIALS

In this retrospective study, a radiomics model was developed in a consecutive 462 patients diagnosed with acute ischemic stroke and who underwent multiparametric MRI between 2017 to 2018 and tested in an independent validation set of 276 patients between 2019 to 2021. For each patient, 140 radiomics features were extracted from FLAIR and GRE image, DWI, and perfusion-weighted imaging including CBF, CBV, K2, MTT, Tmax, and TTP maps. HT was classified as either presence of HT (HT) or the presence of parenchymal hemorrhage (PH). Radiomics features for predicting outcomes were selected using random forest, and the model was developed by using logistic regression classifier. The diagnostic performance was calculated and compared among imaging sequences in the independent validation set using the area under the curve (AUC) from a receiver operating characteristic curve analysis, sensitivity, specificity, and accuracy.

RESULTS

For predicting HT, 8 out of 10 top features were from perfusion-weighted imaging using variable importance including TTP, CBF, and Tmax. For predicting PH, 8 out of 10 top features were from perfusion-weighted imaging including CBV, CBF, MTT, and K2. Volume and compactness of DWI and FLAIR also become significant predictors. In the test cohort, the perfusion-based radiomics model significantly improved performance (AUC 0.725) compared with DWI or FLAIR alone (AUC 0.665 and 0.679, respectively) for predicting HT. For predicting PH, the perfusion-based radiomics model also significantly improved performance (AUC 0.732) compared with DWI or FLAIR alone (AUC, 0.693 and 0.702, respectively).

CONCLUSION

s Utilizing perfusion-weighted imaging for the radiomics model significantly improved the prediction of hemorrhagic transformation as well as parenchymal hemorrhage in patients with acute stroke.

CLINICAL RELEVANCE/APPLICATION

HT following cerebral ischemia has been postulated to result in a negative impact on the clinical course. A radiomics model that utilized perfusion-weighted imaging showed improved diagnostic performance for predicting hemorrhagic transformation than conventional imaging or diffusion-weighted imaging alone. These findings support the role of perfusion MRI in identifying patients who are at increased risk for secondary HT following acute ischemic stroke and may assist patient management for clinicians.

R5A-SPNR-3

Disorganized Subcortical Functional Gradients in Schizophrenia and the Treatment Effects After Administration of Antipsychotics

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Chengmin Yang, (*Presenter*) Nothing to Disclose

PURPOSE

Growing evidence indicates that subcortex is pivotal in the pathophysiology of schizophrenia, and changes in subcortical regions were also sensitive indicators of pharmacological treatments. However, how the subcortex embeds within the macroscale cortical system, and the structural constraints and functional emergences of spatial arrangements, remain unclear. The new concept of gradients focused on spatial relationships, which revealed that macroscale gradients integrated systematic information into more abstract representations. Exploring the subcortex in the broader cortical landscape as well as investigating its feature as treatment target in schizophrenia is promising for its extensive connections with the entire cerebral cortex.

METHODS AND MATERIALS

Leveraging connectome gradients, we systematically scrutinized abnormalities of functional connectome gradient in antipsychotic-naïve first-episode schizophrenia patients (FES0W, n = 57) at baseline, comparing to healthy controls (HCs, n = 64), as well as longitudinal comparisons of baseline with 6-week (FES6W, n = 19) and 12-month (FES12M, n = 57) follow-up, respectively. And further examined the reproducibility in an independent validation sample (vFES0W, n = 22; HCs, n = 25), and the patients with 6-week (vFES6W, n = 22) follow-up. Correlational analyses were conducted between the longitudinal functional gradient alterations and the psychopathological ratings, including Positive and Negative Syndrome Scale (PANSS) and Global Assessment of Functioning (GAF) scores.

RESULTS

In both primary and validation datasets, patients at baseline showed the higher gradients mainly in limbic system and lower gradients in thalamus and caudate , and the longitudinal functional gradients alterations showed the improved trend over time (all $p < 0.001$, Bonferroni corrected, Figure 1 and 2). Namely, in the period of antipsychotic treatment, the increased gradients were positively while the decreased gradients were negatively correlated with symptom improvement.

CONCLUSION

s Our findings provided a novel insight into the functional system hierarchy alterations of subcortical organization, which were sensitive to illness and treatment effects. This might extend our understanding of the functional connectome organization of subcortex in schizophrenia, and this measure makes a promising indicator of treatment response.

CLINICAL RELEVANCE/APPLICATION

This study provided the new perspective on the abnormal subcortical hierarchy organization in schizophrenia and its longitudinal gradient changes could be sensitive to reflect the antipsychotic treatment effect.

Use of Real Life Safety Data From International Pharmacovigilance Databases to Assess the Importance of Symptoms Associated With Gadolinium Exposure

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Imran Shahid, (*Presenter*) Nothing to Disclose

PURPOSE

Recent scientific publications have reported cases of patients who complained from a variety of symptoms after they received a gadolinium-based contrast agent (GBCA). The aim of this study was to appreciate the importance of these clinical manifestations in the overall population by assessing the weight of "symptoms associated with gadolinium exposure" (SAGE) among the bulk of safety experiences reported to major health authorities.

METHODS AND MATERIALS

SAGE symptoms were identified from a review of the scientific literature, and the corresponding preferred terms (PTs) were searched in each system organ class (SOC) category recorded in the European and North American pharmacovigilance databases, EudraVigilance (EV) and FDA Adverse Event Reporting System (FAERS), respectively. The numbers of SAGE symptoms per PT, and cumulatively per SOC, were recorded and their weights in the overall spectrum of AEs was determined for each GBCA.

RESULTS

The literature search led to identify 11 articles from which the most prevalent SAGE symptoms were selected. The extraction and analysis of such AEs in EV and FAERS revealed a significantly higher SAGE weight for gadobenate dimeglumine (EV: 25.83%, FAERS: 32.24%) than for gadoteridol (EV: 15.51%; FAERS: 21.13%), and significantly lower SAGE weights for gadobutrol (EV: 7.75%; FAERS: 13.31%) and gadoterate meglumine (EV: 8.66%; FAERS: 12.99%). The SOCs "skin and subcutaneous tissue disorders", "musculoskeletal and connective tissue disorders", "general disorders and administration site conditions" and "psychiatric disorders" were consistent with this ranking, with gadoteridol showing alternately a SAGE profile aligned on the linear GBCA or on the other macrocyclic GBCAs.

CONCLUSION

s This study showed that SAGE symptoms represent a significant percentage of the bulk of adverse events reported to the health authorities for each GBCA. It provided real-life arguments suggesting that SAGE symptoms may be more prevalent with linear than macrocyclic GBCAs, and that gadoteridol may present a higher SAGE risk than the other macrocyclic contrast agents.

CLINICAL RELEVANCE/APPLICATION

This study investigates, in EMA and FDA pharmacovigilance databases, the proclivity of symptoms associated with gadolinium exposure (SAGE) in patients exposed to gadolinium-based MRI contrast agents.

Variation in Prices for Outpatient Brain MRI in the US

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Kinpritma Sangha, PhD, MPH, (*Presenter*) Employee, Siemens AG

PURPOSE

The 2021 Hospital Price Transparency Rule was implemented to require hospitals to publish payer-specific negotiated commercial prices for medical services. Payer-negotiated prices vary across the country and are based on hospital and state characteristics, with the greatest markup from mean negotiated prices compared with Medicare reimbursement to be for magnetic resonance imaging (MRI). The objective of this study was to analyze the variation in MRI brain exam prices and to estimate the association between state characteristics and the median MRI brain exam price in the US.

METHODS AND MATERIALS

This cross-sectional study examined MRI brain exam prices in the hospitals across US using payer-negotiated prices from the Turquoise Health dataset. MRI brain exam, as a billable service, was identified using the Current Procedural Terminology (CPT) code of 70551. Price variance analysis was performed for all states and characteristics including Herfindahl-Hirschman Index (HHI) and certificate of need (CON) program in the state. Multivariable regression analyses were conducted to determine factors that impact brain MRI exam price among the states.

RESULTS

A total of 2504 hospitals disclosed the payer-negotiated prices in 2021 Turquoise Health dataset for brain MRI exams. The greatest price variation in brain MRI exams was for commercial payers with median price of $1531, ranging from $3230 to $611.57. Alaska, with the least number of hospitals, has the highest median price of $3230, while New York, with 84 hospitals has the lowest median price of $611.57. States with the CON program had a higher median price (by $164) than states without the CON program and states with a high HHI index (HHI>6000), indicating a less competitive market, have a higher median price (by $412) than states with a more competitive market. Both the number of health systems in the state (p=0.001) and having commercial payers (p=0.000) were found to be statistically significant in affecting impact the median MRI brain exam prices.

CONCLUSION

s While MRI brain exam prices vary throughout the US, more health systems and commercial payers in the state drive the prices higher.

CLINICAL RELEVANCE/APPLICATION

This study helps to understand the factors affecting price variation in brain MRIs in the US.

R5A-SPNR-7

Clinical Evaluation of Scout Accelerated Motion Estimation and Reduction (SAMER) For Brain MRI in an Emergency and Inpatient Setting

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Azadeh Tabari, MD, Boston, MA (*Presenter*) Nothing to Disclose

PURPOSE

A navigation-free retrospective motion-correction method (SAMER) has been developed to achieve rapid motion estimation and correction. In this work, we performed an initial evaluation of SAMER in a clinical setting

METHODS AND MATERIALS

In this prospective IRB approved and HIPAA compliant study, 97 patients from emergency and inpatient care settings were scanned on a 3T system (MAGNETOM Skyra, Siemens) using a 20-channel head-neck coil, between August 2021 and January 2022. The imaging protocol included a 4-fold accelerated T1-weighted MPRAGE sequence, which was acquired using a custom linear+checkered sequence reordering. This sequence was incorporated into routine brain MRI to assess the performance of motion correction on non-contrast and contrast-enhanced exams. Retrospective reconstructions of the MPRAGE data were performed with and without SAMER motion correction. All 97 cases were reviewed by two neuroradiologists in a blinded manner to rate the impact of motion artifacts on diagnostic image quality using a previously published 5-tier scale (None, minimal, mild, moderate, severe). Discrepancies in the two neuroradiologists' scores were adjudicated by a third neuroradiologist

RESULTS

There was no significant difference in the performance of motion correction between the contrast-enhanced (n=58) and non-contrast (n=42) exams ($p>0.05$). Six (6.1%) of cases showed no motion, 46 (47.4%) showed minimal motion, 30 (31%) showed mild motion, 8 (8.2%) showed moderate motion, and 10 (10.3%) showed severe motion. The prevalence of repeat sequences was 3% of total MRI examinations. Following motion correction with SAMER, there was a significant improvement in motion score ($P<0.005$ for both raters). The motion score improvement was defined as the pre-correction motion score minus the post-correction score. For cases with motion scores of "none" or "minimal", SAMER had negligible impact on the motion score. For cases with "mild", "moderate", and "severe" motion, SAMER improved the motion score by an average score of 0.36, 1.1, and 1.2 points, respectively

CONCLUSION

s SAMER improves diagnostic image quality of clinical brain MR exams in the presence of motion, and the improvement is most pronounced when motion is moderate or severe

CLINICAL RELEVANCE/APPLICATION

Motion artifacts are common in emergency and inpatient brain MRI exams. SAMER demonstrates utility in a clinical setting to reduce motion artifacts in these studies, which may facilitate timely diagnosis and require fewer repeat sequences and callbacks for critically ill patients

Preoperative Visualization of the Transverse and Sigmoid Sinuses Using Non-contrast Virtual Monochromatic CT Images for the Lateral Suboccipital Retrosigmoid Approach

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Tomomi Omura, Akita, Japan (*Presenter*) Nothing to Disclose

PURPOSE

In the surgical planning of suboccipital retrosigmoid craniotomy, it is important for neurosurgeons to recognize tortuosity of the transverse and sigmoid sinuses and their relationship to superficial landmarks including asterion. This study aimed to improve the depiction of those venous sinuses in preoperative non-contrast (NC) virtual monochromatic images (VMIs).

METHODS AND MATERIALS

Thirty-one patients (24 women and 7 men; mean age, 63 ± 19 years) who underwent NCCT retrosigmoid craniotomy were included. The NCCT was scanned using dual-source CT (SOMATOM Drive, Siemens Healthineers, Forchheim, Germany). The NC-DECT images were acquired at a kV-pair of 80 kV and 140 kV with tin-filtration at about 70 mGy using automatic exposure control. Mixed-120 kV images were synthesized by compositing both kV images. The native VMIs were generated at 40, 70, 100, 130, 160, and 190 keV using a CT vendor's workstation. In the reconstructed sagittal section of each image, a circular region of interest (ROI) was set in the transverse sinus and cerebral cortex as a reference. Standard deviation (SD) and attenuation value (HU) were measured in each ROI to obtain the difference in HU values between the transverse sinus and cerebral cortex (?HU) and contrast-to-noise ratio (CNR).

RESULTS

The median ?HU for each VMI was increased with higher keV, and each ?HU for 100, 130, 160, and 190 keV was significantly higher than that for Mixed-120 kV (9.6, 10.3, 10.5, and 11.0 HU for 100, 130, 160, and 190 keV respectively, and 8.8 HU for Mixed-120 kV, $P<0.001$ for each). The median CNR for each VMI was also increased with higher keV, and each CNR for 100, 130, 160, and 190 keV was significantly higher than that for Mixed-120 kV (6.8, 6.8, 6.7, and 7.3 for 100, 130, 160, and 190 keV respectively, and 3.2 for Mixed-120 kV, $P<0.001$ for each).

CONCLUSION

s Both ?HU and CNR of transverse sinuses were improved at VMIs above 100 keV. The results suggest that high keV VMIs improve visualization of the transverse sinus and are useful in surgical planning for suboccipital retrosigmoid craniotomy.

CLINICAL RELEVANCE/APPLICATION

High keV VMI is less susceptible to beam hardening, so structures and findings adjacent to bone are clearly delineated.

R5A-SPNR-9

Blood-Brain Barrier Dysfunction in Patients with Heart Failure

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Kamlesh Jobanputra, MD, Birmingham, AL (*Presenter*) Nothing to Disclose

PURPOSE

Heart failure (HF) patients show brain tissue injury in sites that mediate autonomic, cognitive, and mood functions, which are deficient in HF and are linked with increased morbidity and mortality and poor quality of life in the condition. However, the pathological mechanisms that may contribute to brain tissue injury in HF are unclear, but blood brain barrier (BBB) disruption might be one of the processes that contribute to brain injury. Our aim was to examine BBB function, based on diffusion-weighted pseudo-continuous arterial spin labeling (DW-pCASL) procedures, in HF and healthy control subjects.

METHODS AND MATERIALS

We performed DW-pCASL imaging in 25 HF [age, 55.4±7.4 years; body-mass-index (BMI), 27.2±4.3 kg/m2; 18 male; NYHA functional class II/III, LVEF <40%] and 56 healthy controls (age, 51.7±9.0 years; BMI, 26.8±3.7 kg/m2; 31 male) using a 3.0-Tesla MRI scanner (Siemens, Magnetom, Prisma Fit). Using DW-pCASL data, arterial transit time (ATT, an index of large artery integrity) and water exchange rate across the BBB (Kw, BBB function) were quantified and whole-brain ATT and Kw maps were generated. Whole-brain ATT and Kw maps were normalized to Montreal neurological institute space, smoothed, and compared voxel-by-voxel between HF and control groups using analysis of covariance (ANCOVA; covariates: age, sex; SPM12, uncorrected $p<0.005$). Brain clusters with significant differences between groups were overlaid onto background images for structural identification.

RESULTS

No significant differences in age ($p=0.08$), sex ($p=0.16$), or BMI ($p=0.65$) appeared between groups. Multiple brain areas, which are involved in cognitive, mood, autonomic functions, showed altered Kw and ATT values in HF over health controls. Increased Kw values were observed in the insular cortices, hippocampus, thalamus, occipital cortices, cerebellar vermis, and other cortices and white matters regions. ATT values were decreased in the prefrontal, temporal, and occipital cortices, and mid brain, and increased in few areas, including the insular cortices and cerebellum in HF patients.

CONCLUSION

s HF patients show compromised BBB function and altered large artery integrity. BBB alterations may introduce neural damage in autonomic, mood, and cognitive regulatory areas, contributing to abnormal functions in HF. The findings suggest a need to repair BBB function in HF with strategies commonly used in other acute and chronic conditions.

CLINICAL RELEVANCE/APPLICATION

Management of neurologic symptoms in patients with heart failure is complex. Translational research focused on need for blood brain barrier repairing strategies in HF patients with brain injury may open new avenues of disease prevention and limiting progression.

R5A-SPOB-1 Deep Learning Image Reconstruction Algorithm for Submillisievert Female Pelvic Computed Tomography: Impact on Image Quality and Lesion Detection

Awards
Trainee Research Prize - Medical Student

Participants
Jing Ren, MD, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

To assess the impact of a new deep learning reconstruction (DLR) algorithm on image quality and lesion detection in submillisievert female pelvic CT, with standard dose (SD) hybrid-iterative reconstruction (IR) images as the reference.

METHODS AND MATERIALS

Fifty consecutive female patients who underwent contrast-enhanced abdominal pelvic CT for indications were enrolled. SD and subsequent low-dose (LD) portal venous phase scans were obtained 60 s after contrast agent injection. A noise index of 15 was set for LD scans to acquire submillisievert pelvic images reconstructed with DLR (body and body sharp kernels), hybrid-IR, and model-based IR (MBIR). SD scans with a noise index of 7.5 were reconstructed using hybrid-IR. Radiation dose, quantitative image quality (noise value, signal-to-noise ratio [SNR], and contrast-to-noise ratio [CNR]), and qualitative image quality (overall image quality and image appearance) using a 5-point Likert scale with 5 being the best were evaluated and compared. Clinically significant pelvic lesions were detected and evaluated by two board-certified radiologists.

RESULTS

The CT dose index volume in submillisievert pelvic CT was reduced by 54.2-70.6% compared to SD scans. Among LD images, DLR (body sharp) provided the best quantitative image quality, followed by DLR (body), MBIR, and hybrid-IR. LD DLR (both body and body sharp kernel) images showed lower noise, and higher SNR and CNR than SD images. Compared to SD hybrid-IR, LD DLR (body kernel) and LD hybrid-IR were considered to have natural appearance (p=0.209 and 0.070). Only LD DLR (body kernel) was rated comparable scores with SD hybrid-IR on overall image quality (p=0.084). In total, 40 pelvic lesions were detected in both SD and LD images. LD DLR (body) and LD DLR (body sharp) exhibited equivalent enhancement characteristic ratings (p=0.655 and 0.372) and diagnostic confidence (p=0.317 and 0.096) with SD hybrid-IR.

CONCLUSION

s A DLR algorithm providing comparable image quality and detectability is considered feasible in submillisievert female pelvic CT. DLR (body kernel) with favorable image appearance and overall image quality is more recommended for clinical settings.

CLINICAL RELEVANCE/APPLICATION

Submillisievert female pelvic CT with deep learning reconstruction exhibited non-inferior image quality and detectability, so it can reduce the radiation burden for patients requiring multiple screenings and long-term follow-up.

R5A-SPOB-2 Differential Diagnosis Value of Contrast-Enhanced Ultrasound in the Diagnosis of Pediatric Ovarian Torsion

Participants
Zehang Hu, Shenzhen, China (*Presenter*) Nothing to Disclose

PURPOSE

Ovarian torsion is a common concern in girls presenting to emergency care with pelvic or abdominal pain, threatening their future fertility. Conventional ultrasound (US) is the imaging modality of choice. We sought to describe contrast enhanced ultrasound (CEUS) characteristics of ovarian torsion in girls, and to assess the potential diagnostic advantages and limitations of method.

METHODS AND MATERIALS

We retrospectively analyzed all cases with clinically suspected ovarian torsion and underwent explorative surgery in Shenzhen children's hospital between 2019 and 2022, all of them were previously evaluated by US and CEUS. Those CEUS ovarian images were retrospectively analyzed with the software SonoLiver®, and the time-intensity curve (TIC) was generated to compare the bilateral ovarian time to peak(TTP)and maximum intensity (IMAX).

RESULTS

Our study included 13 cases with age range 4 months~13 years old (median age 10 years), We identified 3/13 torsion-confirmed cases and 10/13 torsion-absent cases by surgical confirmation. Of those torsion-absent cases, 6/13 cases with ovarian tumors ,3/13 cases with hemorrhagic corpus luteum, and 1/13 case with normal ovaries. US identified 4/13 cases with torsion (2 torsion-confirmed cases; 2 torsion-absent cases); 9/13 cases without torsion (8 torsion-absent cases, 1 torsion-confirmed case). In this study, the sensitivity, specificity and overall accuracy of US in the diagnosis of ovarian torsion were 66.7%, 81.4% and 76.9% respectively. US combined with CEUS identified 4/13 cases with torsion (3 torsion-confirmed cases, all torsion ovaries appeared hypo-enhancing or non-enhancing compared with healthy ovaries, and showed prolonged TTP and lower IMAX; 1 case proven without torsion); CEUS identified 9/13 cases without torsion (9 torsion-absent cases). In this study, the sensitivity, specificity and overall accuracy of CEUS in the detection of ovarian torsion were 100%, 90% and 92.3% respectively.

CONCLUSION

s US combined with CEUS has a higher sensitivity, specificity and overall accuracy than US in the detection of ovarian torsion.

CLINICAL RELEVANCE/APPLICATION

CEUS may be used as a supplementary means of US to increase the diagnostic accuracy of ovarian torsion.

R5A-SPPD-1 Application of Deep Learning Reconstruction in Low-Dose Brain CT of Children With Cerebral Trauma for Image Quality Improvement

Participants
Wei Weian, (*Presenter*) Nothing to Disclose

PURPOSE

To explore the application value of deep learning reconstruction (DLR) in low-dose brain CT imaging for children with acute cerebral trauma by comparing with ASIR-V.

METHODS AND MATERIALS

51 children with cerebral trauma complicated with intracerebral hemorrhage who experienced low dose brain CT were retrospectively collected. Scanning parameters: axial scan, rotation speed: 0.5s/rotation, 100 kVp and 250 mAs for children younger than 1.5 years old (y), 120 kVp and 250 mAs for children of 1.5 to 7y, 120 kVp and 300 mAs for those older than 7y. All images were reconstructed at 1.25 mm and 5 mm slice thickness utilizing two reconstruction algorithms with different strengths and divided into six subgroups: ASIR-V0%, ASIR-V50%, ASIR-V100%, DLR-L, DLR-M and DLR-H. The CT attenuation, SNR and CNR of dorsal thalamus, white matter of frontal lobe and hemorrhage lesion, as well as skull base artifact noise, background noise, and overall subjective image quality score of DLR and ASIR-V images were compared by one-way ANOVA and Kruskal-Wails H test. Two-sample t and Mann Whitney U were used for comparison between two groups.

RESULTS

The average CTDIvol and DLP of head CT were 16.79 ±0.55 mGy and 240.79 ±11.49 mGy*cm. At the same thickness, the subjective scores of DLR images were better than those of ASIR-V ($p<0.05$), and a higher reconstruction grade of ASIR-V and DLR led to higher SNR and CNR values of each structure as well as lower SD value ($p<0.05$). Among them, the SDartifact and SDbackground of DLR-H images (3.55±0.83 HU and 2.87±0.59 HU for 5mm; 5.21±1.24 HU and 4.63±1.20 HU for 1.25 mm) and ASIR-V100% (3.32±0.74 HU and 2.74±0.55 HU for 5mm; 5.22±1.16 HU and 4.78±1.09 HU for 1.25 mm) were the lowest and similar ($p>0.05$), but at 1.25mm thickness, CNR value for gray and white matter of DLR-H images was higher than that of ASIR-V100% (1.95±0.69 vs. 1.63±0.60, $p<0.05$). With the decrease of slice thickness, the image quality was decreased, but the average subjective scores of 1.25mm DLR images were still more than 3 points, while those of ASIR-V images were less than 3 points and could not fully meet the needs of diagnosis. In addition, the scoring of 1.25mm DLR-H was similar with that of 5mm ASIR-V50% (3.93±0.22 vs. 3.17±0.39, $p>0.05$), but the DLR group improved the spatial resolution and the detection capability of micro-hemorrhagic foci.

CONCLUSION

s In children's low-dose cerebral CT, DLR shows powerful ability to reduce noise and artifacts, also improve the display of general structure and microhemorrhagic foci, therein DLR-H has the best performance.

CLINICAL RELEVANCE/APPLICATION

In head CT for children, DLR holds great potential in decline of radiation dose and improvement of image quality, valuable for the diagnosis of brain disease especially for microhemorrhagic foci.

The average CTDIvol and DLP of head CT were 16.79 ±0.55 mGy and 240.79 ±11.49 mGy*cm. At the same thickness, the subjective scores of DLR images were better than those of ASIR-V ($p<0.05$), and a higher reconstruction grade of ASIR-V and DLR led to higher SNR and CNR values of each structure as well as lower SD value ($p<0.05$). Among them, the SDartifact and SDbackground of DLR-H images (3.55±0.83 HU and 2.87±0.59 HU for 5mm; 5.21±1.24 HU and 4.63±1.20 HU for 1.25 mm) and ASIR-V100% (3.32±0.74 HU and 2.74±0.55 HU for 5mm; 5.22±1.16 HU and 4.78±1.09 HU for 1.25 mm) were the lowest and similar ($p>0.05$), but at 1.25mm thickness, CNR value for gray and white matter of DLR-H images was higher than that of ASIR-V100% (1.95±0.69 vs. 1.63±0.60, $p<0.05$). With the decrease of slice thickness, the image quality was decreased, but the average subjective scores of 1.25mm DLR images were still more than 3 points, while those of ASIR-V images were less than 3 points and could not fully meet the needs of diagnosis. In addition, the scoring of 1.25mm DLR-H was similar with that of 5mm ASIR-V50% (3.93±0.22 vs. 3.17±0.39, $p>0.05$), but the DLR group improved the spatial resolution and the detection capability of micro-hemorrhagic foci.

CONCLUSION

s In children's low-dose cerebral CT, DLR shows powerful ability to reduce noise and artifacts, also improve the display of general structure and microhemorrhagic foci, therein DLR-H has the best performance.

CLINICAL RELEVANCE/APPLICATION

In head CT for children, DLR holds great potential in decline of radiation dose and improvement of image quality, valuable for the diagnosis of brain disease especially for microhemorrhagic foci.

Sub-Events

R5A-SPPH-1 Comparison of Computed Tomographic Dose Data of Tin Filter With Conventional Scanning Protocols Using Thermoluminescence Dosimeter Measurements

Participants
Simone Schuele, (*Presenter*) Nothing to Disclose

PURPOSE

We aim to investigate whether there are differences in the applied dose (TLD measurements (thermoluminescence dosimeter)) between different scanning protocols in computed tomography for the same CTDIvol (Computed Tomography Dose Index). Special focus is on the tin filter technique (Sn).

METHODS AND MATERIALS

Sixteen TLD measurements (3 measurement repetitions each) were performed in a water phantom (diameter 32 cm) using five different scan protocols (Sn 150 kV, 150 kV, 120 kV, 100 kV, Sn 100 kV) at three (CTDIvol: 29 mGy, 8.5 mGy, and 2.8 mGy) dose settings on a 3-generation dual source CT scanner. With the Sn 100 kV protocol, limited by the scanner, irradiations were only possible up to 6.4 mGy (CTDIvol). The TLDs were positioned centrally in the water phantom. TLD measurement results and the slope of the linear regression of the different protocols were compared. ANOVA or Kruskal-Wallis-test was used for statistical testing, where applicable.

RESULTS

Compared to the 100 kV, 120 kV, and 150 kV protocols, the tin filter protocols (Sn 150 kV, Sn 100 kV) applied higher doses (average dose difference: 16% +/- 4%) at all dose settings studied ($p<0.01$) except for the comparison between the Sn 150 kV and 150 kV protocols at a CTDIvol of 29 mGy ($p=0.072$). The Sn 150 kV protocol showed a steeper slope of the linear regression than the 100 kV and 120 kV protocols ($p<0.05$).

CONCLUSION

s The CTDIvol information from the scanner underestimates the dose of the Sn 150 kV and Sn 100 kV protocols compared to protocols without tin filtration.

CLINICAL RELEVANCE/APPLICATION

Tin filter protocols expose patients to higher radiation doses than standard protocols at the same CTDIvol. This must be taken into account when using the tin filter technique in computed tomography for radiation protection reasons.

R5A-SPPH-2 Multicenter, International Study of CT Practices and Radiation Doses from 5 African Countries: An International Atomic Energy Agency (IAEA) Baseline Study

Participants
Giridhar Dasegowda, MBBS, Boston, MA (*Presenter*) Nothing to Disclose

PURPOSE

There are few studies on CT practices from Africa to inform about the implementation of justification and optimization principles for radiation protection of patients. Therefore, under the framework of the IAEA Technical Cooperation Regional Project RAF9/064 entitled" a comprehensive baseline study was conducted to under to assess CT practices and radiation doses from multiple hospitals across several African countries and better determine the needs for improved radiation protection of patients.

METHODS AND MATERIALS

Six hospitals from Mauritius, Tunisia, Kenya, Sudan, Burkina Faso contributed information on 20-30 consecutive patients who underwent head, chest, and/or abdomen-pelvis CT examinations. Prior to the data recording step, all sites had a mandatory one-hour training on best practices in recording the relevant data elements without any personal health identifiers. The recorded data elements included patient age, gender, weight, height, CT protocol name, scanner information, scan factors (tube current, automatic exposure control, tube potential, number and names of scan phases), and radiation dose metrics including series-specific CT dose index volume (CTDIvol in mGy) and dose length product (DLP in mGy.cm). Information was recorded by either on-site CT technologists or medical physicists and radiologists between January-April 2022. For statistical analysis, we estimated median and interquartile range of body-region specific CTDIvol and DLP and compared data with Kruskal Wallis H test.

RESULTS

There were substantial variations in radiation doses between the different hospitals with minimum and maximum CTDIvol and DLP of 33-81mGy and 638-1891mGy.cm for head CT, 6-25mGy and 192-974mGy.cm for chest CT, and 6-15mGy and 303-1375mGy.cm for abdomen-pelvis CT ($p < 0.01$). There was no significant difference between body mass index (BMI) or age across the different sites. Most sites used multiphase CT protocols for chest-abdomen-pelvis (6/6 sites) and chest CT (3/6 sites), regardless of clinical indications. Total DLP values for head, chest, abdomen, and chest-abdomen-pelvis CT at 3/6, 4/6, 4/6, and 5/6 sites were above the American College of Radiology and European reference dose levels.

CONCLUSION

s There are concerning variations in CT practices and protocols across several hospitals in Africa emphasizing need for protocol optimization to improve radiation protection of patients.

CLINICAL RELEVANCE/APPLICATION

Use of higher than recommended CT radiation doses in several African sites underscore critical need for optimization and oversight of CT practices.

R5A-SPPH-3 Effect of Hormone Therapy on Target Volume in Radio-theraphy of Localized Prostate Cancer

Participants
Ayse Dagli, Istanbul, Turkey (*Presenter*) Nothing to Disclose

PURPOSE

To determine the extent of tumor volume reduction and normal organ doses in prostate cancer (PCa) patients, with large prostate volumes that are geometrically unsuitable, treated with radiotherapy (RT) and combined androgen deprivation therapy (ADT).

METHODS AND MATERIALS

Ten patients with localized PCa included into the study. Median patient age was 71.6. (60-76). Patients underwent neoadjuvant ADT at least three months (3-36 months). Simulation CT images were obtained before the initiation of ADT (Plan 1) and 2 months after ADT (Plan 2). All patients were simulated in supine position with full bladder and empty rectum. RT treatment plans were done on each image set. All plans were done with VMAT using two full arcs. Prescribed dose was 76 Gy with 2 Gy/day in 38 fractions. Tumor volume and normal organ doses were dosimetrically compared. Maximum target doses (Dmax), homogeneity index (HI) and conformity index (CI), bladder, rectum and penile bulb doses were compared between two plans. Statistical analysis was done using paired t test. $P<0.05$ was accepted as statistically significant.

RESULTS

The median prostate volume was 77 cc (range: 51-113 cc) in Plan 1 images and the median prostate volume was 56 cc (range: 35-90 cc) in the Plan 2 images. Median prostate volume reduction with ADT was 17 cc, representing a 23% reduction in the target volume ($p<0.001$). The Dmax ($p=0.77$), HI ($p=0.16$) and CI ($p=0.66$) was not statistically different in two plans. Bladder ($p=0.48$) and rectum ($p=0.07$) volumes were not significantly different between two plans. Bladder volumes receiving 30 Gy (V30),40 Gy (V40), 50 Gy (V50), 56 Gy (V56), 65 Gy (V65), 75 Gy (V75) decreased 14%, 8%,7%, 4%, 4%, 1%, respectively combined ADT. Bladder Dmax was decreased 7% but Dmean did not change. Rectum volumes receiving 30 Gy (V30), 40 Gy (V40), 50 Gy (V50), 56 Gy (V56), 60 Gy (V60), 70 Gy (V70),75 Gy(V75) decreased 21% 26%, 34%, 35%, 34%, 33%, 35%, respectively combined ADT. Rectum Dmean was decreased 19% but Dmax did not change. Doses to 90 ml (D90) penile bulb was decreased 8%; mean and maximum penile bulb doses were decreased 9% and 2%, respectively.

CONCLUSION

s Prostate shrinkage after combined ADT provides significant reduction in normal organ doses in PCa RT. This benefit may result in fewer acute and late radiotherapy complications. Clinical studies are needed to supported this data.

CLINICAL RELEVANCE/APPLICATION

It may be necessary to revise target volume in treatment planning, as it provides significant reduction in prostate volume after combined ADT.

R5A-SPPH-4 Cumulative Radiation Exposure in Covid-19 Patients Admitted to the Intensive Care Unit

Participants
Lama HADID, (*Presenter*) Nothing to Disclose

PURPOSE

Medical imaging plays a major role in coronavirus disease-2019 (COVID-19) patient diagnosis and management. However, the radiation dose received from medical procedures by these patients has been poorly investigated. We aimed to estimate the cumulative effective dose (CED) related to medical exposure in COVID-19 patients admitted to the intensive care unit (ICU) in comparison to the usual critically ill patients.

METHODS AND MATERIALS

We designed a descriptive cohort study including 90 successive ICU COVID-19 patients admitted between March and May 2020 and 90 successive non-COVID 19 patients admitted between March and May 2019. In this study, the CED resulting from all radiological examinations was calculated and clinical characteristics predictive of higher exposure risk identified.

RESULTS

The number of radiological examinations was 12.0 (5.0-26.0) [median (interquartile range) in COVID-19 vs. 4.0 (2.0-8.0) in non-COVID-19 patient ($P < 0.001$)]. The CED during a fourmonth period was 4.2 mSv (1.9-11.2) in the COVID-19 vs. 1.2 mSv (0.13-6.19) in the non-COVID-19 patients ($P < 0.001$). In the survivors, the CED in COVID-19 vs. non-COVID-19 patients was =100 mSv in 3% vs. 0%, 10-100 mSv in 23% vs. 15%, 1-10 mSv in 56% vs. 30% and ,1 mSv in 18% vs. 55%. The CED ($P < 0.001$) and CED per ICU hospitalization day ($P = 0.004$) were significantly higher in COVID-19 than non-COVID-19 patients. The CED correlated significantly with the hospitalization duration ($r = 0.45$, $P < 0.001$) and the number of conventional radiological examinations ($r =$

0.8, P < 0.001).

CONCLUSION

s To conclude, more radiological examinations were performed in critically ill COVID-19 patients than non-COVID-19 patients resulting in higher CED. In COVID-19 patients, contribution of strategies to limit CED should be investigated in the future.

CLINICAL RELEVANCE/APPLICATION

This study is relevant for Covid-19 patients cared for in radiology departments and intensive care units.

R5A-SPPH-5 Patient-Specific Analysis of Dose Metrics and Organ Doses Based on Monte Carlo Simulation in Multiphase Abdominal CT Examinations

Participants
Keisuke Fujii, PhD, Nagoya, Japan (*Presenter*) Nothing to Disclose

PURPOSE

The aims of this study are to determine organ doses based on Monte Carlo (MC) simulations for individual patients in multiphase abdominal CT examinations and to evaluate the correlations between the organ doses and dose metrics.

METHODS AND MATERIALS

The voxelized models of 30 adults (15 normal weight patients with body mass index (BMI) of 18.5-25.0 and 15 overweight patients with BMI more than 25.0) undergoing four phase abdominal CT examinations with Aquilion ONE ViSION (n=10) and Aquilion Precision (n=20) (Canon Medical Systems) were created by inputting the CT images into MC simulation software ImpactMC (Advanced Breast CT, GmbH). MC simulations for each voxelized phantom were performed by inputting the detailed descriptions of the CT scanners and scanning parameters into ImpactMC. The scan range for pre-contrast, arterial phase, and delayed phase and for portal phase was set to upper abdomen and chest-abdomen-pelvis, respectively. Next, region of interests (ROIs) of seven radiosensitive organs (thyroid, lung, esophagus, breast, liver, stomach, and bladder) were created by delineating each organ on the CT images. Each ROI was set on the dose distribution images obtained as the simulation results and organ doses for each organ were evaluated as average doses within each organ ROI. For dose metrics, volume CT dose index (CTDIvol) and size-specific dose estimates (SSDE) were collected, and organ-specific SSDE were calculated using the average CTDIvol and water equivalent diameter over each organ position.

RESULTS

Organ doses for liver and stomach within scan range at all phase in abdominal CT examinations were approximately 17-48 mGy at each phase and 70-190 mGy in total. The doses had strong linear relationships with organ-specific SSDE, and the doses for overweight patients in the CT examinations with one of the CT scanners were approximately 60-70% higher than those for normal weight patients. Organ doses in lung and esophagus partially included in scan range at the pre-contrast, arterial and delayed phase were approximately 6-32 mGy at each phase, and the doses accounted for approximately 50-70% of 30-140 mGy in total at the four phases.

CONCLUSION

s Organ doses for organs within or partially included in scan range in multiphase abdominal CT examinations will widely vary depending on the types of CT scanners and patient size. Organ-specific SSDE can be useful for total organ dose estimations for organs within scan range in the CT examinations.

CLINICAL RELEVANCE/APPLICATION

The reduction of organ doses for individual patients in multiphase abdominal CT examinations will require the optimization of scanning parameters including tube current modulation for each CT scanner.

R5A-SPPH-6 Patient-Specific Organ Dose and Cancer Risk Estimation in Adult Computed Tomography: Impact of a 7 Years Dose Optimization Process

Participants
Benoit Dufour, Sion, Switzerland (*Presenter*) Nothing to Disclose

PURPOSE

To estimate the impact of dose optimization on cancer risks from adult computed tomography (CT).

METHODS AND MATERIALS

From 2016 to 2022, after a phase (P0) of protocol harmonization according to clinical indication, three successive phases of dose optimization were implemented at our institution (9 centers). P1 (first dose optimization round); P2 (second dose optimization round with the introduction of new generation CT scanners); P3 (third dose optimization round with the introduction of deep learning reconstruction). To estimate cancer risk for each patient and phase, patient-specific organ doses, age at exposure and sex were needed. Patient-specific organ doses were computed using the organ dosimetry module of a dose monitoring system (DoseWatch, GE Healthcare). Finally, lifetime risk and organ-specific risk of developing cancer were estimated using RadRAT (version 4.2.1). Results from each phase were compared by using the mean risk (Kruskal-Wallis test, significance $p<0.05$). Data were also stratified per anatomical region and clinical indication (chest (emphysema, pulmonary embolism and pneumonia) and abdomen (appendicitis, diverticulitis, kidney stones, liver, pancreas tumor, renal tumor and infection)).

RESULTS

Preliminary results on comparing P3 (4698 examinations) and P1 (678 examinations) showed an overall reduction of 49.5% lifetime risk of developing cancer. Stratifying per anatomical region, the reduction was 53.7%/27.6% for abdomen/thorax respectively. The highest excessive risk reduction was observed for the pancreas tumor (66.7%), diverticulitis (62.7%), and kidney stone (50.4%) protocols. The lowest impact was on the pneumonia and renal infection protocols, with 11.4% and 23.6% respectively. Statistical analyses for P0 and P4 and stratification per organ are ongoing.

CONCLUSION

s Patient-specific lifetime risk of developing cancer from CT imaging have been estimated for adult patients. The continuous process of CT protocol optimization allowed for a significant reduction of cancer risk associated with ionizing radiation.

CLINICAL RELEVANCE/APPLICATION

Excess of radiation-induced cancer cases can be reduced by fostering continuous dose optimization and avoiding scanner obsolescence.

R5A-SPPH-7 Establishment of CT Local Diagnostic Reference Levels at King Faisal Specialist Hospital and Research Centre

Participants
Omar Mohamed Noor, MSc, (*Presenter*) Nothing to Disclose

PURPOSE

To establish local diagnostic reference levels at KFSHRC for computed tomography examinations of adults and identify the need for optimization.

METHODS AND MATERIALS

Data for over 4500 patients who have undergone CT scans in 2021 were analyzed. Four anatomical regions were considered for this study, namely head, head neck, chest, and abdomen-pelvis. In total, there are six CT scanners with multislice capability at KFSHRC. Sectra Dose Track management system was used to extract patient dose information. CT-dose index (CTDIvol, mGy) and dose length product (DLP, mGy.cm) were the selected dose matrices for the study. The 25th, 50th and 75th percentiles of these two quantities were calculated for each scanner. The local DRL values were then determined by calculating the 75th percentile of the distribution of median values. The results were compared with national and international DRL values.

RESULTS

The determined CTDIvol/DLP for the head, head neck, chest, and abdomen-pelvis protocols were 51.93/1054, 17/564, 7/244 and 13/891, respectively.

CONCLUSION

s The established local DRL values have shown appreciable improvement compared to prior estimated values in 2018, up to 30% improvement for some protocols. Also, the established values are relatively lower than the national DRL values by an average of 12% and are comparable to international values.

CLINICAL RELEVANCE/APPLICATION

Diagnostic reference levels are a great quality control tool to ensure optimal diagnostic imaging radiation doses and adherence to international best practices.

R5A-SPPH-8 Fluoroscopic X-Ray Beam Optimization for Improved Radiation Safety in Neurosurgery Imaging

Participants
Xinhua Li, PhD, Boston, MA (*Presenter*) Employee, MorphoSys AG ;Employee, Elevation Oncology

PURPOSE

Fluoroscopic-guided neurosurgery may be associated with prolonged procedure time, intensive use of radiation, and notable adverse radiation effects. This study examines x-ray spectral optimization to achieve dose reduction and improved safety for patients and operators.

METHODS AND MATERIALS

Through this retrospective cohort study, radiation exposure to consecutive patients who underwent neurosurgery in two biplane procedure rooms, each with Artis zee replaced by Artis icono (Siemens Healthineers), was analyzed. Tests with anthropomorphic phantom (ATOM 701-B, CIRS Inc., VA; Weight 73 kg, height 173 cm) on Artis icono were conducted and effective x-ray beam filtration was characterized with x-ray spectral modeling.

RESULTS

No. of procedures was 716 (median age at procedure, 58; range 7-95) on Artis zee (Jan-Nov,2021) and 415 (59; 7-95) on Artis icono (Oct,2021-Apr,2022),with insignificant difference in age (p=0.098, two-tailed t test) between them. Dosage was 881.4 (838.5-924.3) mGy [mean (95% CI)] for air kerma at the reference point, 110.9 (105.1-116.7) Gy·cm2 for air kerma-area product, and 26.0 (24.4-27.5) minutes for fluoroscopic time on Artis zee and it was 402.3 (361.2-443.4) mGy, 54.8 (49.7-59.9) Gy·cm2, and 25.0 (22.9-27.2) minutes on Artis icono. In phantom tests [FL Neuro Sharp, mag1 (40 cm), 7.5 P/S], AP plane used 66-67 kV, Cu filters of 0.9, 0.6 and 0.3 mm and LAT plane used 64-68 kV, Cu filters of 0.6, 0.6 and 0.3 mm for low, normal, and high dose modes. Half value layer (HVL) was 7.19, 6.42 and 5.25 mmAl (effective energy 51,48,43 keV; FWHM 19.5, 22, 24.5 keV) (AP) and 5.86, 6.27, and 5.08 mmAl (effective energy 46,47,42 keV; FWHM 21.5, 23.2, 25.2 keV) (LAT).

CONCLUSION

s Substantial (=50.6%) dose reduction is achieved in neurosurgery imaging by optimizing x-ray beam spectrum.

CLINICAL RELEVANCE/APPLICATION

Optimization of x-ray beam filtration and spectrum can facilitate radiation dose reduction in neurosurgery imaging for improved radiation safety for patients and the staff.

R5A-SPPH-9 Usefulness of Generative Adversarial Network-Based Low-Dose Digital Breast Tomosynthesis for Image Quality Improvement

Participants
Tsutomu Gomi, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the image quality improvement in digital breast tomosynthesis under low-radiation-dose conditions of prereconstruction processing using conditional generative adversarial networks (cGAN [pix2pix]).

METHODS AND MATERIALS

The pix2pix prereconstruction processing (p2p) with filtered back projection (FBP) and simultaneous algebraic reconstruction technique total variation first-iterative shrinkage-thresholding algorithm (SART-TV-FISTA) was compared with and without multiscale bilateral filtering. Noise reduction and preserve contrast rates were compared using full width at half-maximum (FWHM), contrast-to-noise ratio, peak signal-to-noise ratio (PSNR), and structural similarity (SSIM) in the in-focus plane using a BR3D phantom at various radiation doses (reference-dose [automatic exposure control reference dose: AECrd]; average glandular dose [AGD] 1.36 mGy, 50% [AGD; 0.66 mGy] and 75% [AGD; 0.31 mGy] reduced AECrd).

RESULTS

The overall performance of p2p-FBP in FWHM, PSNR, and SSIM was effective for both with and without MSBF prereconstruction processing with FBP and SART-TV-FISTA. At ~75% radiation-dose reduction, p2p-FBP in FWHM yielded good results independent of microcalcification (MC) sizes equivalent to that of the reference images, but without significant difference in statistical results (FBP p2p of 0.196 mm [$p = 0.98$], 0.23 mm [$p = 0.72$], and 0.29 mm [$p = 0.60$]; FBP with MSBF of 0.196 mm [$p = 0.11$], 0.23 mm [$p < 0.05$], and 0.29 mm [$p < 0.05$]; FBP without MSBF of 0.196 mm [$p = 0.74$], 0.23 mm [$p = 1.00$], and 0.29 mm [$p = 0.99$]; SART-TV-FISTA p2p of 0.196 mm [$p = 1.00$], 0.23 mm [$p = 0.80$], and 0.29 mm [$p = 0.55$]; SART-TV-FISTA with MSBF of 0.196 mm [$p = 0.91$], 0.23 mm [$p < 0.05$], and 0.29 mm [$p < 0.05$]; SART-TV-FISTA without MSBF of 0.196 mm [$p = 0.82$], 0.23 mm, [$p = 0.91$], and 0.29 mm, [$p = 0.96$]) in preserving the MC structure and mass contrast. PSNR results showed that p2p-FBP demonstrated the minimum error with reference images at a ~75% reduction in radiation dose. SSIM analysis indicated that p2p-FBP yielded superior similarity at ~75% radiation-dose reduction, with features most similar to the reference images.

CONCLUSION

s This phantom study revealed that a ~75% reduction in radiation dose is feasible using our proposed p2p-FBP.

CLINICAL RELEVANCE/APPLICATION

The p2p-FBP can significantly reduce noise with preserved contrast and radiation-dose reduction in clinical practice.

Comparison of Computed Tomographic Dose Data of Tin Filter With Conventional Scanning Protocols Using Thermoluminescence Dosimeter Measurements

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Simone Schuele, (*Presenter*) Nothing to Disclose

PURPOSE

We aim to investigate whether there are differences in the applied dose (TLD measurements (thermoluminescence dosimeter)) between different scanning protocols in computed tomography for the same CTDIvol (Computed Tomography Dose Index). Special focus is on the tin filter technique (Sn).

METHODS AND MATERIALS

Sixteen TLD measurements (3 measurement repetitions each) were performed in a water phantom (diameter 32 cm) using five different scan protocols (Sn 150 kV, 150 kV, 120 kV, 100 kV, Sn 100 kV) at three (CTDIvol: 29 mGy, 8.5 mGy, and 2.8 mGy) dose settings on a 3-generation dual source CT scanner. With the Sn 100 kV protocol, limited by the scanner, irradiations were only possible up to 6.4 mGy (CTDIvol). The TLDs were positioned centrally in the water phantom. TLD measurement results and the slope of the linear regression of the different protocols were compared. ANOVA or Kruskal-Wallis-test was used for statistical testing, where applicable.

RESULTS

Compared to the 100 kV, 120 kV, and 150 kV protocols, the tin filter protocols (Sn 150 kV, Sn 100 kV) applied higher doses (average dose difference: 16% +/- 4%) at all dose settings studied ($p<0.01$) except for the comparison between the Sn 150 kV and 150 kV protocols at a CTDIvol of 29 mGy ($p=0.072$). The Sn 150 kV protocol showed a steeper slope of the linear regression than the 100 kV and 120 kV protocols ($p<0.05$).

CONCLUSION

s The CTDIvol information from the scanner underestimates the dose of the Sn 150 kV and Sn 100 kV protocols compared to protocols without tin filtration.

CLINICAL RELEVANCE/APPLICATION

Tin filter protocols expose patients to higher radiation doses than standard protocols at the same CTDIvol. This must be taken into account when using the tin filter technique in computed tomography for radiation protection reasons.

Effect of Hormone Therapy on Target Volume in Radio-theraphy of Localized Prostate Cancer

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Ayse Dagli, Istanbul, Turkey (*Presenter*) Nothing to Disclose

PURPOSE

To determine the extent of tumor volume reduction and normal organ doses in prostate cancer (PCa) patients, with large prostate volumes that are geometrically unsuitable, treated with radiotherapy (RT) and combined androgen deprivation therapy (ADT).

METHODS AND MATERIALS

Ten patients with localized PCa included into the study. Median patient age was 71.6. (60-76). Patients underwent neoadjuvant ADT at least three months (3-36 months). Simulation CT images were obtained before the initiation of ADT (Plan 1) and 2 months after ADT (Plan 2). All patients were simulated in supine position with full bladder and empty rectum. RT treatment plans were done on each image set. All plans were done with VMAT using two full arcs. Prescribed dose was 76 Gy with 2 Gy/day in 38 fractions. Tumor volume and normal organ doses were dosimetrically compared. Maximum target doses (Dmax), homogeneity index (HI) and conformity index (CI), bladder, rectum and penile bulb doses were compared between two plans. Statistical analysis was done using paired t test. $P<0.05$ was accepted as statistically significant.

RESULTS

The median prostate volume was 77 cc (range: 51-113 cc) in Plan 1 images and the median prostate volume was 56 cc (range: 35-90 cc) in the Plan 2 images. Median prostate volume reduction with ADT was 17 cc, representing a 23% reduction in the target volume ($p<0.001$). The Dmax ($p=0.77$), HI ($p=0.16$) and CI ($p=0.66$) was not statistically different in two plans. Bladder ($p=0.48$) and rectum ($p=0.07$) volumes were not significantly different between two plans. Bladder volumes receiving 30 Gy (V30),40 Gy (V40), 50 Gy (V50), 56 Gy (V56), 65 Gy (V65), 75 Gy (V75) decreased 14%, 8%,7%, 4%, 4%, 1%, respectively combined ADT. Bladder Dmax was decreased 7% but Dmean did not change. Rectum volumes receiving 30 Gy (V30), 40 Gy (V40), 50 Gy (V50), 56 Gy (V56), 60 Gy (V60), 70 Gy (V70),75 Gy(V75) decreased 21% 26%, 34%, 35%, 34%, 33%, 35%, respectively combined ADT. Rectum Dmean was decreased 19% but Dmax did not change. Doses to 90 ml (D90) penile bulb was decreased 8%; mean and maximum penile bulb doses were decreased 9% and 2%, respectively.

CONCLUSION

s Prostate shrinkage after combined ADT provides significant reduction in normal organ doses in PCa RT. This benefit may result in fewer acute and late radiotherapy complications. Clinical studies are needed to supported this data.

CLINICAL RELEVANCE/APPLICATION

It may be necessary to revise target volume in treatment planning, as it provides significant reduction in prostate volume after combined ADT.

R5A-SPPH-4

Cumulative Radiation Exposure in Covid-19 Patients Admitted to the Intensive Care Unit

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Lama HADID, (*Presenter*) Nothing to Disclose

PURPOSE

Medical imaging plays a major role in coronavirus disease-2019 (COVID-19) patient diagnosis and management. However, the radiation dose received from medical procedures by these patients has been poorly investigated. We aimed to estimate the cumulative effective dose (CED) related to medical exposure in COVID-19 patients admitted to the intensive care unit (ICU) in comparison to the usual critically ill patients.

METHODS AND MATERIALS

We designed a descriptive cohort study including 90 successive ICU COVID-19 patients admitted between March and May 2020 and 90 successive non-COVID 19 patients admitted between March and May 2019. In this study, the CED resulting from all radiological examinations was calculated and clinical characteristics predictive of higher exposure risk identified.

RESULTS

The number of radiological examinations was 12.0 (5.0-26.0) [median (interquartile range) in COVID-19 vs. 4.0 (2.0-8.0) in non-COVID-19 patient ($P < 0.001$)]. The CED during a fourmonth period was 4.2 mSv (1.9-11.2) in the COVID-19 vs. 1.2 mSv (0.13-6.19) in the non-COVID-19 patients ($P < 0.001$). In the survivors, the CED in COVID-19 vs. non-COVID-19 patients was =100 mSv in 3% vs. 0%, 10-100 mSv in 23% vs. 15%, 1-10 mSv in 56% vs. 30% and ,1 mSv in 18% vs. 55%. The CED ($P < 0.001$) and CED per ICU hospitalization day ($P = 0.004$) were significantly higher in COVID-19 than non-COVID-19 patients. The CED correlated significantly with the hospitalization duration ($r = 0.45$, $P < 0.001$) and the number of conventional radiological examinations ($r = 0.8$, $P < 0.001$).

CONCLUSION

s To conclude, more radiological examinations were performed in critically ill COVID-19 patients than non-COVID-19 patients resulting in higher CED. In COVID-19 patients, contribution of strategies to limit CED should be investigated in the future.

CLINICAL RELEVANCE/APPLICATION

This study is relevant for Covid-19 patients cared for in radiology departments and intensive care units.

R5A-SPPH-5

Patient-Specific Analysis of Dose Metrics and Organ Doses Based on Monte Carlo Simulation in Multiphase Abdominal CT Examinations

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Keisuke Fujii, PhD, Nagoya, Japan (*Presenter*) Nothing to Disclose

PURPOSE

The aims of this study are to determine organ doses based on Monte Carlo (MC) simulations for individual patients in multiphase abdominal CT examinations and to evaluate the correlations between the organ doses and dose metrics.

METHODS AND MATERIALS

The voxelized models of 30 adults (15 normal weight patients with body mass index (BMI) of 18.5-25.0 and 15 overweight patients with BMI more than 25.0) undergoing four phase abdominal CT examinations with Aquilion ONE ViSION (n=10) and Aquilion Precision (n=20) (Canon Medical Systems) were created by inputting the CT images into MC simulation software ImpactMC (Advanced Breast CT, GmbH). MC simulations for each voxelized phantom were performed by inputting the detailed descriptions of the CT scanners and scanning parameters into ImpactMC. The scan range for pre-contrast, arterial phase, and delayed phase and for portal phase was set to upper abdomen and chest-abdomen-pelvis, respectively. Next, region of interests (ROIs) of seven radiosensitive organs (thyroid, lung, esophagus, breast, liver, stomach, and bladder) were created by delineating each organ on the CT images. Each ROI was set on the dose distribution images obtained as the simulation results and organ doses for each organ were evaluated as average doses within each organ ROI. For dose metrics, volume CT dose index (CTDIvol) and size-specific dose estimates (SSDE) were collected, and organ-specific SSDE were calculated using the average CTDIvol and water equivalent diameter over each organ position.

RESULTS

Organ doses for liver and stomach within scan range at all phase in abdominal CT examinations were approximately 17-48 mGy at each phase and 70-190 mGy in total. The doses had strong linear relationships with organ-specific SSDE, and the doses for overweight patients in the CT examinations with one of the CT scanners were approximately 60-70% higher than those for normal weight patients. Organ doses in lung and esophagus partially included in scan range at the pre-contrast, arterial and delayed phase were approximately 6-32 mGy at each phase, and the doses accounted for approximately 50-70% of 30-140 mGy in total at the four phases.

CONCLUSION

s Organ doses for organs within or partially included in scan range in multiphase abdominal CT examinations will widely vary depending on the types of CT scanners and patient size. Organ-specific SSDE can be useful for total organ dose estimations for organs within scan range in the CT examinations.

CLINICAL RELEVANCE/APPLICATION

The reduction of organ doses for individual patients in multiphase abdominal CT examinations will require the optimization of scanning parameters including tube current modulation for each CT scanner.

R5A-SPPH-6

Patient-Specific Organ Dose and Cancer Risk Estimation in Adult Computed Tomography: Impact of a 7 Years Dose Optimization Process

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Benoit Dufour, Sion, Switzerland (*Presenter*) Nothing to Disclose

PURPOSE

To estimate the impact of dose optimization on cancer risks from adult computed tomography (CT).

METHODS AND MATERIALS

From 2016 to 2022, after a phase (P0) of protocol harmonization according to clinical indication, three successive phases of dose optimization were implemented at our institution (9 centers). P1 (first dose optimization round); P2 (second dose optimization round with the introduction of new generation CT scanners); P3 (third dose optimization round with the introduction of deep learning reconstruction). To estimate cancer risk for each patient and phase, patient-specific organ doses, age at exposure and sex were needed. Patient-specific organ doses were computed using the organ dosimetry module of a dose monitoring system (DoseWatch, GE Healthcare). Finally, lifetime risk and organ-specific risk of developing cancer were estimated using RadRAT (version 4.2.1). Results from each phase were compared by using the mean risk (Kruskal-Wallis test, significance $p<0.05$). Data were also stratified per anatomical region and clinical indication (chest (emphysema, pulmonary embolism and pneumonia) and abdomen (appendicitis, diverticulitis, kidney stones, liver, pancreas tumor, renal tumor and infection)).

RESULTS

Preliminary results on comparing P3 (4698 examinations) and P1 (678 examinations) showed an overall reduction of 49.5% lifetime risk of developing cancer. Stratifying per anatomical region, the reduction was 53.7%/27.6% for abdomen/thorax respectively. The highest excessive risk reduction was observed for the pancreas tumor (66.7%), diverticulitis (62.7%), and kidney stone (50.4%) protocols. The lowest impact was on the pneumonia and renal infection protocols, with 11.4% and 23.6% respectively. Statistical analyses for P0 and P4 and stratification per organ are ongoing.

CONCLUSION

s Patient-specific lifetime risk of developing cancer from CT imaging have been estimated for adult patients. The continuous process of CT protocol optimization allowed for a significant reduction of cancer risk associated with ionizing radiation.

CLINICAL RELEVANCE/APPLICATION

Excess of radiation-induced cancer cases can be reduced by fostering continuous dose optimization and avoiding scanner obsolescence.

Establishment of CT Local Diagnostic Reference Levels at King Faisal Specialist Hospital and Research Centre

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Omar Mohamed Noor, MSc, (*Presenter*) Nothing to Disclose

PURPOSE

To establish local diagnostic reference levels at KFSHRC for computed tomography examinations of adults and identify the need for optimization.

METHODS AND MATERIALS

Data for over 4500 patients who have undergone CT scans in 2021 were analyzed. Four anatomical regions were considered for this study, namely head, head neck, chest, and abdomen-pelvis. In total, there are six CT scanners with multislice capability at KFSHRC. Sectra Dose Track management system was used to extract patient dose information. CT-dose index (CTDIvol, mGy) and dose length product (DLP, mGy.cm) were the selected dose matrices for the study. The 25th, 50th and 75th percentiles of these two quantities were calculated for each scanner. The local DRL values were then determined by calculating the 75th percentile of the distribution of median values. The results were compared with national and international DRL values.

RESULTS

The determined CTDIvol/DLP for the head, head neck, chest, and abdomen-pelvis protocols were 51.93/1054, 17/564, 7/244 and 13/891, respectively.

CONCLUSION

s The established local DRL values have shown appreciable improvement compared to prior estimated values in 2018, up to 30% improvement for some protocols. Also, the established values are relatively lower than the national DRL values by an average of 12% and are comparable to international values.

CLINICAL RELEVANCE/APPLICATION

Diagnostic reference levels are a great quality control tool to ensure optimal diagnostic imaging radiation doses and adherence to international best practices.

Fluoroscopic X-Ray Beam Optimization for Improved Radiation Safety in Neurosurgery Imaging

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Xinhua Li, PhD, Boston, MA (*Presenter*) Employee, MorphoSys AG ;Employee, Elevation Oncology

PURPOSE

Fluoroscopic-guided neurosurgery may be associated with prolonged procedure time, intensive use of radiation, and notable adverse radiation effects. This study examines x-ray spectral optimization to achieve dose reduction and improved safety for patients and operators.

METHODS AND MATERIALS

Through this retrospective cohort study, radiation exposure to consecutive patients who underwent neurosurgery in two biplane procedure rooms, each with Artis zee replaced by Artis icono (Siemens Healthineers), was analyzed. Tests with anthropomorphic phantom (ATOM 701-B, CIRS Inc., VA; Weight 73 kg, height 173 cm) on Artis icono were conducted and effective x-ray beam filtration was characterized with x-ray spectral modeling.

RESULTS

No. of procedures was 716 (median age at procedure, 58; range 7-95) on Artis zee (Jan-Nov,2021) and 415 (59; 7-95) on Artis icono (Oct,2021-Apr,2022),with insignificant difference in age (p=0.098, two-tailed t test) between them. Dosage was 881.4 (838.5-924.3) mGy [mean (95% CI)] for air kerma at the reference point, 110.9 (105.1-116.7) Gy·cm2 for air kerma-area product, and 26.0 (24.4-27.5) minutes for fluoroscopic time on Artis zee and it was 402.3 (361.2-443.4) mGy, 54.8 (49.7-59.9) Gy·cm2, and 25.0 (22.9-27.2) minutes on Artis icono. In phantom tests [FL Neuro Sharp, mag1 (40 cm), 7.5 P/S], AP plane used 66-67 kV, Cu filters of 0.9, 0.6 and 0.3 mm and LAT plane used 64-68 kV, Cu filters of 0.6, 0.6 and 0.3 mm for low, normal, and high dose modes. Half value layer (HVL) was 7.19, 6.42 and 5.25 mmAl (effective energy 51,48,43 keV; FWHM 19.5, 22, 24.5 keV) (AP) and 5.86, 6.27, and 5.08 mmAl (effective energy 46,47,42 keV; FWHM 21.5, 23.2, 25.2 keV) (LAT).

CONCLUSION

s Substantial (=50.6%) dose reduction is achieved in neurosurgery imaging by optimizing x-ray beam spectrum.

CLINICAL RELEVANCE/APPLICATION

Optimization of x-ray beam filtration and spectrum can facilitate radiation dose reduction in neurosurgery imaging for improved radiation safety for patients and the staff.

R5A-SPPH-9

Usefulness of Generative Adversarial Network-Based Low-Dose Digital Breast Tomosynthesis for Image Quality Improvement

Thursday, Dec. 1 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Tsutomu Gomi, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the image quality improvement in digital breast tomosynthesis under low-radiation-dose conditions of prereconstruction processing using conditional generative adversarial networks (cGAN [pix2pix]).

METHODS AND MATERIALS

The pix2pix prereconstruction processing (p2p) with filtered back projection (FBP) and simultaneous algebraic reconstruction technique total variation first-iterative shrinkage-thresholding algorithm (SART-TV-FISTA) was compared with and without multiscale bilateral filtering. Noise reduction and preserve contrast rates were compared using full width at half-maximum (FWHM), contrast-to-noise ratio, peak signal-to-noise ratio (PSNR), and structural similarity (SSIM) in the in-focus plane using a BR3D phantom at various radiation doses (reference-dose [automatic exposure control reference dose: AECrd]; average glandular dose [AGD] 1.36 mGy, 50% [AGD; 0.66 mGy] and 75% [AGD; 0.31 mGy] reduced AECrd).

RESULTS

The overall performance of p2p-FBP in FWHM, PSNR, and SSIM was effective for both with and without MSBF prereconstruction processing with FBP and SART-TV-FISTA. At ~75% radiation-dose reduction, p2p-FBP in FWHM yielded good results independent of microcalcification (MC) sizes equivalent to that of the reference images, but without significant difference in statistical results (FBP p2p of 0.196 mm [$p = 0.98$], 0.23 mm [$p = 0.72$], and 0.29 mm [$p = 0.60$]; FBP with MSBF of 0.196 mm [$p = 0.11$], 0.23 mm [$p < 0.05$], and 0.29 mm [$p < 0.05$]; FBP without MSBF of 0.196 mm [$p = 0.74$], 0.23 mm [$p = 1.00$], and 0.29 mm [$p = 0.99$]; SART-TV-FISTA p2p of 0.196 mm [$p = 1.00$], 0.23 mm [$p = 0.80$], and 0.29 mm [$p = 0.55$]; SART-TV-FISTA with MSBF of 0.196 mm [$p = 0.91$], 0.23 mm [$p < 0.05$], and 0.29 mm [$p < 0.05$]; SART-TV-FISTA without MSBF of 0.196 mm [$p = 0.82$], 0.23 mm, [$p = 0.91$], and 0.29 mm, [$p = 0.96$]) in preserving the MC structure and mass contrast. PSNR results showed that p2p-FBP demonstrated the minimum error with reference images at a ~75% reduction in radiation dose. SSIM analysis indicated that p2p-FBP yielded superior similarity at ~75% radiation-dose reduction, with features most similar to the reference images.

CONCLUSION

s This phantom study revealed that a ~75% reduction in radiation dose is feasible using our proposed p2p-FBP.

CLINICAL RELEVANCE/APPLICATION

The p2p-FBP can significantly reduce noise with preserved contrast and radiation-dose reduction in clinical practice.

R5A-SPVA-1 Investigation of Metal Artifact Reduction Applications: Comparing Four Different Angiographic Systems

Participants
Mitsuharu Osawa, RT, MA, (*Presenter*) Nothing to Disclose

PURPOSE

Cone-beam CT as an indispensable tool for endovascular treatment has a big pitfall, the degradation of image quality due to the metal artifacts with coils and other highly absorptive materials. The applications for metal artifact reduction (MAR) have been usually installed in any angiography machines. We studied the usefulness of this tools based on the comparison between the angiography systems of four makers about the effect and difference of artifact reduction (reduction effect).

METHODS AND MATERIALS

Angiography systems used for this study are follows: Artis Q (Siemens, Germany), Azurion7 (Philips, Netherlands), Alphenix (Canon, Japan), and Innova IGS 630 (GE, the United States America). A cylindrical water phantom was used to evaluate artifacts with six patterns of various CT values of iodine contrast agents for CT (2300, 3300, 4500, 5000, 6000, and 8300) and a metal clip as high absorbing artifact sources. The CBCT protocol for the head was used for imaging of each device. The acquired images were subjected to MAR processing, and the artifacts were compared quantitatively and isotropically between the images with and without MAR by extreme value statistical analysis using the Gumbel evaluation method (Imai's index).

RESULTS

Azurion7 showed a reduction effect in the image with a CT value of more than 3300, while the other three showed it from the value of more than 6000. Although the threshold in recognizing metals was clear in MARs of Alphenix and Artis Q, Azurion7 had lower threshold than those of the others. Innova IGS 630 has a special function, automatic detection and MAR process for coils and clips using AI technology. It enabled to recognize clips regardless of the size of the CT value and to realize the useful reduction processing.

CONCLUSION

s We found that the difference of MAR reduction effect between angiographic systems of 4 makers depending on the CT value including clips. It is necessary to understand the difference of the effect of MAR by each machine on the evaluation of images of embolized patients, particularly the ones undergoing the embolization with medium density materials of approximately 3000 to 5000, such as NBCA and Onyx. Also we must know that some machines have less effects of MAR around the clips.

CLINICAL RELEVANCE/APPLICATION

Metal artifact reduction system for highly absorbent materials with high density, such as coils is applied in any angiographic systems. However, some machines have weak points to realize the effect of MAR, so the adequate machines should be used to get the higher quality image by each case with embolization.

R5B-SPBR-2 Improved Breast 2D-SWE Algorithm to Eliminate False Negative Cases

Participants
Richard G. Barr, MD, PhD, Canfield, OH (*Presenter*) Consultant, Siemens AG;Speakers Bureau, Siemens AG;Research Grant, Siemens AG;Consultant, Koninklijke Philips NV;Speakers Bureau, Koninklijke Philips NV;Consultant, Canon Medical Systems Corporation;Advisor, Hologic, Inc;Research Grant, Hologic, Inc

PURPOSE

To evaluate a new breast 2D-SWE algorithm and compare to the existing algorithm.

METHODS AND MATERIALS

This prospective, single-center study was approved by our local IRB and HIPAA compliant. From 4/25/19 to 1/18/22 raw shear wave data was saved to a hard drive on patients having an examination on a research Siemens Sequoia ultrasound unit. After removing benign lesions <2-year follow-up (80), cysts (44), scars (10), not breast lesion (16), and artifacts (9), there were 210 patients with 268 lesions for analysis with biopsy proven pathology or >2-year follow-up. Raw data from these lesions were proceeded using the standard algorithm (SA) and a new algorithm (NA). 3mm ROIs were placed in the highest stiffness in the lesion or adjacent 3mm on the SA. Stiffness values (SWS, Max) in this location from both algorithms were recorded. The 3mm ROI was then placed in the highest SWS area on the NA. Statistics were calculated for each ROI location.

RESULTS

The mean patient age was 55.8±9.9 years (range 20-91). The mean lesion size was 12.6±12.0mm (range 4-43mm). There were 129 benign (>2-year follow-up) and 139 biopsied lesions (38 benign; 101 malignant). Max stiffness for benign lesions were (2.07±1.20, 3.07±1.74, 3.03±1.86) m/s and for malignant lesions (4.74±1.79, 8.10±1.65, 8.35±1.38) m/s for the SA, NA with the SA ROI, and NA respectively. The AUROC was 0.90 SA and 0.97 NA (both ROI placements). Using a cut-off value of 4.5m/s the sensitivity increased from 0.54 to 1.0 and the specificity changed from 0.95 to 0.82. For the NA the PPV was 0.77 and the NPV was 1.0 and a NLR or 0.00. Using the SA in cancers there were 30 (30.4%) color filled, 36 (35.3%) with high SWV ring, and 35 (34.3%) with no elevated SWS. With the NA there were 95 (93.1%) color filled, 7 (6.9%) with high SWV ring and 0% with no SWS elevation.

CONCLUSION

s Using a new breast SWE algorithm significantly improve the sensitivity of the technique with a small decrease in specificity, virtually eliminating the "soft" cancer issue.

CLINICAL RELEVANCE/APPLICATION

Breast SWE has been limited due to artifactual false negative cases; a new algorithm significantly decreases these false negative cases increasing sensitivity to 99%.

R5B-SPBR-3 Positive Predictive Value of Axillary Lymph Node Cortical Thickness and Nodal, Clinical and Tumor Characteristics in Newly Diagnosed Breast Cancer Patients

Participants
Anne-Sophie Loonis, MD, MSc, Boston, MA (*Presenter*) Nothing to Disclose

PURPOSE

To determine the positive predictive value (PPV) of cortical thickness of abnormal axillary lymph nodes (LNs) in newly diagnosed breast cancer patients and identify nodal, clinical and tumor characteristics associated with likelihood of axillary metastasis.

METHODS AND MATERIALS

IRB-approved, retrospective review of all axillary LN fine needle aspirations (FNAs) performed 1/1/2018-12/31/2019 was completed. Patients with contralateral breast cancer, no subsequent axillary surgery, male sex, or lymphoma were excluded. There were 135 ipsilateral axillary FNAs in 134 patients with newly diagnosed breast cancer. Patient demographics, clinical characteristics, histopathology results, and imaging features were obtained from medical records. Hypothesis testing was performed using independent samples t-tests and multivariable binary logistic regression to identify statistically significant predictors of axillary LN metastasis.

RESULTS

Of 135 axillary LN FNAs, cytology was positive in 72 (53.3%), negative in 61 (45.2%), and nondiagnostic in 2 (1.5%). At axillary surgery, histopathology was positive in 84 (62.2%) and negative in 51 (37.8%). Lymph node cortices were thicker in metastatic compared to negative nodes (p<0.0001). PPV of axillary LNs with cortical thickness greater than 3mm, 3.5 mm, 4 mm and 4.25 mm was 0.62 (95% CI 0.53, 0.70), 0.63 (0.54, 0.72), 0.67 (0.57, 0.76) and 0.74 (0.64, 0.83), respectively. At multivariable analysis, abnormal hilum was statistically significantly associated with nodal metastasis (OR=3.44, p=0.016) while focal/eccentric cortical thickening was inversely associated with metastasis (OR=0.35, p=0.038). Other nodal, clinical, and tumor characteristics were not associated with increased likelihood of axillary LN metastasis.

CONCLUSION

s Increasing axillary LN cortical thickness is associated with likelihood of nodal metastasis in newly diagnosed cancer patients. PPV of axillary LN cortical thickness >3 mm and >3.5 mm is similar, but PPV is statistically significantly higher for cortical thickness >4 mm and >4.25 mm. Higher likelihood of metastasis is associated with axillary LNs with abnormal fatty hilum and diffuse cortical thickening.

CLINICAL RELEVANCE/APPLICATION

FNA of axillary LNs with cortical thickness >4 mm should be performed. FNA of axillary lymph nodes with cortical thickness <4 mm may be unnecessary for some patients undergoing sentinel LN biopsy.

R5B-SPBR-4 Comparison of Digital Breast Tomosynthesis-Guided Biopsy versus Ultrasound-Guided Biopsy of Non-Calcified Breast Lesions

Participants
Masoud Baikpour, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Historically, mammographic-guided core needle biopsy is performed almost exclusively for calcifications. Increasingly centers are shifting to mammographic-guided biopsy for non-calcified breast lesions given improved efficiency and comfort with new approaches of digital breast tomosynthesis-guided biopsy (DBT-bx). This study aims to compare the characteristics and cancer rates of non-calcified breast lesions that underwent DBT-bx vs. ultrasound-guided biopsy (US-bx).

METHODS AND MATERIALS

This retrospective study included consecutive patients who underwent DBT-bx and US-bx of non-calcified breast lesions between 4/1/2016 and 3/31/2018. Lesions without mammographic findings were excluded. Medical records were reviewed for patient demographics, mammographic breast density, imaging findings, and final pathology results. Mann-Whitney U test and Pearson's Chi-squared test were used to compare the DBT-bx and US-bx groups.

RESULTS

The study cohort consisted of 1211 patients with 1279 biopsies (226 DBT-bx in 217 patients [58.6±12.2 years, range 23-88] and 1053 US-bx in 994 patients [56.7±14.6 years, range 25-96]). DBT-bx was performed in more women with non-dense breasts (65%) compared to US-bx (48%, p<.001). Distributions of non-calcified mammographic findings sampled in the DBT-bx and US-bx groups differed significantly (p<.001), with DBT-bx more commonly performed for asymmetry (44.7% vs. 30.8%) and architectural distortion (33.2% vs. 1.3%) compared to US-bx. The positive predictive value (PPV3) of DBT-bx (32.7%, 74/226) was lower than that of US-bx (44.7%, 471/1053, p=.001). Specifically, PPV3 was significantly lower for asymmetry (26.7% vs. 50.9%; p<.001) and architectural distortion (30.7% vs. 71.4%; p=.004) in the DBT-bx group vs. the US-bx group. Among malignant outcomes, DBT-bx yielded higher proportions of invasive lobular carcinoma (24.3% vs. 14.2%, p=.026) and ductal carcinoma in situ (17.6% vs. 4.1%, p<.001) than US-bx.

CONCLUSION

s While the malignancy rates of asymmetry and distortion sampled via DBT-bx were significantly lower than those sampled under US, the PPVs remain high and warrant biopsy.

CLINICAL RELEVANCE/APPLICATION

Ultrasound (US) evaluation and biopsy of breast asymmetry and architectural distortion remain vital even with improved mammographic-guided biopsy, which should be performed for suspicious non-calcified lesions without definitive US correlates.

R5B-SPBR-5 AI-Radiologist Disagreement on Ultrasound Examinations: Predictors of Malignancy

Participants
Sarah Ricklan, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To examine an artificial intelligence system's (AIS) ability to diagnose breast cancer on ultrasound (US) in a dataset of discordant predictions between the AIS and radiologists. Our AIS shows high accuracy in diagnosing breast cancer on US. We evaluated exams in which the AIS and an expert radiologist consensus disagreed on the probability of malignancy (POM).

METHODS AND MATERIALS

This is an IRB approved retrospective study of an AIS using 288,767 US exams (AUC 0.976). We selected reader cases in which a consensus of ten board-certified radiologists and the AIS provided contradictory POM predictions. The full reader set was 663 exams (644 patients, 1,048 areas of interest (cases)). Of these, 10.8% (113/1048) (109 exams, 108 patients, 113 cases, mean age 54.1 ± 14.1 yrs) had discordant benign-malignant determinations between the AIS and the radiologists; AIS was correct in 47.8% (54/113) of cases. 4.4% (5/113) of cases had a biopsy-determined malignancy. We compared demographic and US features including age, mean POM, mammographic breast density, and mass features between AI correct and AI incorrect discordant cases using t-, Mann-Whitney, and chi-square tests. Ground truth was tissue diagnosis or imaging stability.

RESULTS

The AIS correctly designated 54/113 (47.8%) discordant cases as benign or malignant. 94.5% (52/55) of cases called by the AIS

as benign but the radiologist as malignant were true negatives; 5.5% (3/55) of AI-benign cases were false negatives. Of 113 cases, 78.8% (89/113) had lesions described as masses; 21.2% (24/113) had no or non-mass lesions (e.g. cysts, scars). The AIS was correct in 49/89 (55.1%) of masses. The AIS was more likely to be correct than the radiologist in cases with dense breasts (p=0.001) and irregular (p<0.001) and non-circumscribed (p=<0.0001) masses. Age, orientation, and posterior features were non-significant.

CONCLUSION

s Compared to breast radiologists, the AIS may be more accurate in dense breasts. The AIS is more likely to correctly identify masses with concerning features (non-circumscribed margins) as benign or malignant. Further research should incorporate these strengths and weaknesses into a hybrid AI/radiologist workflow.

CLINICAL RELEVANCE/APPLICATION

Hybrid AI-radiologist US systems may be more accurate in identifying findings in dense breasts and in downgrading benign lesions that radiologists initially find concerning.

R5B-SPBR-7 Diagnostic Performance of Supplemental Breast US Screening to Digital Breast Tomosynthesis and to Digital Mammography in Women with Dense Breasts: A Matched Cohort Study

Participants
Jung Min Chang, MD, Seoul, (*Presenter*) Research Consultant, Genoray Co, Ltd

PURPOSE

Comparative screening performance of supplemental breast US after digital breast tomosynthesis (DBT) versus digital mammography (DM) in women with dense breasts is not well-known. This study was to evaluate and compare the performance of supplemental US screening following DBT and DM in women with dense breasts.

METHODS AND MATERIALS

A retrospective database search identified consecutive asymptomatic women with dense breasts who underwent breast cancer screening with DBT or DM and whole-breast US simultaneously between June 2016 and July 2019. Combined DBT with US (DBT+US) and DM with US (DM+US) were matched 1:2 according to mammographic density, age, menopausal status, hormone replacement therapy, and family history of breast cancer. Cancer detection rate (CDR) per 1000 screening examination, sensitivity, specificity, and abnormal interpretation rate were compared.

RESULTS

A total of 863 women in DBT+US group were matched with 1726 women in DM+ US group (mean age 53 years). 26 breast cancers (DBT+US group, 4 ductal carcinoma in situ [DCIS] and 5 invasive ductal carcinoma [IDC]; DM+US group, 7 DCIS and 10 IDC) were identified. The CDRs were not significantly different in DBT+US and DM+US groups (10.4 vs. 9.8; P =.89 [overall], 4.0 vs. 3.3 per 1000 examinations; P =.80 [negative DBT or DM]), with higher abnormal interpretation in DBT+US than DM+US group (32% vs. 22%; P <.001 [overall], 24% vs. 16%; P < .001 [negative DBT or DM]). Sensitivities in both DBT+US and DM+US groups were 100% without interval cancers. Supplemental US contributed more cancer detection after negative DBT (1 DCIS and 2 IDC) or DM (1 DCIS and 4 IDC), especially invasive cancers, however, there was no statistical significant difference in terms of pathological results between both DBT+US and DM+US groups.

CONCLUSION

s Supplemental US examination after negative DBT or DM yielded additional cancer detection in asymptomatic women with dense breasts, however, no significant improvement in diagnostic performances was noted in DBT+US than DM+US screening.

CLINICAL RELEVANCE/APPLICATION

In asymptomatic women with dense breasts planned to be screened with the whole-breast US, baseline screening with DBT has no benefit over DM in regard to diagnostic performance.

R5B-SPBR-2

Improved Breast 2D-SWE Algorithm to Eliminate False Negative Cases

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - BR DPS

Participants
Richard G. Barr, MD, PhD, Canfield, OH (*Presenter*) Consultant, Siemens AG;Speakers Bureau, Siemens AG;Research Grant, Siemens AG;Consultant, Koninklijke Philips NV;Speakers Bureau, Koninklijke Philips NV;Consultant, Canon Medical Systems Corporation;Advisor, Hologic, Inc;Research Grant, Hologic, Inc

PURPOSE

To evaluate a new breast 2D-SWE algorithm and compare to the existing algorithm.

METHODS AND MATERIALS

This prospective, single-center study was approved by our local IRB and HIPAA compliant. From 4/25/19 to 1/18/22 raw shear wave data was saved to a hard drive on patients having an examination on a research Siemens Sequoia ultrasound unit. After removing benign lesions <2-year follow-up (80), cysts (44), scars (10), not breast lesion (16), and artifacts (9), there were 210 patients with 268 lesions for analysis with biopsy proven pathology or >2-year follow-up. Raw data from these lesions were proceeded using the standard algorithm (SA) and a new algorithm (NA). 3mm ROIs were placed in the highest stiffness in the lesion or adjacent 3mm on the SA. Stiffness values (SWS, Max) in this location from both algorithms were recorded. The 3mm ROI was then placed in the highest SWS area on the NA. Statistics were calculated for each ROI location.

RESULTS

The mean patient age was 55.8±9.9 years (range 20-91). The mean lesion size was 12.6±12.0mm (range 4-43mm). There were 129 benign (>2-year follow-up) and 139 biopsied lesions (38 benign; 101 malignant). Max stiffness for benign lesions were (2.07±1.20, 3.07±1.74, 3.03±1.86) m/s and for malignant lesions (4.74±1.79, 8.10±1.65, 8.35±1.38) m/s for the SA, NA with the SA ROI, and NA respectively. The AUROC was 0.90 SA and 0.97 NA (both ROI placements). Using a cut-off value of 4.5m/s the sensitivity increased from 0.54 to 1.0 and the specificity changed from 0.95 to 0.82. For the NA the PPV was 0.77 and the NPV was 1.0 and a NLR or 0.00. Using the SA in cancers there were 30 (30.4%) color filled, 36 (35.3%) with high SWV ring, and 35 (34.3%) with no elevated SWS. With the NA there were 95 (93.1%) color filled, 7 (6.9%) with high SWV ring and 0% with no SWS elevation.

CONCLUSION

s Using a new breast SWE algorithm significantly improve the sensitivity of the technique with a small decrease in specificity, virtually eliminating the "soft" cancer issue.

CLINICAL RELEVANCE/APPLICATION

Breast SWE has been limited due to artifactual false negative cases; a new algorithm significantly decreases these false negative cases increasing sensitivity to 99%.

R5B-SPBR-3

Positive Predictive Value of Axillary Lymph Node Cortical Thickness and Nodal, Clinical and Tumor Characteristics in Newly Diagnosed Breast Cancer Patients

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - BR DPS

Participants
Anne-Sophie Loonis, MD, MSc, Boston, MA (*Presenter*) Nothing to Disclose

PURPOSE

To determine the positive predictive value (PPV) of cortical thickness of abnormal axillary lymph nodes (LNs) in newly diagnosed breast cancer patients and identify nodal, clinical and tumor characteristics associated with likelihood of axillary metastasis.

METHODS AND MATERIALS

IRB-approved, retrospective review of all axillary LN fine needle aspirations (FNAs) performed 1/1/2018-12/31/2019 was completed. Patients with contralateral breast cancer, no subsequent axillary surgery, male sex, or lymphoma were excluded. There were 135 ipsilateral axillary FNAs in 134 patients with newly diagnosed breast cancer. Patient demographics, clinical characteristics, histopathology results, and imaging features were obtained from medical records. Hypothesis testing was performed using independent samples t-tests and multivariable binary logistic regression to identify statistically significant predictors of axillary LN metastasis.

RESULTS

Of 135 axillary LN FNAs, cytology was positive in 72 (53.3%), negative in 61 (45.2%), and nondiagnostic in 2 (1.5%). At axillary surgery, histopathology was positive in 84 (62.2%) and negative in 51 (37.8%). Lymph node cortices were thicker in metastatic compared to negative nodes ($p<0.0001$). PPV of axillary LNs with cortical thickness greater than 3mm, 3.5 mm, 4 mm and 4.25 mm was 0.62 (95% CI 0.53, 0.70), 0.63 (0.54, 0.72), 0.67 (0.57, 0.76) and 0.74 (0.64, 0.83), respectively. At multivariable analysis, abnormal hilum was statistically significantly associated with nodal metastasis (OR=3.44, $p=0.016$) while focal/eccentric cortical thickening was inversely associated with metastasis (OR=0.35, $p=0.038$). Other nodal, clinical, and tumor characteristics were not associated with increased likelihood of axillary LN metastasis.

CONCLUSION

s Increasing axillary LN cortical thickness is associated with likelihood of nodal metastasis in newly diagnosed cancer patients. PPV of axillary LN cortical thickness >3 mm and >3.5 mm is similar, but PPV is statistically significantly higher for cortical thickness >4 mm and >4.25 mm. Higher likelihood of metastasis is associated with axillary LNs with abnormal fatty hilum and diffuse cortical thickening.

CLINICAL RELEVANCE/APPLICATION

FNA of axillary LNs with cortical thickness >4 mm should be performed. FNA of axillary lymph nodes with cortical thickness <4 mm may be unnecessary for some patients undergoing sentinel LN biopsy.

R5B-SPBR-4

Comparison of Digital Breast Tomosynthesis-Guided Biopsy versus Ultrasound-Guided Biopsy of Non-Calcified Breast Lesions

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - BR DPS

Participants
Masoud Baikpour, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Historically, mammographic-guided core needle biopsy is performed almost exclusively for calcifications. Increasingly centers are shifting to mammographic-guided biopsy for non-calcified breast lesions given improved efficiency and comfort with new approaches of digital breast tomosynthesis-guided biopsy (DBT-bx). This study aims to compare the characteristics and cancer rates of non-calcified breast lesions that underwent DBT-bx vs. ultrasound-guided biopsy (US-bx).

METHODS AND MATERIALS

This retrospective study included consecutive patients who underwent DBT-bx and US-bx of non-calcified breast lesions between 4/1/2016 and 3/31/2018. Lesions without mammographic findings were excluded. Medical records were reviewed for patient demographics, mammographic breast density, imaging findings, and final pathology results. Mann-Whitney U test and Pearson's Chi-squared test were used to compare the DBT-bx and US-bx groups.

RESULTS

The study cohort consisted of 1211 patients with 1279 biopsies (226 DBT-bx in 217 patients [58.6±12.2 years, range 23-88] and 1053 US-bx in 994 patients [56.7±14.6 years, range 25-96]). DBT-bx was performed in more women with non-dense breasts (65%) compared to US-bx (48%, p<.001). Distributions of non-calcified mammographic findings sampled in the DBT-bx and US-bx groups differed significantly (p<.001), with DBT-bx more commonly performed for asymmetry (44.7% vs. 30.8%) and architectural distortion (33.2% vs. 1.3%) compared to US-bx. The positive predictive value (PPV3) of DBT-bx (32.7%, 74/226) was lower than that of US-bx (44.7%, 471/1053, p=.001). Specifically, PPV3 was significantly lower for asymmetry (26.7% vs. 50.9%; p<.001) and architectural distortion (30.7% vs. 71.4%; p=.004) in the DBT-bx group vs. the US-bx group. Among malignant outcomes, DBT-bx yielded higher proportions of invasive lobular carcinoma (24.3% vs. 14.2%, p=.026) and ductal carcinoma in situ (17.6% vs. 4.1%, p<.001) than US-bx.

CONCLUSION

s While the malignancy rates of asymmetry and distortion sampled via DBT-bx were significantly lower than those sampled under US, the PPVs remain high and warrant biopsy.

CLINICAL RELEVANCE/APPLICATION

Ultrasound (US) evaluation and biopsy of breast asymmetry and architectural distortion remain vital even with improved mammographic-guided biopsy, which should be performed for suspicious non-calcified lesions without definitive US correlates.

Diagnostic Performance of Supplemental Breast US Screening to Digital Breast Tomosynthesis and to Digital Mammography in Women with Dense Breasts: A Matched Cohort Study

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - BR DPS

Participants
Jung Min Chang, MD, Seoul, (*Presenter*) Research Consultant, Genoray Co, Ltd

PURPOSE

Comparative screening performance of supplemental breast US after digital breast tomosynthesis (DBT) versus digital mammography (DM) in women with dense breasts is not well-known. This study was to evaluate and compare the performance of supplemental US screening following DBT and DM in women with dense breasts.

METHODS AND MATERIALS

A retrospective database search identified consecutive asymptomatic women with dense breasts who underwent breast cancer screening with DBT or DM and whole-breast US simultaneously between June 2016 and July 2019. Combined DBT with US (DBT+US) and DM with US (DM+US) were matched 1:2 according to mammographic density, age, menopausal status, hormone replacement therapy, and family history of breast cancer. Cancer detection rate (CDR) per 1000 screening examination, sensitivity, specificity, and abnormal interpretation rate were compared.

RESULTS

A total of 863 women in DBT+US group were matched with 1726 women in DM+ US group (mean age 53 years). 26 breast cancers (DBT+US group, 4 ductal carcinoma in situ [DCIS] and 5 invasive ductal carcinoma [IDC]; DM+US group, 7 DCIS and 10 IDC) were identified. The CDRs were not significantly different in DBT+US and DM+US groups (10.4 vs. 9.8; P =.89 [overall], 4.0 vs. 3.3 per 1000 examinations; P =.80 [negative DBT or DM]), with higher abnormal interpretation in DBT+US than DM+US group (32% vs. 22%; P <.001 [overall], 24% vs. 16%; P < .001 [negative DBT or DM]). Sensitivities in both DBT+US and DM+US groups were 100% without interval cancers. Supplemental US contributed more cancer detection after negative DBT (1 DCIS and 2 IDC) or DM (1 DCIS and 4 IDC), especially invasive cancers, however, there was no statistical significant difference in terms of pathological results between both DBT+US and DM+US groups.

CONCLUSION

s Supplemental US examination after negative DBT or DM yielded additional cancer detection in asymptomatic women with dense breasts, however, no significant improvement in diagnostic performances was noted in DBT+US than DM+US screening.

CLINICAL RELEVANCE/APPLICATION

In asymptomatic women with dense breasts planned to be screened with the whole-breast US, baseline screening with DBT has no benefit over DM in regard to diagnostic performance.

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - CA DPS

Sub-Events

R5B-SPCA-1 Hemodynamic Signatures of Aortic Root and Ascending Aorta Aneurysm by 4D Flow MRI

Participants
Joe Juffermans, MSc, Leiden, Netherlands (*Presenter*) Nothing to Disclose

PURPOSE

Thoracic aortic aneurysms (TAA) are found in the aortic root and ascending aorta in patients with tricuspid aortic valves (TAV). Since aorta hemodynamic changes have been associated with aneurysm formation, the aim of this study was to determine hemodynamic signatures of aortic root and ascending aorta aneurysms in TAV patients.

METHODS AND MATERIALS

Eighty TAV patients underwent aortic 4D flow MRI. Left ventricular stroke volume, normalized flow displacement, flow jet angle, wall shear stress (WSS) magnitude, axial WSS, circumferential WSS, WSS angle, vorticity magnitude, absolute helicity and aortic diameter were assessed at peak systole in the aortic root and ascending aorta. Root and ascending z-scores were calculated and used to categorize the aneurysm type according to the Della Corte's classification (i.e., root, ascending or no aneurysm). To assess hemodynamic differences between the aneurysm cohorts, Kruskal-Wallis test was performed with subsequent Mann-Whitney U-tests for post-hoc analysis. Hemodynamics signatures were illustrated by radial plots.

RESULTS

After classification, three aneurysm cohorts were identified: aortic root aneurysm (n=40), ascending aorta aneurysm (n=19), and no aorta aneurysm (n=21) (48±11years, 54±11years, and 49±10years, respectively; p=0.25). Root aneurysm patients presented a significantly higher stroke volume compared to patients with ascending or no aneurysm (both $p<0.05$). Ascending aneurysm patients presented a significantly higher normalized flow displacement, flow jet angle and WSS angle together with lower WSS magnitude and axial WSS compared to patients with root or no aneurysms (all $p<0.01$; see Figure 1). Patients with no aneurysm demonstrated a significantly higher vorticity magnitude and absolute helicity at the ascending aorta compared to patients with root or ascending aneurysm (all p=0.01).

CONCLUSION

s Patients with root or ascending aneurysm demonstrated two distinct hemodynamic signatures, as compared to patients without an aneurysm. Root aneurysm patients have a significantly higher left ventricular stroke volume and ascending aneurysm patients have a significantly higher normalized flow displacement, flow jet angle and WSS angle.

CLINICAL RELEVANCE/APPLICATION

Aortic 4D flow MRI revealed two distinct hemodynamic signatures in patients with aortic root or ascending aorta aneurysm, as compared to patients without aneurysm.

R5B-SPCA-2 Impact on Clinical Outcome of High-pitch non-ECG-gated CT Angiography for Transcatheter Aortic Valve Implantation Planning as Compared to An ECG-gated CTA Protocol

Participants
Martin Sinn, Hamburg, Germany (*Presenter*) Nothing to Disclose

PURPOSE

The question of whether to use ECG-guided or non-ECG-guided high-grid CT angiography (CTA) in planning transcatheter aortic valve implantation (TAVI) has been controversial, with ECG-guided CTA currently recommended. However, the impact on clinical outcome, including post-interventional paravalvular leakage (PVL), remains unclear. Therefore, the aim of this study was to compare a retrospective ECG-guided CTA protocol with a non-ECG-guided high-pitch CTA protocol for TAVI planning and the associated impact on clinical outcome.

METHODS AND MATERIALS

This retrospective, institutional review board-approved study included 231 subjects (age 80±7 years) who underwent implantation of an Evolut R (Medtronic, Minneapolis, USA) self-expandable transcatheter heart valve. Thereof, 48 subjects received retrospective ECG-guided CTA (group A) prior intervention, and 183 subjects received non-ECG-guided high-pitch CTA (group B). The amount of aortic valve calcification (Agatston score), aortic annulus diameter, and circumferential area were measured using commercially available software tools. Visual motion scoring of the aortic root and valve was performed by two radiologists. For each patient, the cover index was calculated 100 × ([prosthesis diameter - annulus diameter] / prosthesis diameter). Clinical outcome parameters were assessed 30 days after TAVI following the Valve Academic Research Consortium-3 consensus document.Paired and unpaired two-sided t-test and Chi-squared test were utilized to compare continuous and categorical

variables, respectively.

RESULTS

There were no significant differences in motion artefacts of the aortic root or aortic valve calcification between both groups (p>.05). A significant difference in cover index was observed, with a higher cover index for group A (group A: 6.6±8.6 vs. group B: -1.3±10.4; p=.001). However, this difference did not lead to significantly different rates of PVL post TAVI (p=.399). Further, there were no significant differences in major adverse cardiac events (MACE) between both groups (p=.49).

CONCLUSION

s Although the cover index for TAVR planning of a high-pitch non-ECG-gated CTA was lower compared to an ECG-gated CTA protocol, rates of PVL and MACE were comparable between groups.

CLINICAL RELEVANCE/APPLICATION

A high-pitch non-ECG-gated CTA protocol may be suitable for TAVI planning.

R5B-SPCA-3 Ex-vivo Swine Model Reveals Characteristic Aortic Flow Alterations After Different Aortic Valve Replacement Strategies

Participants
Maren Balks, (*Presenter*) Nothing to Disclose

PURPOSE

Aortic hemodynamics can be altered by aortic valve replacement (AVR) with studies suggesting differences in flow alterations after different types of replacement. Ozaki aortic valve neocuspidization is a new, promising procedure for reconstructing the aortic valve using the patient's own pericardium. In order to perform any open AVR, an incision in the ascending aorta (aortotomy) is obligatory to gain access to the valve. Little is known about impact of the surgical incision itself on aortic flow. The purpose of this work was to establish a biological model to comprehensively evaluate the impact of the surgical pathway alone and in combination with different valve replacement strategies on aortic hemodynamics.

METHODS AND MATERIALS

Six fresh swine aortas were anastomosed to an in-house developed piston pump pumping blood-mimicking fluid at 3l/min and 60bpm. 4D Flow MRI was acquired at 3Tesla (Achieva, Philips, The Netherlands). Each aorta was imaged with the native valve, after aortotomy, and after valve replacement with either a mechanical valve (MecValve, n=2; Standard Masters, St. Jude Medical, USA), a biological valve (BioValve n=2; Perimount Magna Ease, Edwards Lifesciences, USA) or Ozaki procedure (Ozaki, n=2). Peak velocity was quantified using GTFlow (GyroTools, Switzerland). Secondary flow patterns such as vortices and helices were visualized. They were graded according to their diameter relative to the vessel diameter as small, medium, or large.

RESULTS

Physiological flow without secondary flow patterns was detected in all native aortas. After aortotomy one secondary flow pattern developed in the ascending aorta in every specimen. AVR induced more pronounced changes in aortic hemodynamics: The mechanical valve induced the least secondary flow patterns (n=1) followed by the Ozaki procedure (n=2). Biological valve replacement induced the most secondary flow patterns (n=3) and an increase in peak velocity.

CONCLUSION

s The surgical pathway alone alters aortic hemodynamics. The new Ozaki procedure induced more secondary flow patterns than mechanical valves but fewer than biological valves. This makes it a promising alternative to biological valves that profoundly alter aortic hemodynamics.

CLINICAL RELEVANCE/APPLICATION

Flow changes after various aortic valve replacement procedures should be monitored in patients because altered hemodynamics may affect valve function and aortic wall integrity.

R5B-SPCA-1

Hemodynamic Signatures of Aortic Root and Ascending Aorta Aneurysm by 4D Flow MRI

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - CA DPS

Participants
Joe Juffermans, MSc, Leiden, Netherlands (*Presenter*) Nothing to Disclose

PURPOSE

Thoracic aortic aneurysms (TAA) are found in the aortic root and ascending aorta in patients with tricuspid aortic valves (TAV). Since aorta hemodynamic changes have been associated with aneurysm formation, the aim of this study was to determine hemodynamic signatures of aortic root and ascending aorta aneurysms in TAV patients.

METHODS AND MATERIALS

Eighty TAV patients underwent aortic 4D flow MRI. Left ventricular stroke volume, normalized flow displacement, flow jet angle, wall shear stress (WSS) magnitude, axial WSS, circumferential WSS, WSS angle, vorticity magnitude, absolute helicity and aortic diameter were assessed at peak systole in the aortic root and ascending aorta. Root and ascending z-scores were calculated and used to categorize the aneurysm type according to the Della Corte's classification (i.e., root, ascending or no aneurysm). To assess hemodynamic differences between the aneurysm cohorts, Kruskal-Wallis test was performed with subsequent Mann-Whitney U-tests for post-hoc analysis. Hemodynamics signatures were illustrated by radial plots.

RESULTS

After classification, three aneurysm cohorts were identified: aortic root aneurysm (n=40), ascending aorta aneurysm (n=19), and no aorta aneurysm (n=21) (48±11years, 54±11years, and 49±10years, respectively; p=0.25). Root aneurysm patients presented a significantly higher stroke volume compared to patients with ascending or no aneurysm (both $p<0.05$). Ascending aneurysm patients presented a significantly higher normalized flow displacement, flow jet angle and WSS angle together with lower WSS magnitude and axial WSS compared to patients with root or no aneurysms (all $p<0.01$; see Figure 1). Patients with no aneurysm demonstrated a significantly higher vorticity magnitude and absolute helicity at the ascending aorta compared to patients with root or ascending aneurysm (all p=0.01).

CONCLUSION

s Patients with root or ascending aneurysm demonstrated two distinct hemodynamic signatures, as compared to patients without an aneurysm. Root aneurysm patients have a significantly higher left ventricular stroke volume and ascending aneurysm patients have a significantly higher normalized flow displacement, flow jet angle and WSS angle.

CLINICAL RELEVANCE/APPLICATION

Aortic 4D flow MRI revealed two distinct hemodynamic signatures in patients with aortic root or ascending aorta aneurysm, as compared to patients without aneurysm.

Impact on Clinical Outcome of High-pitch non-ECG-gated CT Angiography for Transcatheter Aortic Valve Implantation Planning as Compared to An ECG-gated CTA Protocol

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - CA DPS

Participants
Martin Sinn, Hamburg, Germany (*Presenter*) Nothing to Disclose

PURPOSE

The question of whether to use ECG-guided or non-ECG-guided high-grid CT angiography (CTA) in planning transcatheter aortic valve implantation (TAVI) has been controversial, with ECG-guided CTA currently recommended. However, the impact on clinical outcome, including post-interventional paravalvular leakage (PVL), remains unclear. Therefore, the aim of this study was to compare a retrospective ECG-guided CTA protocol with a non-ECG-guided high-pitch CTA protocol for TAVI planning and the associated impact on clinical outcome.

METHODS AND MATERIALS

This retrospective, institutional review board-approved study included 231 subjects (age 80±7 years) who underwent implantation of an Evolut R (Medtronic, Minneapolis, USA) self-expandable transcatheter heart valve. Thereof, 48 subjects received retrospective ECG-guided CTA (group A) prior intervention, and 183 subjects received non-ECG-guided high-pitch CTA (group B). The amount of aortic valve calcification (Agatston score), aortic annulus diameter, and circumferential area were measured using commercially available software tools. Visual motion scoring of the aortic root and valve was performed by two radiologists. For each patient, the cover index was calculated 100 × ([prosthesis diameter - annulus diameter] / prosthesis diameter). Clinical outcome parameters were assessed 30 days after TAVI following the Valve Academic Research Consortium-3 consensus document.Paired and unpaired two-sided t-test and Chi-squared test were utilized to compare continuous and categorical variables, respectively.

RESULTS

There were no significant differences in motion artefacts of the aortic root or aortic valve calcification between both groups (p>.05). A significant difference in cover index was observed, with a higher cover index for group A (group A: 6.6±8.6 vs. group B: -1.3±10.4; p=.001). However, this difference did not lead to significantly different rates of PVL post TAVI (p=.399). Further, there were no significant differences in major adverse cardiac events (MACE) between both groups (p=.49).

CONCLUSION

s Although the cover index for TAVR planning of a high-pitch non-ECG-gated CTA was lower compared to an ECG-gated CTA protocol, rates of PVL and MACE were comparable between groups.

CLINICAL RELEVANCE/APPLICATION

A high-pitch non-ECG-gated CTA protocol may be suitable for TAVI planning.

Ex-vivo Swine Model Reveals Characteristic Aortic Flow Alterations After Different Aortic Valve Replacement Strategies

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - CA DPS

Participants
Maren Balks, (*Presenter*) Nothing to Disclose

PURPOSE

Aortic hemodynamics can be altered by aortic valve replacement (AVR) with studies suggesting differences in flow alterations after different types of replacement. Ozaki aortic valve neocuspidization is a new, promising procedure for reconstructing the aortic valve using the patient's own pericardium. In order to perform any open AVR, an incision in the ascending aorta (aortotomy) is obligatory to gain access to the valve. Little is known about impact of the surgical incision itself on aortic flow. The purpose of this work was to establish a biological model to comprehensively evaluate the impact of the surgical pathway alone and in combination with different valve replacement strategies on aortic hemodynamics.

METHODS AND MATERIALS

Six fresh swine aortas were anastomosed to an in-house developed piston pump pumping blood-mimicking fluid at 3l/min and 60bpm. 4D Flow MRI was acquired at 3Tesla (Achieva, Philips, The Netherlands). Each aorta was imaged with the native valve, after aortotomy, and after valve replacement with either a mechanical valve (MecValve, n=2; Standard Masters, St. Jude Medical, USA), a biological valve (BioValve n=2; Perimount Magna Ease, Edwards Lifesciences, USA) or Ozaki procedure (Ozaki, n=2). Peak velocity was quantified using GTFlow (GyroTools, Switzerland). Secondary flow patterns such as vortices and helices were visualized. They were graded according to their diameter relative to the vessel diameter as small, medium, or large.

RESULTS

Physiological flow without secondary flow patterns was detected in all native aortas. After aortotomy one secondary flow pattern developed in the ascending aorta in every specimen. AVR induced more pronounced changes in aortic hemodynamics: The mechanical valve induced the least secondary flow patterns (n=1) followed by the Ozaki procedure (n=2). Biological valve replacement induced the most secondary flow patterns (n=3) and an increase in peak velocity.

CONCLUSION

s The surgical pathway alone alters aortic hemodynamics. The new Ozaki procedure induced more secondary flow patterns than mechanical valves but fewer than biological valves. This makes it a promising alternative to biological valves that profoundly alter aortic hemodynamics.

CLINICAL RELEVANCE/APPLICATION

Flow changes after various aortic valve replacement procedures should be monitored in patients because altered hemodynamics may affect valve function and aortic wall integrity.

R5B-SPCH-1 Clinical Outcome of Incidental Pulmonary Embolism Detected by Artificial Intelligence Software: A Retrospective Analysis

Participants
Nahyun Jo, MD, Galveston, TX (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this study is to evaluate the clinical outcomes in retrospectively screened patients for incidental pulmonary embolism (iPE) by Artificial Intelligence (AI) algorithm on standard contrast-enhanced Chest Computed Tomography (Chest CT).

METHODS AND MATERIALS

The iPE algorithm was applied to 2793 consecutive patients undergoing Chest CT between 05/2020 to 01/2021 and AI results were compared to the original radiology report. Concordant cases between the original report and AI were considered ground truth. Discordant cases deemed positive by AI and negative by the report were reassessed by an experienced Chest Radiologist to establish the true diagnosis. Clinical outcomes were determined by a retrospective review of the medical record, including readmission, outpatient encounters, follow-up imaging, or death.

RESULTS

The prevalence of iPE was 2.3% (65/2792). 45 cases were found to be positive by both AI and radiologist report. AI detected 23 additional discordant positive cases. Of these, 87% (20/23) were considered true positive on the Chest Radiologist's secondary review. The AI-enhanced detection rate was 44.4% (20/45). 10% (2/20) were chronic PE, while 90% (18/20) were acute/subacute PE. 70% (14/20) were subsegmental PE. No follow-up imaging was found in 60% (12/20). 40% (8/20) had follow-up imaging: 5% (1/20) was a patient with known PE under treatment in whom resolution was noted on follow-up CT. In 50% (4/8), iPE spontaneously resolved. In 38% (3/8), iPE was noticed on follow-up and reported. In all 3, anticoagulation therapy was initiated. The average treatment delay in these patients was 132 days. As for the discrepant cases, in 35% (3/20) anticoagulation was given for other reasons. In the remaining 65% (13/20), iPE was unnoticed by radiologists or clinicians and the patient did not receive any treatment. No clear direct negative outcome from iPE was found in these patients. 25% (5/20) of patients died of unrelated causes.

CONCLUSION

s A substantial number of patients with retrospectively confirmed iPE by AI appeared to have had limited clinical implications. However, the improved detection rate of iPE by AI may bring significant benefits for prompt management in selected individuals, especially the ones at risk for recurrent thromboembolic events.

CLINICAL RELEVANCE/APPLICATION

The advantages of AI for PE detection had been demonstrated when actively searching for thromboembolic disease. We retrospectively explored the potential added benefit of scrutinizing CT contrast studies, other than Pulmonary CT Angiograms, for iPE diagnosis, management, and outcome implications. Future prospective studies utilizing AI in daily practice would provide additional information, particularly in the assessment of high-risk populations.

R5B-SPCH-2 Prospective Real-world Comparison of Standard of Care vs AI Assistance for Detection and Triage of Acute Pulmonary Emboli on CTPA

Participants
Steven Rothenberg, MD, Birmingham, AL (*Presenter*) Founder, Empower Therapeutics Inc ;Member, Translation Holdings LLC;Consultant, Radiostics LLC

PURPOSE

To compare the accuracy and efficiency of radiologists at detection and triage of PE on CTPA using standard of care vs. AI detection and triage.

METHODS AND MATERIALS

For this IRB-approved prospective single center study, 1529 consecutive adult patients with suspected PE who underwent a CTPA were included. The study was conducted in two phases in a real-world clinical practice setting. In phase 1, consecutive CTPAs (N=503) were evaluated independently by radiologists and by an FDA-cleared AI detection and triage system (CADt), with the CADt

results blocked from interacting with the interpreting radiologists. In phase 2, consecutive CTPAs (N=1026) were evaluated by radiologists interpreting the exams while using CADt. Five radiologists independently re-reviewed all positive, discrepant, and 20% of negative CTPA exams. All exams with discrepancies between the primary radiologist report, AI algorithm, and secondary radiologist interpretation were adjudicated by a committee of chest radiologists to determine ground truth.

RESULTS

In phase 1 and 2, 14.3% (72/503) and 15.6% (160/1026) CTPA exams were positive for any PE (p=0.512), and 10.3% (52/503) and 9.5% (97/1026) were positive for clinically-significant PE (p=0.622). The radiologist miss rate for any PE was 11.1% in phase 1 and 5.00% in phase 2 (p=0.089). The radiologist miss rate for clinically-significant PE was 3.9% in phase 1 and 1.0% in phase 2 (p=0.244). The accuracy, sensitivity, specificity, PPV, and NPV of the radiologist for any PE was 97.8%, 88.9%, 99.3%, 95.5%, and 98.2% in phase 1 and 98.8%, 95.0%, 99.5%, 97.4%, and 99.1% in phase 2. Mean exam TAT (turnaround time; from exam order to final report) was 210.7 min in phase 1 and 212.1 min in phase 2 (p=0.523). Mean interpretation TAT (from resident/radiologist opening imaging exam to final report) was 34.0 min in phase 1 and 30.0 min in phase 2 (p=0.2824). Mean interpretation TAT for positive cases was 34.9 min in phase 1 and 33.0 min in phase 2 (p=0.267).

CONCLUSION

s In a single-center prospective real-world study, the miss rate and accuracy of radiologists for detection of PE on CTPA and exam and report TATs did not significantly change when radiologists used AI detection and triage.

CLINICAL RELEVANCE/APPLICATION

The accurate and efficient detection and triage of an acute pulmonary embolus (PE) on a CT pulmonary angiogram (CTPA) has the potential to be augmented using an AI algorithm and triage system.

R5B-SPCH-3 Feasibility of Pulmonary Artery Pulse Wave Velocity Measurements Using Phase-resolved Functional Lung (PREFUL) Magnetic Resonance Imaging in Chronic Obstructive Disease

Participants
Gesa Helen Pohler, Hannover, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To measure pulmonary arterial pulse wave velocity using phase-resolved functional lung (PREFUL) MRI, its repeatability and compare with main pulmonary artery distensibility.

METHODS AND MATERIALS

Twenty-three COPD patients underwent MRI of three coronal slices with 2D PREFUL technique (Spoiled gradient echo sequence, 128 x128 matrix, 15 mm) at baseline and after 14 days. After flexible registration, cardiac cycle with 15 phases was reconstructed. Based on this, a pulmonary pulse transit time map (ms) was calculated as the time the pulse wave travels from main pulmonary artery to the microvasculature. Then, the distance in m between two regions of interest (ROI) of the main pulmonary artery and a distal in-plane located pulmonary arterial segment was calculated. Mean pulse wave velocity in m/s of each patient was defined as the distance difference (distanceROI) divided by difference of the two above defined pulsetransit time ROI´s. Relative cross-sectional area change (%) of the main pulmonary artery was computed with magnitude-images of phase contrast cine MRI. Each parameter´s median (25-75% quartile) of scan 1 and 2 were assessed by Wilcoxon sign rank test, Bland-Altman analysis, coefficient of variation, Spearman r.

RESULTS

There were no bias and no significant differences between both MRI´s for all parameters (all p>0.2). Pulse wave velocity of scan 1 was 3.1 (2-8) m/s, distanceROI was 2.8 (2.4-3.6) cm, proximal and distal pulmonary arterial pulse transit times were 8.4 (-3-26) ms and 21 (2-35) ms, pulmonary pulse transit times´ difference was 11 (7-17) ms. Pulse wave velocities coefficient of variation was 9.3 (3.6-12.7) %. Relative cross-sectional area change was 40.7 (32.8-65.5) %. Pulse wave velocity of scan 1 and 2 correlated inversely to relative area change (r:-0.64, -0,67; p=0.0009, p=0.0004).

CONCLUSION

s PREFUL MRI pulse wave velocity was good repeatable over two scans and increases with main pulmonary artery stiffness in COPD patients.

CLINICAL RELEVANCE/APPLICATION

PREFUL MRI pulse wave velocity offers a contrast agent-free tool for monitoring pulmonary arterial distensibility in chronic lung disease, which may be relevant for clinical descion-making in the future.

R5B-SPCH-4 Myocardial Extracellular Volume Assessment at Computed Tomography Novel Coronavirus Disease (COVID-19) Patients with Regards to Pulmonary Embolism

Participants
Caterina Monti, MD, PhD, Milan, Italy (*Presenter*) Travel support, Bracco Group

PURPOSE

to assess myocardial extracellular volume (ECV) in patients with novel coronavirus disease (COVID-19) with regards to the presence of pulmonary embolism (PE).

METHODS AND MATERIALS

we retrospectively reviewed consecutive patients who underwent contrast-enhanced computed tomography (CT) for the assessment of PE, and whose CT scans included at least one unenhanced and one venous phase acquisition performed at 1 minute after contrast administration for evaluating the mediastinum. Included patients were also to have hematocrit values obtained at most one day from the CT scan. Regions of interest were placed in the myocardium and ventricular blood pool of both the unenhanced and venous phase scan, and ECV was subsequently calculated.

RESULTS

our final population counted 94 patients, 63 (67%) of whom males, with a median age of 70 years (interquartile range, IQR, 56-76 years), 28 of whom with PE visible at CT. Median hematocrit was 39% (IQR 35-43%). Median overall ECV was 31% (IQR 26-35%), whereas median ECV in patients with PE was 34% (IQR 29-38%), significantly higher than in those without PE (30%, IQR 25-34%, P=.010).

CONCLUSION

s myocardial ECV is high in COVID-19 patients, possibly indicating a likelihood of underlying myocardial damage. The higher ECV in patients with PE may relate to the ventricular overload rising from subsequent pulmonary hypertension.

CLINICAL RELEVANCE/APPLICATION

CT-derived myocardial ECV could be used as a biomarker of cardiovascular involvement in COVID-19 patients, obtaining further data from an investigation that is already part of clinical workflows.

R5B-SPGI-1 Hepatic and Pancreatic Extracellular Volume Fraction Using Contrast-Enhanced CT in Patients with Impaired Glucose Tolerance

Participants
Takashi Ota, MD,PhD, Suita, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Liver fibrosis and pancreatic fibrosis are each associated with impaired glucose tolerance (IGT). Furthermore, liver fibrosis can be associated with pancreatic fibrosis. The purpose of the present study was to investigate the relationship between hepatic and pancreatic extracellular volume fraction (fECV) that correlates with tissue fibrosis and their relationships with IGT.

METHODS AND MATERIALS

The study included 100 consecutive patients with known or suspected liver and/or pancreatic diseases who underwent contrast-enhanced CT, including the precontrast and the equilibrium phase (62 males and 38 females; median age, 62 years; range, 28-93 years). Patients were classified into three groups based on the American Diabetes Association criteria: non-diabetes subjects, HbA1c?<?5.7% or fasting plasma glucose (FPG) < 100 mg/dL; pre-diabetes, 5.7%?=?HbA1c?<?6.5% or 100 = FPG < 125 mg/dL; and type 2 diabetes mellitus (T2DM), HbA1c?=?6.5% or FPG > 125 mg/dL. Subtraction images between unenhanced and equilibrium phase images were prepared using a new subtraction algorithm. The liver and the pancreas were automatically extracted excluding focal lesions, major vascular branches and ducts using a high-speed 3D image analysis system and mean CT values for them were calculated, respectively. The enhancement degree of the aorta (?Aorta) was also measured. fECV was calculated using the following equation: fECV=(100-hematocrit)*?Pancreas / ?Aorta. We investigated the differences in hepatic fECV and pancreatic fECV among the three patient groups using Kruskal-Wallis and Dwass-Steel-Crichlow-Fligner multiple comparisons statistical test and the correlation between the each two in hepatic fECV, pancreatic fECV and HbA1c using Spearman's rho coefficient.

RESULTS

Pancreatic fECV positively correlated with hepatic fECV and HbA1c (r?=?0.51, P?<?0.001 and r?=?0.51, P?<?0.001, respectively). Pancreatic fECV differed significantly among the three groups (P?<?0.001). Pancreatic fECV was significantly greater in T2DM compared with pre-diabetes or no-diabetes subjects and in pre-diabetes compared with no-diabetes subjects (P?<?0.001). Hepatic fECV was significantly greater in T2DM compared with non-diabetes subjects (P?<?0.05).

CONCLUSION

s There is a close relationship between hepatic fECV, pancreatic fECV and IGT.

CLINICAL RELEVANCE/APPLICATION

Hepatic fECV is associated with pancreatic fECV and diabetes mellitus. Hepatic fECV may be possible to use for the assessment of IGT in conjunction with pancreatic fECV.

R5B-SPGI-3 3-Dimensional Dual-Frequency Magnetic Resonance Elastography Derived Viscosity as a Surrogate of Hepatic Inflammation, Independent of Simultaneously Measured Stiffness

Participants
Jenna Feeley, BS, (*Presenter*) Nothing to Disclose

PURPOSE

The traditional Magnetic Resonance Elastography (MRE) method that is used to detect liver inflammation utilizes the damping ratio (DR) which factors stiffness (Gd) into the calculation. Hence, the purpose of this study is to identify a surrogate of liver inflammation, independent of stiffness, using 3-Dimensional (3D) dual-frequency (2F-MRE).

METHODS AND MATERIALS

45 patients with chronic liver disease (Hepatis C or Steatohepatitis) were included in this prospective study. 3D 2F-MRE was performed at 56 and 28 Hz on a 3T scanner. Liver viscosity (Gl) and stiffness (Gd) were measured at both frequencies. The difference in tissue viscosity and stiffness derived from the two frequencies was calculated (?Gl, ?Gd). All patients had liver biopsies for ISHAK scoring (inflammation range 0-18, fibrosis range 0-6). Statistical analysis was used to evaluate the degree of correlation between inflammation and fibrosis scores obtained from biopsy versus Gl and Gd, respectively (28 Hz and 56 Hz separately), and ?Gl and ?Gd obtained from 3D 2F-MRE. Lastly, diagnostic performance was evaluated by Receiver Operating Characteristic (ROC)

curves.

RESULTS

The average patient age and BMI were 56.16 ± 9.26 years and 27.82 ± 3.98 kg/m2, respectively, and 11 were women. Of the three viscosity parameters measured (GI28, GI56, and ?GI), ?GI showed the most significant correlation with ISHAK inflammation scores (P=0.0041). Stepwise multilinear regression analysis revealed that ?GI was the only significant surrogate of hepatic inflammation (R2 = 0.1975, P = 0.0025) and excluded all GI and Gd values (from both frequencies) from the model. ?GI also showed a strong diagnostic performance for detecting moderate/severe hepatic inflammation (ISHAK > 8: AUC = 0.8, Sensitivity 80%, Specificity 73.5%, P = 0.0001). All Gd values correlated similarly with fibrosis and no difference in diagnostic performance was found.

CONCLUSION

s These results indicate that the difference in liver viscosity, ?GI, obtained by 3D 2F-MRE is a significant and independent surrogate of liver inflammation and has a robust diagnostic performance for detecting moderate/severe liver inflammation. Unlike other MRE methods, ?GI derived from 3D 2F-MRE is an independent measurement that does not rely on the DR which factors in liver stiffness.

CLINICAL RELEVANCE/APPLICATION

3D 2F-MRE-derived ?GI is an independent surrogate marker of liver inflammation. This non-invasive measure provides early detection of liver inflammation and, with monitored treatment, may help mitigate the progression to fibrosis.

R5B-SPGI-4 Ultrasound shear wave elastography and shear wave dispersion imaging for diagnosis and staging of hepatic fibrosis

Participants
Kibo Nam, PhD, Philadelphia, PA (*Presenter*) Equipment support, Canon Medical Systems Corporation;Equipment support, General Electric Company ;Support, Lantheus Medical Imaging;Research funded, Canon Medical Systems Corporation

PURPOSE

To compare ultrasound shear wave elastography (SWE) and shear wave dispersion slope (SWDS) values to the fibrosis diagnosis and staging by a liver biopsy or MRE in non-alcoholic fatty liver disease (NAFLD) suspected patients.

METHODS AND MATERIALS

Subjects underwent a liver biopsy or MRE for suspected NAFLD and were scanned with an i8C1 probe on the Aplio i800 scanner (Canon Medical Systems). Five SWE (in kPa) and five SWDS (in m/s/KHz) values were obtained from the right liver lobe of each patient using built-in software. A circular region of interest (ROI) with a 1 cm diameter was placed =1 cm below the liver capsule manually in the liver parenchyma, referring to the shear wave propagation map. The obtained values met the criteria of IQR/median= 0.30 for SWE and =0.15 for SWDS. The mean SWE and SWDS values were compared with the reference results using a t-test and Pearson's correlation coefficient (r).

RESULTS

Among 54 patients, 30 underwent liver biopsy and 24 had MRE. Fibrosis was diagnosed in 27 patients (18 by biopsy and 9 by MRE; 10 stage 1, 6 stage 1 to 2, 1 stage 2, 5 stage 2 to 3, 1 stage 3, and 4 stage 4), while 27 patients showed stage 0 (12 by biopsy and 15 by MRE). The SWE and SWDS values were significantly higher in fibrotic livers compared to normal livers (7.1±1.7 vs. 5.5±1.2 kPa; p<0.0001 and 12.1±2.8 vs. 10.5±2.3 m/s/kHz; p=0.012, respectively). There was a fair correlation between fibrosis stage and mean SWE and SWDS values among all patients regardless of the reported clinical reference standard (r=0.69 and r=0.52, respectively). Liver biopsy fibrosis staging was moderately correlated with SWE and SWDS (r=0.70 and r=0.60, respectively). The correlation between MRE stiffness values (in kPa) with SWE and SWDS was weaker (r=0.63 and r=0.34, respectively).

CONCLUSION

s Ultrasound SWE showed a higher correlation with the diagnosis and staging of liver fibrosis by biopsy and/or MRE compared to SWDS.

CLINICAL RELEVANCE/APPLICATION

Ultrasound SWE has more potential for diagnosis and staging of liver fibrosis in NAFLD compared to SWDS values.

R5B-SPGI-5 Preoperative ultrasound radiomics for predicting clinically relevant postoperative pancreatic fistula after pancreatectomy

Participants
Yi Dong, MD, PhD, Shanghai, China (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the efficacy of the radiomics model based on preoperative grayscale ultrasound and shear wave elastography (SWE) in predicting the occurrence of clinically relevant postoperative pancreatic fistula (CR-POPF) after pancreatectomy.

METHODS AND MATERIALS

This prospective study was conducted from Jan 2020 to Nov 2021. Patients who scheduled to undergo pancreatectomy were initially enrolled and received ultrasound assessment within one week before surgery. The risk factors of POPF (grades B and C) were analyzed. Preoperative grayscale ultrasound images, ultrasound SWE values of pancreatic lesions and their surrounding parenchyma were used to build preoperative prediction radiomics model. Radiomic signatures were extracted and constructed using a minimal Redundancy Maximal Relevance (mRMR) algorithm and a L1 penalized logistic regression. Combined model was built using multivariate regression which incorporating radiomics signatures and clinical variables.

RESULTS

Finally, 147 patients (median age 62.0 y) were prospectively enrolled. Among which, 85 patients underwent distal pancreatectomy, and 62 patients underwent pancreaticoduodenectomy. During the three-weeks follow-up after pancreatectomy, the incidence rates

of grade B/C POPF were 28.6% (42/147 patients). Radiomic signatures constructed from grayscale ultrasound images of pancreas parenchymal regions (panRS) achieved an AUC of 0.75, accuracy of 68.7%, sensitivity of 85.7 % and specificity of 61.9 % in preoperative noninvasive prediction of CR-POPF. AUC of radiomics model increased to 0.81 when panRS was used for the prediction of CR-POPF after pancreaticoduodenectomy.

CONCLUSION

s Radiomics model based on ultrasound images was potentially useful for preoperative noninvasively predicting of CR-POPF.

CLINICAL RELEVANCE/APPLICATION

Patients with high-risk factors of CR-POPF could be closely monitored during the postoperative period.

R5B-SPGI-6 Longitudinal Changes in Liver Imaging Biomarkers Following Low Calorie Liquid Diet

Participants
Jake Weeks, La Jolla, CA (*Presenter*) Nothing to Disclose

PURPOSE

Low calorie liquid diet (LCLD) prior to bariatric surgery has been shown to reduce liver volume by ~20% on average, resulting in improved outcomes by reducing the technical difficulty of the operation. The effect of LCLD on liver volume has been well-documented, but relationships between liver shrinkage and other liver biomarkers are poorly understood. Changes to liver stiffness could also explain improved outcomes in bariatric surgery, but the effects of preparatory diet on liver stiffness have not been reported. This study describes changes in automated MR-based liver volume, steatosis, and stiffness after LCLD to elucidate the mechanisms of improved bariatric surgery outcomes.

METHODS AND MATERIALS

Forty-five adults with obesity scheduled for bariatric surgery were prospectively recruited to participate in an ongoing research study which includes two non-contrast MR imaging exams at 3.0T (GE Signa Premier, or GE Discovery MR750, GE Healthcare, Waukesha WI) at baseline and 2-3 days prior to surgery. LCLD was prescribed for 14-21 days during this interval. Imaging biomarkers included MRI-PDFF (IDEAL-IQ), liver volume based on MR imaging (3D convolutional neural network developed at our institution), and 2D SE-EPI MR Elastography. Mean PDFF was quantified by a 9-segment ROI analysis. Elastography was analyzed manually using the MRE Quant™ software (Resoundant, Inc., Minnesota, USA). BMI was examined for correlation with these parameters.

RESULTS

Following LCLD, mean liver volume decreased 414.36 cm3 (2098.32 cm3 to 1683.96 cm3). Mean liver PDFF decreased 3.45% (8.51% to 5.06%). Mean liver stiffness decreased by 0.09 kPa (2.07 kPa to 1.98 kPa). Mean BMI decreased by 2.13kg/m2 (46.15 kg/m2 to 44.02 kg/m2). Rate of change of volume demonstrated moderate, statistically significant correlations with the rates of change for MRE (? = 0.43, p = 0.004), PDFF (? = 0.38, p = 0.013), and BMI (? = 0.32, p = 0.040).

CONCLUSION

s The results of this study agree with previous data showing reductions in liver volume and steatosis following LCLD. We also found that liver stiffness is reduced during the dieting phase. MRE-derived liver stiffness change is correlated with liver volume change following LCLD. Reduced liver stiffness may affect outcomes in bariatric surgery, but the sample size was small and requires additional investigation. Further research within larger cohorts is needed to validate these findings.

CLINICAL RELEVANCE/APPLICATION

Longitudinal changes in MRI biomarkers following preparatory diet in bariatric surgery patients may help explain mechanisms underlying improved surgical outcomes.

R5B-SPGI-7 Splenic Volume is Associated with Survival in Patients Receiving Immunotherapy for Advanced Hepatocellular Carcinoma

Participants
Bang Bin Chen, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the association of splenic volume and its changes with survival outcomes among patients who underwent immunotherapy for advanced hepatocellular carcinoma (HCC).

METHODS AND MATERIALS

In this retrospective analysis, patients who initiated immunotherapy for advanced HCC were included. The baseline splenic volume and its relative changes after 1~3 months (median 55 days) on CT or MRI were measured by volumetric segmentation using 3D slicer software. The association between splenic volume at baseline and its relative change [(posttherapy - baseline)/baseline] and progression-free survival (PFS) or overall survival (OS) were evaluated using univariate and multivariate Cox analyses.

RESULTS

A total of 134 patients were included (men/women = 118/16; mean age, 59.5 ± 11.5 years (standard deviation)). The median follow-up duration was 30.5 months (95% confidence interval (CI) = 20.7-40.3). The overall response rate was 30.6%, and the disease control rate was 68.7%. The median PFS was 4 months (95% CI = 2.9-5.1), and the median OS was 17.2 months (95% CI = 10.9-23.5). After treatment, splenic volume was increased in 95 (70.9%) patients, and decreased in 39 (29.1%) patients. At baseline, patients with splenomegaly exhibited significantly shorter PFS (median, 4.0 vs. 5.4 months, P = 0.019) and OS (median, 11.2 vs. 19.3 months, P < 0.001) than patients without splenomegaly. After treatment, patients with increased splenic volume exhibited significantly better PFS (median, 2.6 vs. 6.7 months, P = 0.003) and OS (median, 12.0 vs. 23.1 months, P = 0.001) than patients with decreased splenic volume. In multivariate analysis adjusting for patient demographics, tumor extent, immunotherapy line, and liver function reserve, splenic volume change remained an independent predictor of PFS (hazard ratio (HR) 0.59; 95% CI: 0.37-0.94, P = 0.025) and OS (HR 0.46; 95% CI: 0.28-0.75, P = 0.002).

CONCLUSION

s Splenic volume may be used as a prognostic marker in patients who received immunotherapy for advanced HCC.

CLINICAL RELEVANCE/APPLICATION

Follow-up splenic volume after 1~3 months post-therapy may help clinicians predict clinical outcomes in HCC patients receiving immunotherapy.

R5B-SPGI-8 Synergistic Anticancer Effect of Pulsed Focused Ultrasound with Ultrasound-Sensitive Nanoparticle IMP301 on Pancreas Cancer Xenograft Model.

Participants
Soojin Kim, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Focused ultrasound (FUS) has been widely investigated for use in drug delivery system as a noninvasive synergistic modality. The purpose of this study was to investigate synergistic anticancer effect of FUS with a novel ultrasound-sensitive nanoparticle IMP 301 (doxorubicin-loaded) on pancreas cancer xenograft model.

METHODS AND MATERIALS

Nude mice were subcutaneously inoculated with human pancreatic cancer cell PANC-1 and randomly divided into six different groups (n=5 per group) for study 1 and 2 respectively. Ectopic pancreatic tumors were conditionally exposed to pHIFU with pre-studied parameters (acoustic power = 72 Watt, gap = 2mm x 2mm, total time = 20 second/spot, duty cycle = 2%, pulse repetition frequency = 250Hz). In Study 1, mice were assigned to 1) control, 2) gemcitabine only (200mg intraperitoneal), 3) doxil (4mg/kg) with FUS, and 4-6) three groups treated with different doses of IMP301 (2,4,6mg/kg) with FUS. In Study 2, mice were assigned to 1) control, 2) FUS only, 3) gemcitabine only, 4) doxil (4mg/kg) with FUS, and 5-6) two groups treated with IMP 301 (4mg/kg) with or without FUS. The presence of synergistic effect of IMP 301 when combined with FUS was evaluated by comparison with other groups in terms of tumor growth suppression.

RESULTS

In Study 1, IMP301 with FUS group showed significantly lower tumor volume (121 mm3 ± 28 mm3) and growth rate (12.1 mm3/week ± 5.2 mm3/week) when dose exceeded 4mg/kg, compared to gemcitabine only (244.7 mm3 ± 47.6 mm3 , 30.5 mm3/week ± 11.7 mm3/week) and doxil with FUS group (208 mm3 ± 25 mm3, 25.6 mm3/week ± 7.7 mm3/week) [$p<0.05$]. In Study 2, IMP301 with FUS group showed significantly lower tumor volume (98 mm3 ± 42 mm3) and growth rate (9.2 mm3/week ± 6.5 mm3/week; $p<0.05$) than gemcitabine only (323 mm3 ± 158 mm3 , 46.7 mm3/week ± 29.1 mm3/week) and doxil with FUS group (236 mm3 ± 60 mm3, 32.2 mm3/week ± 11.9 mm3/week) [$p<0.05$]. However, IMP301 without FUS group (256 mm3 ± 107 mm3, 35.6 mm3/week ± 18.8 mm3/week) showed no significant difference with gemcitabine only and doxil with FUS group.

CONCLUSION

s In conclusion, IMP301 combined with short duty cycle FUS exhibited significantly higher and persistent tumor suppression effect, compared to the single use of conventional drug or IMP 301 or the combined use of conventional drug and FUS, showing the potential of IMP 301 with FUS for the treatment of pancreatic cancer.

CLINICAL RELEVANCE/APPLICATION

Ultrasound-sensitive drug release by FUS can be applied in treatment for nonoperative pancreatic cancer patients as a highly effective noninvasive localized therapeutic modality.

R5B-SPGI-9 An Attention-Based Convolutional Neural Network for Differentiating Benign from Malignant Focal Liver Lesions in Wash-In and Wash-Out Contrast-Enhanced Ultrasonography

Participants
Thodsawit Tiyarattanachai, (*Presenter*) Nothing to Disclose

PURPOSE

Contrast-enhanced ultrasound (CEUS) is increasingly used to characterize focal liver lesions (FLLs). We have previously developed deep learning models to support interpretation of wash-in CEUS data in FLL characterization. In this work, we investigated whether including wash-out data into our models can improve differentiation of benign from malignant FLLs.

METHODS AND MATERIALS

This study used CEUS data from an ongoing multi-institutional IRB-approved study and informed consent was obtained from all patients. A wash-in cine was used as input into a "wash-in subnetwork" based on a three-dimensional (3D) convolutional neural network (CNN). Variable instances of wash-out images were used as inputs into six "wash-out subnetworks" based on two-dimensional (2D) CNNs. Since wash-out data are usually acquired as an ambiguous number of images and not cines, an attention module was built on top of the wash-in and wash-out subnetworks to deal with such variable instances of wash-out images. To evaluate the add-on utility of the attention module, the following three models were compared: 1) a simple 3D CNN, which was inspired by previously published works, receiving as input a wash-in cine (Model A); 2) a simple 3D CNN receiving as input a wash-in cine temporally appended with wash-out images (Model B); and 3) the model with attention module built on top of wash-in and wash-out subnetworks (Model C). 5-fold cross validation was performed. Mean SD of performance results across all folds were reported. Area under receiver operating characteristic curve (AUROC), sensitivity and specificity were used as evaluation metrics.

RESULTS

A total of 158 FLLs from 130 patients were included. Of these, 31 (19.6%) FLLs were benign, and 127 (80.4%) FLLs were malignant based on a composite reference standard of pathology, CT and MRI. Model A achieved AUROC of 0.75+-0.10, sensitivity of 76.9%+-14.5% and specificity of 78.6%+-24.2%. Model B achieved AUROC of 0.76+-0.10, sensitivity of 74.9%+-9.7% and specificity of 84.3%+-15.6%. With incorporation of the attention module, Model C achieved the highest AUROC of 0.86+-0.08, sensitivity of 84.2%+-8.1% and specificity of 87.1%+-7.3%.

CONCLUSION

s The attention module improved performance of CNN in differentiating benign from malignant FLLs on wash-in and wash-out CEUS.

CLINICAL RELEVANCE/APPLICATION

The Attention-based CNN can be used to characterize FLLs on CEUS acquired in clinical practice, where the number of recorded wash-out instances is variable.

Hepatic and Pancreatic Extracellular Volume Fraction Using Contrast-Enhanced CT in Patients with Impaired Glucose Tolerance

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - GI DPS

Participants
Takashi Ota, MD,PhD, Suita, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Liver fibrosis and pancreatic fibrosis are each associated with impaired glucose tolerance (IGT). Furthermore, liver fibrosis can be associated with pancreatic fibrosis. The purpose of the present study was to investigate the relationship between hepatic and pancreatic extracellular volume fraction (fECV) that correlates with tissue fibrosis and their relationships with IGT.

METHODS AND MATERIALS

The study included 100 consecutive patients with known or suspected liver and/or pancreatic diseases who underwent contrast-enhanced CT, including the precontrast and the equilibrium phase (62 males and 38 females; median age, 62 years; range, 28-93 years). Patients were classified into three groups based on the American Diabetes Association criteria: non-diabetes subjects, HbA1c?<?5.7% or fasting plasma glucose (FPG) < 100 mg/dL; pre-diabetes, 5.7%?=?HbA1c?<?6.5% or 100 = FPG < 125 mg/dL; and type 2 diabetes mellitus (T2DM), HbA1c?=?6.5% or FPG > 125 mg/dL. Subtraction images between unenhanced and equilibrium phase images were prepared using a new subtraction algorithm. The liver and the pancreas were automatically extracted excluding focal lesions, major vascular branches and ducts using a high-speed 3D image analysis system and mean CT values for them were calculated, respectively. The enhancement degree of the aorta (?Aorta) was also measured. fECV was calculated using the following equation: fECV=(100-hematocrit)*?Pancreas / ?Aorta. We investigated the differences in hepatic fECV and pancreatic fECV among the three patient groups using Kruskal-Wallis and Dwass-Steel-Crichlow-Fligner multiple comparisons statistical test and the correlation between the each two in hepatic fECV, pancreatic fECV and HbA1c using Spearman's rho coefficient.

RESULTS

Pancreatic fECV positively correlated with hepatic fECV and HbA1c (r?=?0.51, P?<?0.001 and r?=?0.51, P?<?0.001, respectively). Pancreatic fECV differed significantly among the three groups (P?<?0.001). Pancreatic fECV was significantly greater in T2DM compared with pre-diabetes or no-diabetes subjects and in pre-diabetes compared with no-diabetes subjects (P?<?0.001). Hepatic fECV was significantly greater in T2DM compared with non-diabetes subjects (P?<?0.05).

CONCLUSION

s There is a close relationship between hepatic fECV, pancreatic fECV and IGT.

CLINICAL RELEVANCE/APPLICATION

Hepatic fECV is associated with pancreatic fECV and diabetes mellitus. Hepatic fECV may be possible to use for the assessment of IGT in conjunction with pancreatic fECV.

3-Dimensional Dual-Frequency Magnetic Resonance Elastography Derived Viscosity as a Surrogate of Hepatic Inflammation, Independent of Simultaneously Measured Stiffness

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - GI DPS

Participants
Jenna Feeley, BS, (*Presenter*) Nothing to Disclose

PURPOSE

The traditional Magnetic Resonance Elastography (MRE) method that is used to detect liver inflammation utilizes the damping ratio (DR) which factors stiffness (Gd) into the calculation. Hence, the purpose of this study is to identify a surrogate of liver inflammation, independent of stiffness, using 3-Dimensional (3D) dual-frequency (2F-MRE).

METHODS AND MATERIALS

45 patients with chronic liver disease (Hepatis C or Steatohepatitis) were included in this prospective study. 3D 2F-MRE was performed at 56 and 28 Hz on a 3T scanner. Liver viscosity (Gl) and stiffness (Gd) were measured at both frequencies. The difference in tissue viscosity and stiffness derived from the two frequencies was calculated (?Gl, ?Gd). All patients had liver biopsies for ISHAK scoring (inflammation range 0-18, fibrosis range 0-6). Statistical analysis was used to evaluate the degree of correlation between inflammation and fibrosis scores obtained from biopsy versus Gl and Gd, respectively (28 Hz and 56 Hz separately), and ?Gl and ?Gd obtained from 3D 2F-MRE. Lastly, diagnostic performance was evaluated by Receiver Operating Characteristic (ROC) curves.

RESULTS

The average patient age and BMI were 56.16 ± 9.26 years and 27.82 ± 3.98 kg/m2, respectively, and 11 were women. Of the three viscosity parameters measured (Gl28, Gl56, and ?Gl), ?Gl showed the most significant correlation with ISHAK inflammation scores (P=0.0041). Stepwise multilinear regression analysis revealed that ?Gl was the only significant surrogate of hepatic inflammation (R2 = 0.1975, P = 0.0025) and excluded all GI and Gd values (from both frequencies) from the model. ?Gl also showed a strong diagnostic performance for detecting moderate/severe hepatic inflammation (ISHAK > 8: AUC = 0.8, Sensitivity 80%, Specificity 73.5%, P = 0.0001). All Gd values correlated similarly with fibrosis and no difference in diagnostic performance was found.

CONCLUSION

s These results indicate that the difference in liver viscosity, ?Gl, obtained by 3D 2F-MRE is a significant and independent surrogate of liver inflammation and has a robust diagnostic performance for detecting moderate/severe liver inflammation. Unlike other MRE methods, ?Gl derived from 3D 2F-MRE is an independent measurement that does not rely on the DR which factors in liver stiffness.

CLINICAL RELEVANCE/APPLICATION

3D 2F-MRE-derived ?Gl is an independent surrogate marker of liver inflammation. This non-invasive measure provides early detection of liver inflammation and, with monitored treatment, may help mitigate the progression to fibrosis.

R5B-SPGI-4

Ultrasound shear wave elastography and shear wave dispersion imaging for diagnosis and staging of hepatic fibrosis

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - GI DPS

Participants
Kibo Nam, PhD, Philadelphia, PA (*Presenter*) Equipment support, Canon Medical Systems Corporation;Equipment support, General Electric Company ;Support, Lantheus Medical Imaging;Research funded, Canon Medical Systems Corporation

PURPOSE

To compare ultrasound shear wave elastography (SWE) and shear wave dispersion slope (SWDS) values to the fibrosis diagnosis and staging by a liver biopsy or MRE in non-alcoholic fatty liver disease (NAFLD) suspected patients.

METHODS AND MATERIALS

Subjects underwent a liver biopsy or MRE for suspected NAFLD and were scanned with an i8C1 probe on the Aplio i800 scanner (Canon Medical Systems). Five SWE (in kPa) and five SWDS (in m/s/KHz) values were obtained from the right liver lobe of each patient using built-in software. A circular region of interest (ROI) with a 1 cm diameter was placed =1 cm below the liver capsule manually in the liver parenchyma, referring to the shear wave propagation map. The obtained values met the criteria of IQR/median= 0.30 for SWE and =0.15 for SWDS. The mean SWE and SWDS values were compared with the reference results using a t-test and Pearson's correlation coefficient (r).

RESULTS

Among 54 patients, 30 underwent liver biopsy and 24 had MRE. Fibrosis was diagnosed in 27 patients (18 by biopsy and 9 by MRE; 10 stage 1, 6 stage 1 to 2, 1 stage 2, 5 stage 2 to 3, 1 stage 3, and 4 stage 4), while 27 patients showed stage 0 (12 by biopsy and 15 by MRE). The SWE and SWDS values were significantly higher in fibrotic livers compared to normal livers (7.1±1.7 vs. 5.5±1.2 kPa; $p<0.0001$ and 12.1±2.8 vs. 10.5±2.3 m/s/kHz; $p=0.012$, respectively). There was a fair correlation between fibrosis stage and mean SWE and SWDS values among all patients regardless of the reported clinical reference standard ($r=0.69$ and $r=0.52$, respectively). Liver biopsy fibrosis staging was moderately correlated with SWE and SWDS ($r=0.70$ and $r=0.60$, respectively). The correlation between MRE stiffness values (in kPa) with SWE and SWDS was weaker ($r=0.63$ and $r=0.34$, respectively).

CONCLUSION

s Ultrasound SWE showed a higher correlation with the diagnosis and staging of liver fibrosis by biopsy and/or MRE compared to SWDS.

CLINICAL RELEVANCE/APPLICATION

Ultrasound SWE has more potential for diagnosis and staging of liver fibrosis in NAFLD compared to SWDS values.

Preoperative ultrasound radiomics for predicting clinically relevant postoperative pancreatic fistula after pancreatectomy

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - GI DPS

Participants
Yi Dong, MD, PhD, Shanghai, China (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the efficacy of the radiomics model based on preoperative grayscale ultrasound and shear wave elastography (SWE) in predicting the occurrence of clinically relevant postoperative pancreatic fistula (CR-POPF) after pancreatectomy.

METHODS AND MATERIALS

This prospective study was conducted from Jan 2020 to Nov 2021. Patients who scheduled to undergo pancreatectomy were initially enrolled and received ultrasound assessment within one week before surgery. The risk factors of POPF (grades B and C) were analyzed. Preoperative grayscale ultrasound images, ultrasound SWE values of pancreatic lesions and their surrounding parenchyma were used to build preoperative prediction radiomics model. Radiomic signatures were extracted and constructed using a minimal Redundancy Maximal Relevance (mRMR) algorithm and a L1 penalized logistic regression. Combined model was built using multivariate regression which incorporating radiomics signatures and clinical variables.

RESULTS

Finally, 147 patients (median age 62.0 y) were prospectively enrolled. Among which, 85 patients underwent distal pancreatectomy, and 62 patients underwent pancreaticoduodenectomy. During the three-weeks follow-up after pancreatectomy, the incidence rates of grade B/C POPF were 28.6% (42/147 patients). Radiomic signatures constructed from grayscale ultrasound images of pancreas parenchymal regions (panRS) achieved an AUC of 0.75, accuracy of 68.7%, sensitivity of 85.7 % and specificity of 61.9 % in preoperative noninvasive prediction of CR-POPF. AUC of radiomics model increased to 0.81 when panRS was used for the prediction of CR-POPF after pancreaticoduodenectomy.

CONCLUSION

s Radiomics model based on ultrasound images was potentially useful for preoperative noninvasively predicting of CR-POPF.

CLINICAL RELEVANCE/APPLICATION

Patients with high-risk factors of CR-POPF could be closely monitored during the postoperative period.

Longitudinal Changes in Liver Imaging Biomarkers Following Low Calorie Liquid Diet

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - GI DPS

Participants
Jake Weeks, La Jolla, CA (*Presenter*) Nothing to Disclose

PURPOSE

Low calorie liquid diet (LCLD) prior to bariatric surgery has been shown to reduce liver volume by ~20% on average, resulting in improved outcomes by reducing the technical difficulty of the operation. The effect of LCLD on liver volume has been well-documented, but relationships between liver shrinkage and other liver biomarkers are poorly understood. Changes to liver stiffness could also explain improved outcomes in bariatric surgery, but the effects of preparatory diet on liver stiffness have not been reported. This study describes changes in automated MR-based liver volume, steatosis, and stiffness after LCLD to elucidate the mechanisms of improved bariatric surgery outcomes.

METHODS AND MATERIALS

Forty-five adults with obesity scheduled for bariatric surgery were prospectively recruited to participate in an ongoing research study which includes two non-contrast MR imaging exams at 3.0T (GE Signa Premier, or GE Discovery MR750, GE Healthcare, Waukesha WI) at baseline and 2-3 days prior to surgery. LCLD was prescribed for 14-21 days during this interval. Imaging biomarkers included MRI-PDFF (IDEAL-IQ), liver volume based on MR imaging (3D convolutional neural network developed at our institution), and 2D SE-EPI MR Elastography. Mean PDFF was quantified by a 9-segment ROI analysis. Elastography was analyzed manually using the MRE Quant™ software (Resoundant, Inc., Minnesota, USA). BMI was examined for correlation with these parameters.

RESULTS

Following LCLD, mean liver volume decreased 414.36 cm3 (2098.32 cm3 to 1683.96 cm3). Mean liver PDFF decreased 3.45% (8.51% to 5.06%). Mean liver stiffness decreased by 0.09 kPa (2.07 kPa to 1.98 kPa). Mean BMI decreased by 2.13kg/m2 (46.15 kg/m2 to 44.02 kg/m2). Rate of change of volume demonstrated moderate, statistically significant correlations with the rates of change for MRE (? = 0.43, p = 0.004), PDFF (? = 0.38, p = 0.013), and BMI (? = 0.32, p = 0.040).

CONCLUSION

s The results of this study agree with previous data showing reductions in liver volume and steatosis following LCLD. We also found that liver stiffness is reduced during the dieting phase. MRE-derived liver stiffness change is correlated with liver volume change following LCLD. Reduced liver stiffness may affect outcomes in bariatric surgery, but the sample size was small and requires additional investigation. Further research within larger cohorts is needed to validate these findings.

CLINICAL RELEVANCE/APPLICATION

Longitudinal changes in MRI biomarkers following preparatory diet in bariatric surgery patients may help explain mechanisms underlying improved surgical outcomes.

Splenic Volume is Associated with Survival in Patients Receiving Immunotherapy for Advanced Hepatocellular Carcinoma

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - GI DPS

Participants
Bang Bin Chen, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the association of splenic volume and its changes with survival outcomes among patients who underwent immunotherapy for advanced hepatocellular carcinoma (HCC).

METHODS AND MATERIALS

In this retrospective analysis, patients who initiated immunotherapy for advanced HCC were included. The baseline splenic volume and its relative changes after 1~3 months (median 55 days) on CT or MRI were measured by volumetric segmentation using 3D slicer software. The association between splenic volume at baseline and its relative change [(posttherapy - baseline)/baseline] and progression-free survival (PFS) or overall survival (OS) were evaluated using univariate and multivariate Cox analyses.

RESULTS

A total of 134 patients were included (men/women = 118/16; mean age, 59.5 ± 11.5 years (standard deviation)). The median follow-up duration was 30.5 months (95% confidence interval (CI) = 20.7-40.3). The overall response rate was 30.6%, and the disease control rate was 68.7%. The median PFS was 4 months (95% CI = 2.9-5.1), and the median OS was 17.2 months (95% CI = 10.9-23.5). After treatment, splenic volume was increased in 95 (70.9%) patients, and decreased in 39 (29.1%) patients. At baseline, patients with splenomegaly exhibited significantly shorter PFS (median, 4.0 vs. 5.4 months, P = 0.019) and OS (median, 11.2 vs. 19.3 months, P < 0.001) than patients without splenomegaly. After treatment, patients with increased splenic volume exhibited significantly better PFS (median, 2.6 vs. 6.7 months, P = 0.003) and OS (median, 12.0 vs. 23.1 months, P = 0.001) than patients with decreased splenic volume. In multivariate analysis adjusting for patient demographics, tumor extent, immunotherapy line, and liver function reserve, splenic volume change remained an independent predictor of PFS (hazard ratio (HR) 0.59; 95% CI: 0.37-0.94, P = 0.025) and OS (HR 0.46; 95% CI: 0.28-0.75, P = 0.002).

CONCLUSION

s Splenic volume may be used as a prognostic marker in patients who received immunotherapy for advanced HCC.

CLINICAL RELEVANCE/APPLICATION

Follow-up splenic volume after 1~3 months post-therapy may help clinicians predict clinical outcomes in HCC patients receiving immunotherapy.

Synergistic Anticancer Effect of Pulsed Focused Ultrasound with Ultrasound-Sensitive Nanoparticle IMP301 on Pancreas Cancer Xenograft Model.

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - GI DPS

Participants
Soojin Kim, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Focused ultrasound (FUS) has been widely investigated for use in drug delivery system as a noninvasive synergistic modality. The purpose of this study was to investigate synergistic anticancer effect of FUS with a novel ultrasound-sensitive nanoparticle IMP 301 (doxorubicin-loaded) on pancreas cancer xenograft model.

METHODS AND MATERIALS

Nude mice were subcutaneously inoculated with human pancreatic cancer cell PANC-1 and randomly divided into six different groups (n=5 per group) for study 1 and 2 respectively. Ectopic pancreatic tumors were conditionally exposed to pHIFU with pre-studied parameters (acoustic power = 72 Watt, gap = 2mm x 2mm, total time = 20 second/spot, duty cycle = 2%, pulse repetition frequency = 250Hz). In Study 1, mice were assigned to 1) control, 2) gemcitabine only (200mg intraperitoneal), 3) doxil (4mg/kg) with FUS, and 4-6) three groups treated with different doses of IMP301 (2,4,6mg/kg) with FUS. In Study 2, mice were assigned to 1) control, 2) FUS only, 3) gemcitabine only, 4) doxil (4mg/kg) with FUS, and 5-6) two groups treated with IMP 301 (4mg/kg) with or without FUS. The presence of synergistic effect of IMP 301 when combined with FUS was evaluated by comparison with other groups in terms of tumor growth suppression.

RESULTS

In Study 1, IMP301 with FUS group showed significantly lower tumor volume (121 mm3 ± 28 mm3) and growth rate (12.1 mm3/week ± 5.2 mm3/week) when dose exceeded 4mg/kg, compared to gemcitabine only (244.7 mm3 ± 47.6 mm3 , 30.5 mm3/week ± 11.7 mm3/week) and doxil with FUS group (208 mm3 ± 25 mm3, 25.6 mm3/week ± 7.7 mm3/week) [$p<0.05$]. In Study 2, IMP301 with FUS group showed significantly lower tumor volume (98 mm3 ± 42 mm3) and growth rate (9.2 mm3/week ± 6.5 mm3/week; $p<0.05$) than gemcitabine only (323 mm3 ± 158 mm3 , 46.7 mm3/week ± 29.1 mm3/week) and doxil with FUS group (236 mm3 ± 60 mm3, 32.2 mm3/week ± 11.9 mm3/week) [$p<0.05$]. However, IMP301 without FUS group (256 mm3 ± 107 mm3, 35.6 mm3/week ± 18.8 mm3/week) showed no significant difference with gemcitabine only and doxil with FUS group.

CONCLUSION

s In conclusion, IMP301 combined with short duty cycle FUS exhibited significantly higher and persistent tumor suppression effect, compared to the single use of conventional drug or IMP 301 or the combined use of conventional drug and FUS, showing the potential of IMP 301 with FUS for the treatment of pancreatic cancer.

CLINICAL RELEVANCE/APPLICATION

Ultrasound-sensitive drug release by FUS can be applied in treatment for nonoperative pancreatic cancer patients as a highly effective noninvasive localized therapeutic modality.

An Attention-Based Convolutional Neural Network for Differentiating Benign from Malignant Focal Liver Lesions in Wash-In and Wash-Out Contrast-Enhanced Ultrasonography

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - GI DPS

Participants
Thodsawit Tiyarattanachai, (*Presenter*) Nothing to Disclose

PURPOSE

Contrast-enhanced ultrasound (CEUS) is increasingly used to characterize focal liver lesions (FLLs). We have previously developed deep learning models to support interpretation of wash-in CEUS data in FLL characterization. In this work, we investigated whether including wash-out data into our models can improve differentiation of benign from malignant FLLs.

METHODS AND MATERIALS

This study used CEUS data from an ongoing multi-institutional IRB-approved study and informed consent was obtained from all patients. A wash-in cine was used as input into a "wash-in subnetwork" based on a three-dimensional (3D) convolutional neural network (CNN). Variable instances of wash-out images were used as inputs into six "wash-out subnetworks" based on two-dimensional (2D) CNNs. Since wash-out data are usually acquired as an ambiguous number of images and not cines, an attention module was built on top of the wash-in and wash-out subnetworks to deal with such variable instances of wash-out images. To evaluate the add-on utility of the attention module, the following three models were compared: 1) a simple 3D CNN, which was inspired by previously published works, receiving as input a wash-in cine (Model A); 2) a simple 3D CNN receiving as input a wash-in cine temporally appended with wash-out images (Model B); and 3) the model with attention module built on top of wash-in and wash-out subnetworks (Model C). 5-fold cross validation was performed. Mean SD of performance results across all folds were reported. Area under receiver operating characteristic curve (AUROC), sensitivity and specificity were used as evaluation metrics.

RESULTS

A total of 158 FLLs from 130 patients were included. Of these, 31 (19.6%) FLLs were benign, and 127 (80.4%) FLLs were malignant based on a composite reference standard of pathology, CT and MRI. Model A achieved AUROC of 0.75+-0.10, sensitivity of 76.9%+-14.5% and specificity of 78.6%+-24.2%. Model B achieved AUROC of 0.76+-0.10, sensitivity of 74.9%+-9.7% and specificity of 84.3%+-15.6%. With incorporation of the attention module, Model C achieved the highest AUROC of 0.86+-0.08, sensitivity of 84.2%+-8.1% and specificity of 87.1%+-7.3%.

CONCLUSION

s The attention module improved performance of CNN in differentiating benign from malignant FLLs on wash-in and wash-out CEUS.

CLINICAL RELEVANCE/APPLICATION

The Attention-based CNN can be used to characterize FLLs on CEUS acquired in clinical practice, where the number of recorded wash-out instances is variable.

R5B-SPGU-1 Proportion of malignancy in Bosniak Classification of Cystic Renal Masses version 2019 (v2019) Classes: Systematic Review and Meta-Analysis

Participants
Nicola Schieda, MD, Ottawa, ON (*Presenter*) Nothing to Disclose

PURPOSE

To determine the proportion of malignancy within Bosniak v2019 Classes.

METHODS AND MATERIALS

MEDLINE and EMBASE were searched. Eligible studies contained patients with cystic renal masses undergoing CT or MRI renal protocol examinations with pathology confirmation, applying Bosniak v2019. Proportion of malignancy was estimated within Bosniak v2019 Class. Risk of bias was assessed using QUADAS-2.

RESULTS

We included 471 patients with 480 cystic renal masses. No Class I malignant masses were observed. Pooled proportion of malignancy were: Class II, 12% (6/51, 95%CI 5-24%), Class IIF, 46% (37/85, 95%CI 28-66%), Class III, 79% (138/173, 95%CI 68-88%), Class IV, 84% (114/135, 95%CI 77-90%). Proportion of malignancy differed between Bosniak v2019 II-IV classes (p=0.004).Four studies reported the proportion of malignancy by wall/septa feature. The pooled proportion of malignancy with 95%CI were: Class III thick smooth wall/septa, 77% (41/56, 95%CI 53-91%), Class III obtuse protrusion =3 mm (irregularity), 83% (97/117, 95%CI 75-89%), Class IV nodule with acute angulation, 86% (50/58, 95%CI 75-93%) or obtuse angulation =4 mm, 83%, (64/77, 95%CI 73-90%). Subgroup analysis by wall/septa feature was limited by small sample size; however, no differences were found comparing Class III masses with irregularity to Class IV masses (p=0.74) or between Class IV masses by acute versus obtuse angles (p=0.62).

CONCLUSION

s Preliminary data suggest Bosniak v2019 Class IIF masses have higher proportion of malignancy compared to the original Classification and there are no differences in proportion of malignancy comparing Class III masses with irregularities to Class IV masses with acute or obtuse nodules.

CLINICAL RELEVANCE/APPLICATION

Our results suggest a potential opportunity for simplification of the Bosniak v2019 Classification, where cystic masses that show any wall or septa protrusion could be considered as Class IV and those with smooth wall or septa thickness considered as Class III.

R5B-SPGU-2 Assessment of muscle invasion in bladder urothelial carcinoma with variant histology using the Vesical Imaging-Reporting and Data System: a multi-institutional multi-reader pair-matched cohort study

Awards
Trainee Research Prize - Fellow

Participants
Yuki Arita, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Recent studies demonstrated high accuracy of the Vesicle Imaging-Reporting and Data System (VI-RADS) for diagnosing muscle-invasive bladder cancer (MIBC), especially for the pure urothelial carcinoma (PUC) patients. However, the diagnostic performance of VI-RADS for variant histology urothelial carcinoma (VUC) remains unknown. This study aimed to investigate the utility of the VI-RADS for muscle-invasion assessment in VUC by comparing its diagnostic performance with that of PUC.

METHODS AND MATERIALS

This multi-institutional study included consecutive treatment-naïve patients with pathologically proven PUC or VUC who underwent bladder multiparametric magnetic resonance imaging (mpMRI) before transurethral bladder tumor resection between 2011 and 2019. Four board-certified radiologists (two fellowship-trained and two fellowship-training), blinded to the clinical information including histopathological findings, independently reviewed the mpMRI data according to the VI-RADS criteria. Histopathological results were used as reference standard. Receiver operating characteristic curve analysis, Z-test, and Wald test were used to evaluate the diagnostic performance.

RESULTS

Of the 122 pair-matched patients (PUC cohort: 61, VUC cohort: 61), 34 (55.7%) and 33 (54.1%) had pathologically confirmed MIBC, while 27 (44.3%) and 28 (45.9) had non-MIBC (NMIBC), respectively. The areas under the curves (AUCs) of the VI-RADS overall scores for MIBC diagnosis in PUC/VUC were 0.94/0.89-0.92. There were no significant differences between the PUC and VUC cohorts in the AUC, sensitivity, and specificity for muscle invasion of the VI-RADS overall scores for all readers ($p>0.05$ for all). In the evaluation by fellowship-training radiologists using diffusion-weighted imaging (DWI) scores alone with a cutoff score of 4, the sensitivity, but not specificity, was significantly lower for VUC than for PUC (54.5/89.3-92.9% vs. 82.4/92.6%, $p=0.01/0.67-0.97$). However, the sensitivity and specificity did not significantly differ between the two cohorts using the VI-RADS overall scores with a cutoff score of 4 (85.3/92.6% vs. 75.8-78.8/85.7-89.3%, $p=0.32-0.49/0.41-0.67$).

CONCLUSION

s VI-RADS overall scores have comparably high diagnostic performance for muscle invasion detection in PUC and VUC regardless of the readers' experience. However, when DWI scores alone are used, there may be a risk of less experienced radiologists underestimating muscle invasion in VUC.

CLINICAL RELEVANCE/APPLICATION

VI-RADS is useful for muscle-invasion assessment both in VUC and PUC. Less experienced radiologists can better assess muscle invasion in VUC using the VI-RADS overall classification algorithm owing to the effect of dynamic contrast-enhanced MRI scores.

Head and Neck Thursday Poster Discussions - B

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - HN DPS

Sub-Events

R5B-SPHN-2 TI-RADS: Improving Patient Care or Just Pain in The Neck: A Retrospective Review

Participants
Tyler Rogers, BA, MMedSc, CHAPEL HILL, NC (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this study was to evaluate the American College of Radiology Thyroid Imaging Reporting and Data Systems (TI-RADS) by correlating TI-RADS score with biopsy results to validate or reaffirm the recommendation of fine needle aspiration (FNA) in the higher scoring nodules. Other covariables investigated included patient age, gender, FDG avidity on Positron Emission Tomography (PET), and echogenic foci as possible independent predictors of malignancy.

METHODS AND MATERIALS

This was a retrospective study performed at a large academic institution. 624 nodules underwent ultrasound (US) examination and US-guided FNA over a three-year period. Chart review included: age, gender, TI-RADS score, presence of echogenic foci, nodule size, pathology from FNA, and method of detection. Both TI-RADS scoring and FNA of nodules were performed by abdominal fellowship trained radiologists. Results were categorized as benign, indeterminate, or malignant based on the Bethesda System for Reporting Thyroid Cytopathology or non-diagnostic. The study implemented a multinomial logistic regression model where the TI-RADS category was the main independent variable, with the following control variables: gender, age, echogenic foci, and PET detection. Additionally, the study evaluated all possible 2-way interactions of control variables using a backwards elimination strategy to remove interactions with $p<0.05$. An ordinal logistic regression was used to determine if higher TI-RADS scores were associated with higher probability of malignancy.

RESULTS

The percentage of malignant nodules in each TI-RADS (TR) category were as follows: TR 2- 0%, TR 3-4.9%, TR 4-3.6%, TR 5-16.3%. The odds ratio for a 1-unit increase in TIRADS was 3.16 [95% CI: 1.25, 7.98, p=0.015] for malignant pathology, consistent with increasing malignant risk with increasing TI-RADS score. No control variables or 2-way interactions were significant.

CONCLUSION

s The study supports the use of the TI-RADS model at our institution. The higher TI-RADS scores were significantly associated with malignant pathology on FNA. This validates the recommendation of FNA in nodules with higher TI-RADS scores.

CLINICAL RELEVANCE/APPLICATION

The higher TIRADS scores were associated with higher probability of malignant pathology at FNA. The decision to biopsy thyroid nodules should continue to be based on TIRADS score.

No control variables or 2-way interactions were significant.

CONCLUSION

s The study supports the use of the TI-RADS model at our institution. The higher TI-RADS scores were significantly associated with malignant pathology on FNA. This validates the recommendation of FNA in nodules with higher TI-RADS scores.

CLINICAL RELEVANCE/APPLICATION

The higher TIRADS scores were associated with higher probability of malignant pathology at FNA. The decision to biopsy thyroid nodules should continue to be based on TIRADS score.

Sub-Events

R5B-SPIN-1 A Robustly Optimized Natural Language Processing Model for Label Extraction in Mammography Report

Participants
Yuxing Tang, Bethesda, MD (*Presenter*) Nothing to Disclose

PURPOSE

To explore RoBERTa (robustly retrained BERT model, namely the Bidirectional Encoder Representations from Transformers) in classifying mammography diagnostic text reports to facilitate large-scale weakly-supervised learning for image-based mammography diagnosis systems.

METHODS AND MATERIALS

Weakly-supervised learning from mammogram images requires binary labels for each view to indicate the presence of a lesion type. Previously these labels were either manually labeled by experienced radiologists, or obtained from the diagnostic reports by applying text processing rules or relatively simple natural language processing (NLP) models. We formulate this task as a text classification problem and propose Mammo-RoBERTa by fine-tuning the pre-trained RoBERTa on our large-scale mammogram report data with whole word masking. Mammo-RoBERTa treats each text report as a sample and takes both the description and impression parts of a report as the input. It consists of 12 encoding layers with 768 hidden units and 12 attention heads. We use the final hidden vector corresponding to the first input token as the aggregate representation of the input sequence. A linear classification layer and a softmax function are applied to predict the probability that a lesion type is present in a mammogram. A large-scale dataset containing 33,630 mammogram studies with diagnostic reports from 30,495 patients was collected, among which 3,753 studies were manually labeled by radiologists.

RESULTS

We perform three-fold cross-validation on 3,753 mammography studies. Mammo-RoBERTa achieves very high accuracy (98.72%±0.24% and 98.19%±0.27% for left and right breasts, respectively) in predicting the presence of a specified lesion type in the mammogram images from the corresponding text reports, far exceeding the previous rule-based text processing approaches ($p<0.05$). The F1 scores (left: 0.973±0.005, right: 0.958±0.006) and weighted F1 scores (left 0.987±0.005, right: 0.982±0.005) also show that the performance of our Mammo-RoBERTa is very robust in general.

CONCLUSION

s We proposed Mammo-RoBERTa, a RoBERTa model fine-tuned on mammogram report data, which can be used to predict the presence of specific lesion types (e.g., mass) in mammograms with very high accuracy, with input from the text report.

CLINICAL RELEVANCE/APPLICATION

The advanced NLP models, such as RoBERTa, can be fine-tuned on clinical text report data to substantially improve the system performance in automatically understanding the content of pervasive clinical diagnostic reports.

R5B-SPIN-2 Machine Learning Methods Based on Injection Pressure to Detect the Contrast Material Extravasation During CT

Participants
Takeshi Nakaura, MD, Kumamoto, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the performance of a machine learning (ML) method to detect the contrast material extravasation based on injection pressure during computed tomography (CT).

METHODS AND MATERIALS

We enrolled 46,666 patients who underwent contrast enhanced CT examination in one hospital. We chose an 8:2 training-to-validation ratio and developed ML software to predict the risk of contrast material extravasation based on injection pressure of first 6 seconds with 0.25 second interval and injection rate settings. This ML software contains ML classifiers for time series data (kNN, ROCKET, TSF, RISE) and the stacking ensemble ML (LightGBM) using the outputs of other ML classifiers as input data. We trained and evaluated ML classifiers using 5-fold cross-validation using the training data (n = 37,336), and we evaluated the performance of best model in the test data (n = 9,330) using areas under the receiver operating characteristic curves (AUCs).

RESULTS

The contrast material extravasation occurred in 0.20% (94/46,666) of the patients. The stacking ensemble ML gave the highest

The contrast material extravasation occurred in 0.20% (94/46,000) of the patients. The stacking ensemble ML gave the highest performance (AUC = 0.748), followed by the kNN (AUC = 0.728), ROCKET (AUC = 0.71), TSF (AUC = 0.648), and RISE (AUC = 0.654). The performance of stacking ensemble ML did not decrease in the test group (AUC = 0.761).

CONCLUSION

s The stacking ensemble ML offered high performance to detect the contrast material extravasation based on injection pressure during CT as compared with ML methods for time series data.

CLINICAL RELEVANCE/APPLICATION

The stacking ensemble ML based on injection pressure might be the useful tool for the early detection of the contrast material extravasation during CT.

R5B-SPIN-3 F-18 FDG Uptake in Axillary Lymph Nodes after Vaccination Against COVID-19

Participants
Kaoru Maruyama, Osaka, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Little is known about the frequency and duration of increased F-18 fluorodeoxyglucose (FDG) uptake in lymph nodes after vaccination. Increased FDG uptake may be mistaken for a sign of malignancy. We assessed the frequency of increased FDG uptake in axillary lymph nodes after vaccination against the coronavirus disease 2019 (COVID-19).

METHODS AND MATERIALS

We collected vaccination data for all individuals at the time FDG positron emission tomography/computed tomography (PET/CT) imaging. Unilateral FDG uptake in axillary lymph node on side (arm) of last vaccination (or, if individual was not sure about side, higher uptake on either side) was examined.

RESULTS

We used data from 181 vaccinated individuals (including 51 healthy individuals and 130 patients) who received one or two dose of the two type of mRNA Covid-19 vaccines (either Pfizer or Moderna). The frequency of increased FDG uptake was 22% (39/181 individuals), occurred within 1 day, and lasted 122 days after vaccination. No uptake in axillary lymph node was detected from 3 days after the first dose, and from 4 days after the second dose. The median onset of local reactions was 17 days after first dose and 18 days after the second dose. Axillary lymph node FDG positive rate was:63% (12 of 19) of individuals at 3-96 days of vaccination after the first dose; 14% (20 of 147) of individuals at 2-135 days after the second dose; and 47% (7 of 15) of individuals at 1-63 days in the unknown (first or second) dose.

CONCLUSION

s Results are consistent with as many as 22% of individuals and long-lasting of increased FDG uptake in lymph node of COVID-19 vaccination, but waning with time. This potential pitfalls in PET/CT should be borne in mind during current COVID-19 vaccination programs.

CLINICAL RELEVANCE/APPLICATION

As COVID-19 vaccination programs expand worldwide, it will be important for oncologists and radiologists to include history of vaccination in interpreting the results of PET imaging studies.

R5B-SPIN-4 Effect of inter-slice resolution improvement for orbital bone segmentation of facial 3D CT images with different slice thicknesses

Participants
Jinseo An, BS, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To make a customized bone template for reconstruction of fractured orbital bone in cranio-maxillofacial surgery, it is necessary to accurately segment and model the orbital bone on facial CT images. However, it is limited by the aliasing effect due to the thick slice thickness and the partial volume effects in the thin bone area. The purpose of this study is to improve the z-axis resolution of the CT images to 1mm and to validate the effect of improved inter-slice resolution on segmentation of orbital bone with thin bone structures.

METHODS AND MATERIALS

To improve the inter-slice resolution downsampled to 2~3mm, a 2D CNN-based network that considers intensity, gradient, and perceptual differences in the sagittal and axial planes is applied. To accurately segment the orbital bone with thin bone structures, 3D U-Net-based segmentation and post-processing are performed according to the characteristics of the bone by dividing it into cortical and thin bones with different intensity ranges. In the experiment, 355 facial CT images with a resolution of 512 x 512, pixel spacing of 0.4~0.619mm, slice thickness of 1mm were randomly divided into 228 training, 56 validation, and 71 test sets, and evaluation ROIs were defined globally and regionally, including whole orbital bone, medial wall, and floor area. Bilinear and bicubic interpolation were used as comparative methods, and the segmentation results were evaluated using the original images with a slice thickness of 1mm and inter-slice resolution improved images from a slice thickness of 2~3mm.

RESULTS

In the interpolation-based methods, the orbital bone region tends to be under-segmented because it is generated by considering only the intensity values without information on the bone shape. On the other hand, the proposed CNN-based method shows improved segmentation performance because it generates a CT image similar to the original image while maintaining shape information. Especially, the jagged-shaped aliasing effect remains in the generated image of the interpolation-based method at the orbital floor with a horizontally gentle slope and shows the results of segmentation of the broken structure, while the proposed CNN-based method produces a reconstruction image similar to that of the original images.

CONCLUSION

s Our method improved the z-axis resolution of CT images with slice thicknesses greater than 1mm and showed similar segmentation performance to the original CT images, which helped to reduce the aliasing effect of the 3D reconstructed orbital bone. (Project Number: 9991007552, KMDF_PR_20200901_0270)

CLINICAL RELEVANCE/APPLICATION

Our method can be used to provide a customized bone template like a slice thickness of 1 mm, even on facial 3D CT images with a thick slice thickness of 2~3mm.

R5B-SPIR-1 The Interim Report of B-RTO Using Candis System

Participants
Masakatsu Tsurusaki, MD, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

Balloon-occluded retrograde transvenous obliteration (B-RTO) has become widely accepted in Japan as a minimally invasive, highly effective treatment for gastric varices (GV). However, in some cases that involve complex types of afferent or draining veins, the use of standard B-RTO for the treatment of GV is associated with difficulties that can lead to unfavorableresults. In such cases, additional techniques are required for successful treatment. A new coaxial balloon catheter system (CANDIS system) developed in Japan by Tanoue et al. (CVIR 2016) that is characterized by a 5 Fr catheter has a high flexibility and can be coaxially inserted into the guiding catheter in advance. The purpose of this study is to evaluate the midterm results of BRTO for gastric varices using the CANDIS system.

METHODS AND MATERIALS

Between 2012 and 2018, 24 cases (male 8 cases, average age 70 years) were treated by B-RTO with CANDIS system for GV. The procedures, including technical success rate (maneuverability of the catheter and successfully injected sclerosing agent), fluoroscopy time, clinical success rate (disappearance of gastric varices after 6 months), complications, and Child-Pugh score were evaluated retrospectively. We compared to 23 cases treated with a single balloon system in the past.

RESULTS

The etiology was HBV 4, HCV 8, NBNC 13 (alcohol 4, NASH 2, PBC 2, IPNB 1, Blue liver syndrome 1, polycistic liver 1, unknown 2) cases. Four cases to improve shunt encephalopathy. Three cases had been treated with a single balloon system in the past. The average fluoroscopy time was 30.7 minutes (v.s. 39.2 minutes in a single balloon system) and the average amount of EOI used was 15.7 mL (v.s. 15.2mL). Pre B-RTO Hirota grade 1/2/3/4/5 was 3/6/7/8/0 cases, and post B-RTO Hirota grade 1/2/3/4/5 was 15/9/0/0/0 cases. The technical success rate was 100% (24/24 cases), the cases which the CANDIS system was effective was 81.8% (18/22), the clinical success rate was 92% (22/24). Minor vascular injuries occurred at 17% (4/24). Development of esophageal varices were seen at 29% (7/24). Child-Pugh score improved at 33% (8/24).

CONCLUSION

s CANDIS system was useful for single balloon B-RTO failure cases. B-RTO could not only reduce GV but also improve liver function for some cases.

CLINICAL RELEVANCE/APPLICATION

There are still insufficient reports that B-RTO with double interruption system leads to the improvement of mid-term and long-term hepatic functional reserve compared with the conventional methods. In the present study, we retrospectively compared and evaluated the outcomes and the long-term effects on liver functional reserve in patients treated with B-RTO for GVs using conventional and double interruption system.

R5B-SPIR-2 Clinical Outcomes of Prophylactic Perioperative IVC Filter Utility in Patients Undergoing Oncological Surgery

Participants
Mensur Koso, BS, (*Presenter*) Nothing to Disclose

PURPOSE

This study evaluated the clinical outcomes of inferior vena cava (IVC) filter use for pulmonary embolism (PE) prophylaxis in patients undergoing cancer-related surgery.

METHODS AND MATERIALS

This single-center retrospective study analyzed characteristics and outcomes of oncological surgery patients from January 2007 to December 2021 who received perioperative prophylactic IVC filters at a large academic medical center. Inclusion criteria included patients with an active malignancy who were undergoing surgery to either cure or palliate cancer. Dual clinical outcomes were assessed, relating to both venous thromboembolism (VTE) occurrence as well as filter retrieval complications. Any definitive VTE events were evaluated from time of placement until at least 3 months post-surgery, to the time of filter retrieval, or until the most current date of available information if no retrieval occurred. Complications were classified according to the Society of Interventional Radiology (SIR) classification system as major or minor. Clinical outcomes were aggregated using mean and value counts as well as relative frequencies (%) for categorical data.

RESULTS

A total of 252 consecutive oncological surgery patients (female 51%/male 49%; median age, 59) received IVC filters for the perioperative prevention of PE. Average filter dwell time for removed filters was 7.5 months (range, 1-39 mo). 36% of IVC filters were ultimately retrieved. Complications involved 1% (two total) of retrievals and were all classified as minor. 15% of patients experienced DVTs and other extremity VTE events in the post-placement pre-retrieval period, while 2% (n=6) experienced definitive PEs. There were 21 noted incidences of thrombi entrapped within or close to the IVC filters (8%). Primary surgical sites included spine (n=91, 36%), orthopedic extremity/joint (n=49, 19%), genitourinary (n=47, 19%), brain/cranial (n=40, 16%), abdominal (n=18, 7%), mixed locations (n=4, 2%), and chest (n=3, 1%).

CONCLUSION

s IVC filters in an oncological surgery cohort resulted in a low complication rate, demonstrated capture of PE-potential thrombi, and ultimately accomplished a low incidence of PE as well as DVT relative to values reported in the literature.

CLINICAL RELEVANCE/APPLICATION

Cancer patients undergoing surgery represent an at-risk population for VTE, although the role of IVC filter prophylaxis has been underexplored and no filter guidelines exist for this population.

R5B-SPIR-3 Proximal Splenic Artery Embolization in Grade IV or V Splenic Trauma - A Single Centre 11-Year Experience

Participants
Kevin Eng, MD, (*Presenter*) Nothing to Disclose

PURPOSE

1. Assess the effectiveness of proximal splenic artery embolization (SAE) with a vascular plug at stopping bleeding and achieving splenic salvage in patients with American Association for the Surgery of Trauma (AAST) grade IV or V splenic injuries. 2. Compare complication and mortality rates between patients receiving single embolization (vascular plug alone) versus combined embolization (vascular plug and coils).

METHODS AND MATERIALS

A retrospective review was performed. Adult trauma patients with AAST grade IV or V splenic injury who underwent proximal SAE with a vascular plug at our level 1 trauma center between November 2010 and January 2021 were included. Data extracted included: splenic injury grade, presence/size of splenic artery pseudoaneurysms, and type and diameter of the plug and coils (if used). Technical success was defined as successful proximal occlusion of the splenic artery, and clinical success was defined as cessation of bleeding or resolution of pseudoaneurysm within 30 days of embolization. Follow-up imaging and clinical notes were reviewed to determine the rate of moderate to severe adverse events (as defined by the Society of Interventional Radiology Adverse Event Classification), new left pleural effusion, and death. The Chi-square test and T-test were used for hypothesis testing, and a p value of <0.05 was considered statistically significant.

RESULTS

76 patients were included. The rates of technical success, clinical success, and splenic salvage were 100% (76/76), 95% (72/26), and 96% (73/76) respectively. The complication rate was 10% (6/58) in the single embolization group and 33% (6/18) in the combined embolization group; the difference was statistically significant (p=0.03). Complications included: splenic infarction, persistent bleeding/pseudoaneurysm necessitating splenectomy, splenic hematoma, and puncture site pseudoaneurysm. The mortality rate was 2% (1/58) in the single embolization group and 6% (1/18) in the combined embolization group (p >0.05). The rate of new left pleural effusions was comparable between the two groups.

CONCLUSION

s Technical success was achieved in all patients with grade IV or V splenic trauma. Clinical success rate and splenic preservation rate was high and comparable to results from literature. Combined embolization has a higher complication rate than single embolization; mortality rates were not significantly different.

CLINICAL RELEVANCE/APPLICATION

In patients with high grade splenic injury, proximal SAE with a vascular plug is highly effective. Additional coils are often deployed if there is inadequate coverage of the dorsal pancreatic artery origin, however higher complication rates with combined embolization support the use of a vascular plug alone when possible.

R5B-SPIR-4 Contrast Medium Free Selective Adrenal Vein Sampling in The Management of Primary Aldosteronism

Participants
Lars Schimmoeller, MD, Dusseldorf, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To analyse contrast free adrenal vein sampling (AVS) for differentiating unilateral from bilateral disease in patients diagnosed with hypertension due to primary aldosteronism (PA).

METHODS AND MATERIALS

Consecutive patients diagnosed with PA and subsequent contrast medium free AVS between 04/2015 and 12/2020 were retrospectively included in this study. Cross-sectional imaging (CSI), AVS data, and clinical data were analysed regarding diagnostic performance of CSI and AVS. In addition, in subgroup analysis patients with lateralisation receiving adrenalectomy were compared to a control group treated with mineralocorticoid antagonists regarding clinical outcome parameters.

RESULTS

In total 193 patients with contrast medium free AVS were included. A success rate of 88% for bilateral catheterization with a median effective dose of 2.9 mSv was observed. CSI had an accuracy of 60% (95%-CI: 0.52-0.67) in the detection of lateralization when compared with AVS as the reference standard. Patients diagnosed with bilateral adrenal hyperplasia and those

with aldosterone-producing adenoma did not differ in clinical data as systolic blood pressure (sBP) (p=0.63) or number of antihypertensive drugs (NAD) (p=0.11) at baseline examination. In the adrenalectomy group, 28 patients were cured (51%; sBP =130mmHg, no antihypertensive drugs), 18 were improved (33%; decrease of sBP =20mmHg and decreased NAD), and 16 were unchanged (16%; unchanged sBP or decrease <20mmHg with increased NAD or increased sBP <20mmHg and decreased NAD). Both groups differed significantly at follow up examination in sBP (median sBP 130mmHg vs. 140mmHg), NAD (median NAD 0 vs. 2), serum potassium (mean 4.3mmol/l vs. 4.1mmol/l), and serum aldosterone (mean 101pg/ml vs. 349pg/ml) (p<0.05).

CONCLUSION

s Contrast medium free AVS is a reliable procedure in the diagnostic management of patients with PA with high technical success rate. The accordance between CSI and results from AVS was only moderate indicating the central role of AVS in the diagnostic work-up of patients with PA. Patients with predominant disease diagnosed with AVS had a high cure rate and/or significant improvement after adrenalectomy.

CLINICAL RELEVANCE/APPLICATION

Contrast medium is not needed at all for adrenal vein sampling in patients with primary hyperaldosteronism. AVS still has an important role in the diagnostic pathway as the accordance with CT scans for detecting unilateral disease was only moderate.

R5B-SPIR-5 Retrospective Review of Optimal Catheter to Vein Size Ratio of Peripherally Inserted Central Catheters (PICC) Line Procedures to Prevent the Symptomatic Deep Venous Thrombosis (DVT) in Pediatric Oncology Patients

Participants
Parth Patel, Germantown, TN (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the effects of catheter to vein size (CV) ratio (ratio comparing the diameter of catheter inserted to the vein diameter at the needle puncture site) on incidences of symptomatic DVT corresponding to PICC line insertion in pediatric oncology patients and to identify the optimal CV size ratio as a threshold ratio to prevent PICC related DVT.

METHODS AND MATERIALS

This retrospective, observational cohort study reviewed pediatric oncology patients at our hospital between January 2019 to December 2021 who had a PICC line placed. Vein diameter was measured at the site of needle access at the time of PICC line placement. A tourniquet was placed around the arm just below the shoulder before PICC placement in each patient. Patient demographics and medical history was collected from the Electronic Medical Record System (EMR). PICC line procedure and technique specific data (Date of procedure, arm placement, PICC lumens, Size of PICC line, Size of Catheter, Vein accessed) were also collected.

RESULTS

Data from 207 pediatric oncology patients (18% Leukemia, 20% Lymphoma, 62% Other) who had PICC line placed was reviewed. Median age was 11 years with 61% males. Study had 14 cases symptomatic DVT related to PICC placement. Receiver Operator Characteristic Curve and Regression Model (ROC) identified that a 49% CV ratio made for an optimal threshold point to maximize sensitivity and specificity (AUC=0.8031, 95% CI-0.7189-0.8873). It was found that the patients with a CV ratio of >49% were 20 times more likely to suffer DVT (p=0.001). On univariate analyses, age, sex, race, catheter size, number of lumens, site of vein or arm for PICC line placement did not reveal any significance.

CONCLUSION

s The study found that a CV ratio of 49% in PICC line procedure was the optimal threshold point with high sensitivity and specificity to reduce risk of PICC related DVT in pediatric oncology patients.

CLINICAL RELEVANCE/APPLICATION

Application of the optimal CV ratio during PICC line insertion procedures could significantly decrease the incidences of PICC line related symptomatic DVTs in pediatric oncology patients.

R5B-SPIR-8 Transjugular Intrahepatic Portosystemic Shunts: A Retrospective Comparative Study of Primary Outcomes Between 6mm, 8mm, 10mm and 12mm Diameter Stents

Participants
Howard Dabbous, MD, Atlanta, GA (*Presenter*) Nothing to Disclose

PURPOSE

To compare differences in primary and clinical outcomes between the different stent diameter sizes utilized in Transjugular intrahepatic portosystemic shunts (TIPS).

METHODS AND MATERIALS

We conducted a retrospective analysis of patients who underwent TIPS placement of sizes 6mm, 8mm, 10mm, and 12mm between 2004 and 2022. Data was collected on baseline characteristics (age, gender, race, MELD-score, Child Pugh score, comorbidities predisposing to thrombosis, liver disease etiology, and indication for TIPS) and on peri- and post-procedural variables (stent size, angioplasty balloon size, adjunct procedures, e.g., embolization, paracentesis and thoracentesis). Measured outcomes consisted of technical success, pre- and post- TIPS portosystemic gradient (PSG), clinical resolution of the indication, hepatic encephalopathy (HE) symptoms. Primary outcomes were patency, liver transplant (LT), death, TIPS revision, and TIPS occlusion and analyzed at 1 year.

RESULTS

A total of 331 patients were evaluated with 30, 111, 118, and 72 patients for sizes 6mm, 8mm, 10mm, and 12mm respectively. TIPS creation was technically successful in all 331 patients (100%). The average percent reduction in PSG for the 4 different stent sizes were -40.5%, -54.8%, -63%, and -71.5% respectively. Resolution of variceal hemorrhage was achieved in 6/9 (67%), 39/45 (87%),

36/38 (95%), and 31/32 (97%) patients who received size 6mm, 8mm, 10mm,and 12mm, respectively. Between the above stent sizes, respectively, decreased ascites/hydrothorax was observed in 8/14(57%), 32/37 (86%), 31/42 (74%), and 22/25 (88%) patients, and new or worsening HE was seen in 10/21 (48%), 23/73 (32%), 23/87 (26%), and 27/55 (49%) patients. At 1-year, patency was 1/6, 26/30, 46/52, and 47/47 of remaining patients. By 1 year, 4/30, 6/111, 7/118, and 3/72 patients underwent LT and 5/30 (17%), 21/111(19%), 21/118 (18%), and 4/72 (6%) patients were deceased. Additionally, 12/30, 12/111, 18/118, and 10/72 patients received a TIPS revision and a further 5/30, 4/111, 6/118, and 0/72 found to have TIPS occlusion.

CONCLUSION

s The various stent sizes overall had similar clinical resolution rates. 1-year mortality rates were similar but lowest for the 12mm size.

CLINICAL RELEVANCE/APPLICATION

For patients receiving TIPS, the varying sizes offer similar resolution of symptoms and 1-year mortality rates.

The Interim Report of B-RTO Using Candis System

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - IR DPS

Participants
Masakatsu Tsurusaki, MD, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

Balloon-occluded retrograde transvenous obliteration (B-RTO) has become widely accepted in Japan as a minimally invasive, highly effective treatment for gastric varices (GV). However, in some cases that involve complex types of afferent or draining veins, the use of standard B-RTO for the treatment of GV is associated with difficulties that can lead to unfavorableresults. In such cases, additional techniques are required for successful treatment. A new coaxial balloon catheter system (CANDIS system) developed in Japan by Tanoue et al. (CVIR 2016) that is characterized by a 5 Fr catheter has a high flexibility and can be coaxially inserted into the guiding catheter in advance. The purpose of this study is to evaluate the midterm results of BRTO for gastric varices using the CANDIS system.

METHODS AND MATERIALS

Between 2012 and 2018, 24 cases (male 8 cases, average age 70 years) were treated by B-RTO with CANDIS system for GV. The procedures, including technical success rate (maneuverability of the catheter and successfully injected sclerosing agent), fluoroscopy time, clinical success rate (disappearance of gastric varices after 6 months), complications, and Child-Pugh score were evaluated retrospectively. We compared to 23 cases treated with a single balloon system in the past.

RESULTS

The etiology was HBV 4, HCV 8, NBNC 13 (alcohol 4, NASH 2, PBC 2, IPNB 1, Blue liver syndrome 1, polycistic liver 1, unknown 2) cases. Four cases to improve shunt encephalopathy. Three cases had been treated with a single balloon system in the past. The average fluoroscopy time was 30.7 minutes (v.s. 39.2 minutes in a single balloon system) and the average amount of EOI used was 15.7 mL (v.s. 15.2mL). Pre B-RTO Hirota grade 1/2/3/4/5 was 3/6/7/8/0 cases, and post B-RTO Hirota grade 1/2/3/4/5 was 15/9/0/0/0 cases. The technical success rate was 100% (24/24 cases), the cases which the CANDIS system was effective was 81.8% (18/22), the clinical success rate was 92% (22/24). Minor vascular injuries occurred at 17% (4/24). Development of esophageal varices were seen at 29% (7/24). Child-Pugh score improved at 33% (8/24).

CONCLUSION

s CANDIS system was useful for single balloon B-RTO failure cases. B-RTO could not only reduce GV but also improve liver function for some cases.

CLINICAL RELEVANCE/APPLICATION

There are still insufficient reports that B-RTO with double interruption system leads to the improvement of mid-term and long-term hepatic functional reserve compared with the conventional methods. In the present study, we retrospectively compared and evaluated the outcomes and the long-term effects on liver functional reserve in patients treated with B-RTO for GVs using conventional and double interruption system.

Clinical Outcomes of Prophylactic Perioperative IVC Filter Utility in Patients Undergoing Oncological Surgery

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - IR DPS

Participants
Mensur Koso, BS, (*Presenter*) Nothing to Disclose

PURPOSE

This study evaluated the clinical outcomes of inferior vena cava (IVC) filter use for pulmonary embolism (PE) prophylaxis in patients undergoing cancer-related surgery.

METHODS AND MATERIALS

This single-center retrospective study analyzed characteristics and outcomes of oncological surgery patients from January 2007 to December 2021 who received perioperative prophylactic IVC filters at a large academic medical center. Inclusion criteria included patients with an active malignancy who were undergoing surgery to either cure or palliate cancer. Dual clinical outcomes were assessed, relating to both venous thromboembolism (VTE) occurrence as well as filter retrieval complications. Any definitive VTE events were evaluated from time of placement until at least 3 months post-surgery, to the time of filter retrieval, or until the most current date of available information if no retrieval occurred. Complications were classified according to the Society of Interventional Radiology (SIR) classification system as major or minor. Clinical outcomes were aggregated using mean and value counts as well as relative frequencies (%) for categorical data.

RESULTS

A total of 252 consecutive oncological surgery patients (female 51%/male 49%; median age, 59) received IVC filters for the perioperative prevention of PE. Average filter dwell time for removed filters was 7.5 months (range, 1-39 mo). 36% of IVC filters were ultimately retrieved. Complications involved 1% (two total) of retrievals and were all classified as minor. 15% of patients experienced DVTs and other extremity VTE events in the post-placement pre-retrieval period, while 2% (n=6) experienced definitive PEs. There were 21 noted incidences of thrombi entrapped within or close to the IVC filters (8%). Primary surgical sites included spine (n=91, 36%), orthopedic extremity/joint (n=49, 19%), genitourinary (n=47, 19%), brain/cranial (n=40, 16%), abdominal (n=18, 7%), mixed locations (n=4, 2%), and chest (n=3, 1%).

CONCLUSION

s IVC filters in an oncological surgery cohort resulted in a low complication rate, demonstrated capture of PE-potential thrombi, and ultimately accomplished a low incidence of PE as well as DVT relative to values reported in the literature.

CLINICAL RELEVANCE/APPLICATION

Cancer patients undergoing surgery represent an at-risk population for VTE, although the role of IVC filter prophylaxis has been underexplored and no filter guidelines exist for this population.

R5B-SPIR-3

Proximal Splenic Artery Embolization in Grade IV or V Splenic Trauma - A Single Centre 11-Year Experience

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - IR DPS

Participants
Kevin Eng, MD, (*Presenter*) Nothing to Disclose

PURPOSE

1. Assess the effectiveness of proximal splenic artery embolization (SAE) with a vascular plug at stopping bleeding and achieving splenic salvage in patients with American Association for the Surgery of Trauma (AAST) grade IV or V splenic injuries. 2. Compare complication and mortality rates between patients receiving single embolization (vascular plug alone) versus combined embolization (vascular plug and coils).

METHODS AND MATERIALS

A retrospective review was performed. Adult trauma patients with AAST grade IV or V splenic injury who underwent proximal SAE with a vascular plug at our level 1 trauma center between November 2010 and January 2021 were included. Data extracted included: splenic injury grade, presence/size of splenic artery pseudoaneurysms, and type and diameter of the plug and coils (if used). Technical success was defined as successful proximal occlusion of the splenic artery, and clinical success was defined as cessation of bleeding or resolution of pseudoaneurysm within 30 days of embolization. Follow-up imaging and clinical notes were reviewed to determine the rate of moderate to severe adverse events (as defined by the Society of Interventional Radiology Adverse Event Classification), new left pleural effusion, and death. The Chi-square test and T-test were used for hypothesis testing, and a p value of <0.05 was considered statistically significant.

RESULTS

76 patients were included. The rates of technical success, clinical success, and splenic salvage were 100% (76/76), 95% (72/26), and 96% (73/76) respectively. The complication rate was 10% (6/58) in the single embolization group and 33% (6/18) in the combined embolization group; the difference was statistically significant ($p=0.03$). Complications included: splenic infarction, persistent bleeding/pseudoaneurysm necessitating splenectomy, splenic hematoma, and puncture site pseudoaneurysm. The mortality rate was 2% (1/58) in the single embolization group and 6% (1/18) in the combined embolization group ($p >0.05$). The rate of new left pleural effusions was comparable between the two groups.

CONCLUSION

s Technical success was achieved in all patients with grade IV or V splenic trauma. Clinical success rate and splenic preservation rate was high and comparable to results from literature. Combined embolization has a higher complication rate than single embolization; mortality rates were not significantly different.

CLINICAL RELEVANCE/APPLICATION

In patients with high grade splenic injury, proximal SAE with a vascular plug is highly effective. Additional coils are often deployed if there is inadequate coverage of the dorsal pancreatic artery origin, however higher complication rates with combined embolization support the use of a vascular plug alone when possible.

Contrast Medium Free Selective Adrenal Vein Sampling in The Management of Primary Aldosteronism

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - IR DPS

Participants
Lars Schimmoeller, MD, Dusseldorf, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To analyse contrast free adrenal vein sampling (AVS) for differentiating unilateral from bilateral disease in patients diagnosed with hypertension due to primary aldosteronism (PA).

METHODS AND MATERIALS

Consecutive patients diagnosed with PA and subsequent contrast medium free AVS between 04/2015 and 12/2020 were retrospectively included in this study. Cross-sectional imaging (CSI), AVS data, and clinical data were analysed regarding diagnostic performance of CSI and AVS. In addition, in subgroup analysis patients with lateralisation receiving adrenalectomy were compared to a control group treated with mineralocorticoid antagonists regarding clinical outcome parameters.

RESULTS

In total 193 patients with contrast medium free AVS were included. A success rate of 88% for bilateral catheterization with a median effective dose of 2.9 mSv was observed. CSI had an accuracy of 60% (95%-CI: 0.52-0.67) in the detection of lateralization when compared with AVS as the reference standard. Patients diagnosed with bilateral adrenal hyperplasia and those with aldosterone-producing adenoma did not differ in clinical data as systolic blood pressure (sBP) (p=0.63) or number of antihypertensive drugs (NAD) (p=0.11) at baseline examination. In the adrenalectomy group, 28 patients were cured (51%; sBP =130mmHg, no antihypertensive drugs), 18 were improved (33%; decrease of sBP =20mmHg and decreased NAD), and 16 were unchanged (16%; unchanged sBP or decrease <20mmHg with increased NAD or increased sBP <20mmHg and decreased NAD). Both groups differed significantly at follow up examination in sBP (median sBP 130mmHg vs. 140mmHg), NAD (median NAD 0 vs. 2), serum potassium (mean 4.3mmol/l vs. 4.1mmol/l), and serum aldosterone (mean 101pg/ml vs. 349pg/ml) (p<0.05).

CONCLUSION

s Contrast medium free AVS is a reliable procedure in the diagnostic management of patients with PA with high technical success rate. The accordance between CSI and results from AVS was only moderate indicating the central role of AVS in the diagnostic work-up of patients with PA. Patients with predominant disease diagnosed with AVS had a high cure rate and/or significant improvement after adrenalectomy.

CLINICAL RELEVANCE/APPLICATION

Contrast medium is not needed at all for adrenal vein sampling in patients with primary hyperaldosteronism. AVS still has an important role in the diagnostic pathway as the accordance with CT scans for detecting unilateral disease was only moderate.

Retrospective Review of Optimal Catheter to Vein Size Ratio of Peripherally Inserted Central Catheters (PICC) Line Procedures to Prevent the Symptomatic Deep Venous Thrombosis (DVT) in Pediatric Oncology Patients

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - IR DPS

Participants
Parth Patel, Germantown, TN (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the effects of catheter to vein size (CV) ratio (ratio comparing the diameter of catheter inserted to the vein diameter at the needle puncture site) on incidences of symptomatic DVT corresponding to PICC line insertion in pediatric oncology patients and to identify the optimal CV size ratio as a threshold ratio to prevent PICC related DVT.

METHODS AND MATERIALS

This retrospective, observational cohort study reviewed pediatric oncology patients at our hospital between January 2019 to December 2021 who had a PICC line placed. Vein diameter was measured at the site of needle access at the time of PICC line placement. A tourniquet was placed around the arm just below the shoulder before PICC placement in each patient. Patient demographics and medical history was collected from the Electronic Medical Record System (EMR). PICC line procedure and technique specific data (Date of procedure, arm placement, PICC lumens, Size of PICC line, Size of Catheter, Vein accessed) were also collected.

RESULTS

Data from 207 pediatric oncology patients (18% Leukemia, 20% Lymphoma, 62% Other) who had PICC line placed was reviewed. Median age was 11 years with 61% males. Study had 14 cases symptomatic DVT related to PICC placement. Receiver Operator Characteristic Curve and Regression Model (ROC) identified that a 49% CV ratio made for an optimal threshold point to maximize sensitivity and specificity (AUC=0.8031, 95% CI-0.7189-0.8873). It was found that the patients with a CV ratio of >49% were 20 times more likely to suffer DVT (p=0.001). On univariate analyses, age, sex, race, catheter size, number of lumens, site of vein or arm for PICC line placement did not reveal any significance.

CONCLUSION

s The study found that a CV ratio of 49% in PICC line procedure was the optimal threshold point with high sensitivity and specificity to reduce risk of PICC related DVT in pediatric oncology patients.

CLINICAL RELEVANCE/APPLICATION

Application of the optimal CV ratio during PICC line insertion procedures could significantly decrease the incidences of PICC line related symptomatic DVTs in pediatric oncology patients.

Transjugular Intrahepatic Portosystemic Shunts: A Retrospective Comparative Study of Primary Outcomes Between 6mm, 8mm, 10mm and 12mm Diameter Stents

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - IR DPS

Participants
Howard Dabbous, MD, Atlanta, GA (*Presenter*) Nothing to Disclose

PURPOSE

To compare differences in primary and clinical outcomes between the different stent diameter sizes utilized in Transjugular intrahepatic portosystemic shunts (TIPS).

METHODS AND MATERIALS

We conducted a retrospective analysis of patients who underwent TIPS placement of sizes 6mm, 8mm, 10mm, and 12mm between 2004 and 2022. Data was collected on baseline characteristics (age, gender, race, MELD-score, Child Pugh score, comorbidities predisposing to thrombosis, liver disease etiology, and indication for TIPS) and on peri- and post-procedural variables (stent size, angioplasty balloon size, adjunct procedures, e.g., embolization, paracentesis and thoracentesis). Measured outcomes consisted of technical success, pre- and post- TIPS portosystemic gradient (PSG), clinical resolution of the indication, hepatic encephalopathy (HE) symptoms. Primary outcomes were patency, liver transplant (LT), death, TIPS revision, and TIPS occlusion and analyzed at 1 year.

RESULTS

A total of 331 patients were evaluated with 30, 111, 118, and 72 patients for sizes 6mm, 8mm, 10mm, and 12mm respectively. TIPS creation was technically successful in all 331 patients (100%). The average percent reduction in PSG for the 4 different stent sizes were -40.5%, -54.8%, -63%, and -71.5% respectively. Resolution of variceal hemorrhage was achieved in 6/9 (67%), 39/45 (87%), 36/38 (95%), and 31/32 (97%) patients who received size 6mm, 8mm, 10mm,and 12mm, respectively. Between the above stent sizes, respectively, decreased ascites/hydrothorax was observed in 8/14(57%), 32/37 (86%), 31/42 (74%), and 22/25 (88%) patients, and new or worsening HE was seen in 10/21 (48%), 23/73 (32%), 23/87 (26%), and 27/55 (49%) patients. At 1-year, patency was 1/6, 26/30, 46/52, and 47/47 of remaining patients. By 1 year, 4/30, 6/111, 7/118, and 3/72 patients underwent LT and 5/30 (17%), 21/111(19%), 21/118 (18%), and 4/72 (6%) patients were deceased. Additionally, 12/30, 12/111, 18/118, and 10/72 patients received a TIPS revision and a further 5/30, 4/111, 6/118, and 0/72 found to have TIPS occlusion.

CONCLUSION

s The various stent sizes overall had similar clinical resolution rates. 1-year mortality rates were similar but lowest for the 12mm size.

CLINICAL RELEVANCE/APPLICATION

For patients receiving TIPS, the varying sizes offer similar resolution of symptoms and 1-year mortality rates.

R5B-SPMK-1 Fast kVp-Switching Dual-energy Computed Tomography Water-hydroxyapatite Decomposition Technique for Detection of Vertebral Compression Fractures Related Bone Marrow Edema in Comparison with Magnetic Resonance Imaging

Participants
Xuee Zhu, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To assess the fast kVp - switching dual-energy computed tomography (DECT) water-hydroxyapatite (HAP) decomposition technique for detection of traumatic bone marrow edema (BME) in patients with vertebral compression fractures (VCFs) compared with that on magnetic resonance imaging (MRI).

METHODS AND MATERIALS

A total of 53 consecutive patients with 338 vertebrae who underwent both DECT and MRI of the spine within 3 days after trauma were retrospectively enrolled. All vertebral bodies were blindly evaluated for the presence of BME on sagittal water-(HAP) images by using color-coded maps. Water concentration and maximum area of BME were measured in those edematous vertebral bodies. Water concentration was also assessed in either chronic VCFs or normal vertebrae. An experienced radiologist blindly evaluated the presence of BME on MR images(reference standard) and calculated the maximum area of it. One-way ANOVA was used to compare water concentration among different groups. The receiver operating characteristic (ROC) curve analysis was conducted and the threshold of water concentration was calculated. Bland Altman analysis was performed to evaluate the consistency of the maximum area of BME measured on CT and MRI.

RESULTS

MRI depicted 53 acute VCFs, 37 chronic VCFs and 248 normal vertebrae. In the visual analysis of VCFs, DECT had an overall sensitivity of 98.1%, specificity of 99.6%, accuracy of 99.4%, positive predictive value of 98.1%, and negative predictive value of 99.6%, respectively. The water concentration had a significant difference between acute and chronic VCFs ($P<0.01$) and between acute VCFs and normal vertebrae ($P<0.01$), but had no significant difference between chronic VCFs and normal vertebrae bodies ($P=0.86$). The ROC analysis of water concentration achieved an AUC of 0.994, and the optimal threshold of 992.5mg/cm^3 provided a sensitivity of 96.2% and specificity of 93.0%. Bland-Altman plots indicated that the maximum area of BME measured on CT and MRI was highly consistent.

CONCLUSION

s Fast kVP-switching DECT water-(HAP) decomposition technique had an excellent diagnostic performance for distinguishing acute VCFs from chronic ones both in visual and quantitative analyses. The depicted areas of BME on DECT and MR were almost the same.

CLINICAL RELEVANCE/APPLICATION

Single-energy CT of the spine is the standard examination for fast exclusion or closer assessment of vertebral compression fractures (VCFs). However, it is sometimes difficult to distinguish between acute and chronic VCFs. Although MRI is the reference standard to distinguish acute and old VCFs, it is contraindicated in many patients. DECT can quickly depict the areas of bone marrow edema to identify acute VCFs from chronic ones with a high sensitivity and specificity.

In this study, we presented our experiences on incidental focal colorectal, thyroid and prostate hypermetabolism to justify the application of F-18 FDG PET/CT imaging to the oncologic patients and the subjects at high risk of developing cancer.

METHODS AND MATERIALS

The final reports of a total of 16,010 F-18 FDG PET/CT scans performed at our hospital between January 2016 and January 2022 were retrospectively reviewed to identify unexpectedly observed focal colorectal or thyroid or prostate FDG uptake. They are classified as malignant, premalignant (for colon/rectum), and benign according to their histopathological reports. The effective dose from FDG PET/CT was estimated and the hypermetabolic uptake was measured and compared amongst the groups to confirm whether the PET parameters were useful in distinguishing malignant from benign lesions and to identify cut-offs.

RESULTS

The estimated average effective dose from a F-18 FDG PET/CT scan was 7.3 ± 0.8mSv, which was comparable to that of pre- and post-contrast chest or abdominal pelvic CT. Overall, 61.6% of the focal colorectal uptake were malignant/premalignant lesions and 59.6% of the focal thyroid uptake were malignant lesions. 56.4% of the focal prostate uptake were malignant Lesions. Maximum SUV was an independent diagnostic parameter to differentiate malignant (and premalignant) from benign lesions in both incidental focal colorectal and thyroid FDG uptake.

CONCLUSION

s With advances in hardware and software technology related to PET/CT equipment, radiation exposure during a F-18 FDG PET/CT scan is gradually decreasing. Incidentally observed focal hypermetabolic colon/rectum or thyroid uptake showed a high rate (approximately 60%) of malignant (or premalignant for colon/rectum) lesions. Hence, these findings justify the encouraged application of PET imaging to the oncologic patients and the subjects at high risk of developing cancer.

CLINICAL RELEVANCE/APPLICATION

Unexpected incidental focal F-18 FDG activity is not an uncommon finding in the clinical PET studies. Due to high malignancy/premalignancy rate in the colorectal or thyroid lesions with incidental focal uptake, authors recommend further active assessment.

R5B-SPNMMI-2 Pre- to Post-Treatment Evolution of PET-CT Parameters in CAR-T Cell Treatment of Lymphoma

Participants
Michael Winkelmann, MD, Munich, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Chimeric antigen receptor (CAR) T-cell therapy with patient-derived T cells against tumor cells are approved for relapsed or refractory (r/r) diffuse large B-cell lymphoma (DLBCL). Anti-tumor activity differs from conventional treatment strategies with so far undefined response criteria. We evaluated changes in morphologic and metabolic parameters from baseline to 3 months and their prognostic value for overall survival (OS).

METHODS AND MATERIALS

Consecutive r/r DLBCL patients with PET-CT imaging at baseline and at 3 months after CAR T-cell transfusion were selected. Overall response was determined based on Lugano criteria with up to 6 target lesions. The sum of the product of diameters (SPD) was used to represent tumor burden and its percent reduction over time (depth of response, DoR). Maximum standard uptake value percent reduction between baseline and 3 months (?SUV) was applied as metabolic response parameter.

RESULTS

22 patients were included (median age: 67 years, 64% male) with median baseline SPD of 6088 mm2 and SUVmax of 25.8. According to Lugano criteria, 12 patients (55%) were in complete metabolic remission at 3 months. A color-coded waterfall plot

shows DoR together with the Lugano response category (Figure 1). The median tumor burden and metabolism were reduced in DoR by 81.5% and in ?SUV by 62.1%. Among patients with reduction in tumor burden and metabolism, DoR and ?SUV showed good correlation (r=0.71, p<0.001, Figure 2A). DoR=50%, ?SUV=40% and complete metabolic response per Lugano showed significant stratification of OS (each with p=0.05; Figure 2B-D).

CONCLUSION

s For r/r DLBCL patients undergoing CAR T-cell therapy, morphologic and metabolic parameters represent different properties. Our preliminary data indicate that both DoR and ?SUV at 3 months may have prognostic information. Further studies should determine which individual parameter or combination is most suitable for survival prognostication after CAR T-cell therapy.

CLINICAL RELEVANCE/APPLICATION

CAR T-cell therapy has emerged as a new effective antigen-driven cell-based immunotherapy to treat patients with r/r DLBCL. Identifying early prognostic parameters is crucial to guide patient care.

R5B-SPNPM-1 Gadolinium-Based Contrast Agent Guideline Considering Serum Bilirubin Level in Patients With Impaired Renal Function for Rapid Elimination and Minimal Retention of Gadolinium

Participants
Jeong Woo Kim, MD, PhD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

In our institution, a gadolinium-based contrast agent (GBCA) guideline for patients with impaired renal function was devised by the consensus of radiologists and nephrologists. This study aimed to evaluate clinical outcomes after following the guideline for seven years in a tertiary hospital.

METHODS AND MATERIALS

This retrospective study identified all patients who were referred to the radiology department due to elevated serum creatinine level among patients scheduled for GBCA-enhanced MRI between January 2012 and December 2018. GBCAs have different concentrations of gadolinium [0.25 M for gadoxetic acid (GA); 0.5 M for gadoterate meglumine (GM); 1.0 M for gadobutrol (GB)] and excretion pathways [dual pathways (50% renal and 50% biliary excretion) for GA; 100% renal excretion for GM and GB]. Considering these characteristics of GBCAs, hemodialysis, estimated glomerular filtration rate (eGFR), serum bilirubin level, and previous GBCA-enhanced MRI examination, patients underwent MRI with the contrast medium and dose recommended in the guideline. GA was recommended for patients with normal serum bilirubin level, and GM or GB was recommended for patients with elevated serum bilirubin level at an adjusted dose. A search of electronic medical records was performed to assess NSF occurrence. In patients who underwent brain MRI during the follow-up period, gadolinium depositions (high signal intensity within dentate nucleus and globus pallidus on precontrast T1-weighted image) were evaluated.

RESULTS

Of the 313 referred patients, a total of 298 patients underwent GBCA-enhanced MRI according to the guideline. These included 76 patients with eGFR of 15-29 mL/min/1.73 m2 (CKD stage 4) and 126 patients with eGFR <15 mL/min/1.73 m2 (CKD stage 5). There were 106 patients on hemodialysis and 178 patients underwent two or more GBCA-enhanced MRI examinations. Ninety-seven patients with eGFR less than 30 mL/min/1.73m2 or undergoing hemodialysis underwent MRI using GA. During the follow-up period, there was no reported NSF case. In addition, there was no evidence of gadolinium deposition in brain tissues (in 12 patients with CKD stage 5 and 3 patients with CKD stage 4).

CONCLUSION

s The GBCA guideline for the use of different GBCAs at an adjusted dose according to serum bilirubin level may be safe with respect to NSF and gadolinium deposition in brain tissues, although further studies are needed to confirm this.

CLINICAL RELEVANCE/APPLICATION

In consideration of the gadolinium concentration and excretion pathway of GBCAs, the GBCA guideline which recommended different GBCAs at an adjusted dose according to serum bilirubin level, can be safely used for patients with impaired renal function by enabling rapid elimination and minimal retention of gadolinium.

R5B-SPNPM-2 Automatic Diagnosis Extraction Using NLP to Monitor the Impact of Clinical Decision Support on CT for Diagnosis of Pulmonary Embolism

Participants
Abdullah Khan, MD, Sacramento, CA (*Presenter*) Nothing to Disclose

PURPOSE

CMS recently mandated that ordering clinicians consult Clinical Decision Support (CDS) when ordering certain high value imaging tests, including CT Pulmonary Angiography (CTPA) for suspected acute pulmonary embolism (PE). The assumption is that CTPA is overutilized and has a low diagnostic yield, and that CDS will decrease utilization and increase the percentage of CTPA exams that are positive for PE. We developed and validated an NLP-based pipeline to identify whether CTPA reports confirmed the presence of PE, and applied it to a corpus of 6953 reports obtained before and after implementing CDS in December 2019.

METHODS AND MATERIALS

Final radiology report impressions for all CTPA exams ordered from the Emergency Department of our quaternary care hospital

between July 2016 and April 2022 were obtained and manually classified as either confirming the presence of PE or not. The report impressions were also processed through a custom NLP pipeline based on the Clinical Text and Knowledge Extraction System (CTAKES), an open-source biomedical NLP toolset. We applied the CTAKES NegexAnnotator to identify negation status, identified a set of UMLS Concept Unique Identifiers (CUIs) that covered the variety of phrases commonly understood to indicate the presence of pulmonary thromboemboli, and applied a custom heuristic to handle lexical complexities common in radiology reports. We compared the accuracy of the NLP pipeline to the manual annotations using a 2x2 contingency table to measure sensitivity, specificity, and F1 score.

RESULTS

The CTAKES-based NLP pipeline correctly classified 888 exams as true positive, 5909 exams as true negatives, and incorrectly predicted 68 false positives and 88 false negatives, yielding sensitivity=0.91, specificity=0.99, accuracy 0.98, and F1-score 0.92. Monthly aggregate exam positivity is very similar between the manual and NLP-derived classification.

CONCLUSION

s An NLP pipeline based on the open-source CTAKES system is accurate in classifying CTPA reports as positive or negative for PE. Such an automated classification system is useful in monitoring the effectiveness of CDS and other quality-improvement initiatives that purport to improve utilization.

CLINICAL RELEVANCE/APPLICATION

Automatic diagnostic accuracy classification is useful in monitoring the impact of CDS and other efforts that purport to improve healthcare utilization.

R5B-SPNR-1 Effective Atomic Number as a Quantitative CT Marker for Myelin Content: A Validation Study Using Synthetic MRI

Participants
Tomohito Hasegawa, Kagoshima, Japan (*Presenter*) Nothing to Disclose

PURPOSE

The effective atomic number (Zeff) reflects the elemental composition in biological tissues. Our purpose was to validate Zeff as a quantitative CT marker for myelin content in vivo.

METHODS AND MATERIALS

Fifteen patients (5 males and 10 females, age range from 35 to 84 years) with apparently normal cerebral parenchyma who underwent MRI scan and spectral detector CT scan within 1 month were included in this retrospective study. Images of myelin volume fraction (Vmy) were generated from synthetic MRI data using the multiparametric model based on the longitudinal and transverse relaxation rates and proton density. Whole brain spectral detector CT scans were performed using a dual-layer CT system, and images of the conventional CT value (CTconv), electron density (ED), and Zeff were obtained. The CT images were coregistered to the corresponding MR images using SPM12. Two independent observers placed elliptical ROIs in 12 gray matter (GM) and 12 white matter (WM) regions in each brain. Correlations between Vmy and CT parameters were evaluated using the Spearman's rank correlation coefficient for GM, WM, and altogether (GM+WM). The interobserver agreement was evaluated using the intraclass correlation coefficient (ICC).

RESULTS

The Vmy ranged from 0.881% to 32.06% in GM and from 25.34% to 48.32% in WM. CTconv, Zeff, and ED were significantly negatively correlated with Vmy for GM+WM. Zeff showed a strong negative correlation with Vmy (?=-0.783, P<0.001), which was stronger than CTconv (?=-0.715, P<0.001). ED showed only a moderate negative correlation with Vmy (?=-0.448, P<0.001). Only Zeff showed significant correlation with Vmy both in GM (?=-0.407, P<0.001) and WM (?=-0.215, P=0.004). The interobserver agreement was excellent for all measurement (ICC ranged from 0.897 to 0.984).

CONCLUSION

s Myelin content was more strongly reflected in Zeff than ED and CTconv. The negative correlation between Zeff and Vmy may be related to elemental composition of WM which is characterized by higher carbon and lower oxygen mass fractions than GM. The Zeff may serve as a quantitative CT marker for myelin content.

CLINICAL RELEVANCE/APPLICATION

The effective atomic number may serve as a quantitative CT marker for myelin content.

R5B-SPNR-10 Investigation on Pre ASiR-v on Image Quality and Radiation Dose of Non Spectral Scanning: A Phantom Study

Participants
Yaoxing Ma, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the influence of different pre adaptative statistical iterative reconstruction - Veo (ASiR-V) level on the image quality and radiation dose of non spectral scanning.

METHODS AND MATERIALS

A polypropylene cylindrical phantom (QSP Phantom) with nine tubes containing different concentrations of iodine (0, 2.5, 5, 10, 20 mgI/ml) was scanned in using spectral CT (Revolution, GE Healthcare) gemstone spectral imaging (GSI) mode using fast kV switch (80/140 kV) ,the tube current was 485mA, the layer thickness was 1.25mm, the collimation width was 80mm, ,noise index (NI) 5HU, pitch 0.992:1. Three groups of pre-ASiR-V level (30%, 40%, 50%) was used for spectral CT scanning. Eleven groups of images were selected from the scan center and five layers above and below. CT value and the area of ROI were measured. The CT dose

index (CTDI) of different pre ASiR-V level scans was recorded. The dose length product (DLP), CT value and noise (SD) of the tube were recorded. Signal noise ratio (SNR) and contrast to noise ratio (CNR) of tubes was calculated. The DLP across three groups were analyzed by simple linear regression analysis. SD, SNR and CNR across three groups were analyzed by one-way ANOVA.

RESULTS

With the increase of pre-selected ASiR-V level, DLP showed decreasing trend. There was significant difference in DLP among groups (9.24mSv, 7.55mSv,6.00mSv for 30%,40%,50%pre-ASiR-V, respectively. P<0.05). There were no significant differences in SD among groups (10.85±0.80(I20),8.38±0.29(I10),8.10±0.41(H2O), for 30% pre-ASiR-V ,10.86±0.74(I20),8.42±0.29(I10),8.05±0.46(H2O)40% pre-ASiR-V ,11.36±0.76(I20),7.97±0.29(I10),7.76±0.34(H2O),50% pre-ASiR-V , F=2.130, p > 0.05).

CONCLUSION

s With the increase of pre-ASiR-V from 30%,40%,50%, radiation dose was reduced effectively, while the image quality was not changed significantly.

CLINICAL RELEVANCE/APPLICATION

Radiation dose is reduced with the increase of pre-ASiR-V and image quality keeps no change. Correlation of clinical application: through the basic research of phantom, compared with conventional kVp scanning, energy spectrum CT scanning can provide the same image quality scanning radiation dose, at the same time, energy spectrum CT scanning can provide different levels (40-140kev) of single energy and effective atomic number, and more energy spectrum information of base material than conventional kVp scanning, This study has guiding significance for the application of energy spectrum scanning in different clinical scenarios.

R5B-SPNR-13 Effects of Different Weighted Iterative Reconstruction on the Image Quality of Head and Neck CTA

Participants
Deng Jie, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the effect of adaptative statistical iterative reconstructionveo (ASIR-V) algorithm on image quality and application value of head and neck CTA scanning.

METHODS AND MATERIALS

A total of 88 patients underwent head and neck CTA. Image reconstruction was performed using Filtered Back Projection (FBP), 20% ASIR-V algorithm, 40% ASIR-V algorithm, 60% ASIR-V algorithm and 80% ASIR-V algorithm, and perform volume projection and maximum density projection processing on the five groups of images. The effects of different reconstruction methods on the image quality of head and neck CTA were evaluated from the two aspects of objective measurement and subjective score.

RESULTS

Comparison of five groups of different reconstruction methods (filtered back projection method) FBP, 20% ASIR, 40% ASIR, 60% ASIR and 80% ASIR in the blood vessels of the head and neck (aortic arch, left common carotid artery, right common carotid artery) Artery, left middle cerebral artery, right middle cerebral artery, left vertebral artery, right vertebral artery, basilar artery) image quality parameter comparison, there is no statistical difference in CT value and SD value among the five groups of images among each blood vessel (P>0.05); when comparing SNR and CNR, the blood vessels in the eight groups were 80%ASIR>60%ASIR>40%ASIR>20%ASIR>FBP (P<0.05). The Kappa value of the subjective rating of quality is 0.75, with strong consistency. The subjective scores were (4.13±1.669), (4.30±2.607), and (4.93±2.640), respectively, and there was no significant difference in the subjective scores among the three groups (F=0.876, P>0.05).

CONCLUSION

s With the gradual increase of the pre-ASIR-V weight, the CT value did not change significantly, and the image noise gradually increased. At the pre-ASIR-V level of 0~40%, the subjective image score was basically stable, and there was no significant difference in image quality. 60%~80% of the pre-ASIR-V level, the subjective scores in each group showed a gradually decreasing trend, and the image quality decreased obviously and gradually.

CLINICAL RELEVANCE/APPLICATION

When the ASIR value of different weights applied to head and neck CTA scans is 40%, the image quality is the best, which can be used in clinical practice.

R5B-SPNR-14 Description of Magnetic Resonance Fingerprinting in Patients with Amyotrophic Lateral Sclerosis

Participants
Philipp Moser, MD, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

Applicability of 3T Magnetic Resonance Fingerprinting (MRF) T1 and T2 mapping for quantitative analysis of the capsula interna in patients with amyotrophic lateral sclerosis (ALS)

METHODS AND MATERIALS

3T single-step MRF T1 and MRF T2 map data acquisition in addition to conventional multi-step MRI image acquisition was performed in patients diagnosed with ALS. In addition, DTI (b-values 0-2500) was analyzed in seven patients. A ROI-based analysis of relaxation times of the left and right capsula interna was performed. Interclass correlation (ICC, 3 repeats) and Pearson correlation coefficient were done for statistical analysis. Data presented as mean +/- SD.

RESULTS

Eighteen patients (mean age 63.712.7 years, male 61%) were included. We found excellent intra-observer ICC values for MRF T1R 0.985 (0.98-0.99, CI 95%) and MRF T2R 0.998 (0.99-1.0, CI 95%). The mean relaxation time of MRF T1R was 103634.1 ms and of MRF T2R was 2742308 ms. We observed a correlation between the MRF T1R values of the left and right capsula interna (R=0.65,

p=0.003) and the MRF T2R values of the left and right capsula interna (R=0.96, p<0.0001). In addition, we found a correlation between MRF T1R and DTI values (R= -0.54, p=0.044) but no correlation between MRF T1R and ADC nor between MRF T2R and ADC or DTI.

CONCLUSION

s MRF T1 and T2 mapping of the capsula interna was successfully performed in patients with ALS and quantitative assessment may provide additional support in the diagnosis of upper motoneuron involvement.

CLINICAL RELEVANCE/APPLICATION

MRF may assist in the assessment of upper motoneuron involvement and disease progression in patients with ALS.

R5B-SPNR-15 A Clinical Application of 3D High-Resolution Contrast Enhanced MR Neurography With Precise Fat Suppression in Lumbosacral Plexus

Participants
Xiangchuang Kong, Wuhan, China (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this study was to investigate the clinical application of precise fat suppression for 3D high-resolution contrast-enhanced MR neurography of lumbosacral plexus.

METHODS AND MATERIALS

32 patients were prospectively selected: 14 patients (group A) with preset TI, and 22 patients (group B) with accurately calculated TI values. All patients were scanned using a 3.0 T MR scanner (Ingenia CX, Philips Healthcare, the Netherlands) with a 32-element phased-array coil. After intravenous injection of Gd-DTPA (0.15mmol/kg), patients were scanned using the 3D NerveView sequence: TI=220ms in group A and calculated TI in group B by a low resolution and fast 3D NerveView scanning with different TI values (TI=180 200 220 230 250 260 270 280 300 320 ms, TR=2200ms). Images were reconstructed on the scanner by the vendor-supplied software package (Compressed SENSE, Philips Healthcare). The signal intensity of fat, and nerve was measured on the original graph and the MIP graph respectively and the signal intensity ratio of nerve to fat was calculated for evaluation of fat suppression. Then the nerve/fat signal ratio (NFR) was calculated. The IBM SPSS22.0 software was used for statistical analysis, and NFR between the two groups was compared by unpaired sample t-test. P<0.05 indicated a statistically significant difference.

RESULTS

1. The proposed TI scout method could improve fat suppression in MRN dramatically. The calculated NFR (precise fat suppression) (13.26±5.47) was about 425.4% higher than that in the preset TI situation (220ms) (2.39±0.55). The difference between the two groups was statistically significant (t=26.495, P<0.05).2. The detection rates of nerve roots and trunks by the two methods were 100% (18/18,14/14); The detection rates of the nerve tracts and branches in precise fat-suppression sequence were 94.4% (17/18) and 83.3% (15/18), respectively. The detection rates of nerve tracts and branches in the preset method were 92.9% (13/14) and 71.4% (10/14), respectively. There was no statistically significant difference between the two methods in the detection rate of nerve tracts and branches (P=1.00, 0.67).

CONCLUSION

s A fast and easy TI scout-based strategy was proposed to improve the fat suppression in 3D MRN of the lumbosacral plexus, which enhanced the image quality significantly. The NFR was increased by about 425.4% more than that in the vendor-provided preset TI scheme.

CLINICAL RELEVANCE/APPLICATION

A fast and easy TI scout-based strategy was proposed to improve the fat suppression in 3D MR neurography of lumbosacral plexus, which enhanced the image quality significantly. The nerve fat signal intensity ratio was increased by about 425.4% than that in vendor-provided preset TI scheme.

R5B-SPNR-16 Rapid Susceptibility-Weighted Imaging using Wave CAIPI for Differentiation of Diamagnetic and Paramagnetic Signal

Participants
Parker Lawson, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Susceptibility-weighted imaging (SWI) is primarily used for the detection of paramagnetic and diamagnetic substances, typically hemorrhage and calcifications respectively. Differentiation between the two can be difficult on post-processed SWI images as both create a similar magnitude of susceptibility and appearance; however, SWI phase imaging can often distinguish the two as their phase shifts and resultant signals are opposite of each other. Unfortunately, differentiation is not always achievable for larger lesions. Wave CAIPI SWI has been recently developed as an alternative to conventional SWI with reduced scan times. Prior to this investigation, Wave CAIPI SWI phase had not been evaluated for its ability to differentiate between paramagnetic and diamagnetic susceptibility.

METHODS AND MATERIALS

126 Brain MRI studies were prospectively selected with the inclusion of a Wave CAIPI SWI sequence at 1.5T and 3T MR units. The images were evaluated by two radiologists for presence and characterization of susceptibility on both conventional SWI (scan time: 4.8 minutes) and Wave CAIPI (scan time: 1.14 minutes) phase and confirmed with head CTs.

RESULTS

Of the 126 studies, 64 demonstrated a focus of susceptibility on conventional SWI and Wave CAIPI SWI. All 64 were identifiable as diamagnetic or paramagnetic on Wave CAIPI phase with homogeneous black or white signal. There were a total of 31 cases in which larger lesions demonstrated heterogeneous or dipole signal on conventional SWI phase, making interpretation difficult; however, Wave CAIPI SWI phase demonstrated homogenous signal facilitating interpretation that was confirmed by CT.

CONCLUSION

s Wave CAIPI SWI phase is a non-inferior alternative to conventional SWI phase in differentiating between paramagnetic and diamagnetic signal and aids interpretation of larger lesions. The findings of this study, coupled with reduced scan times, support the inclusion of Wave CAIPI SWI sequences into routine brain imaging.

CLINICAL RELEVANCE/APPLICATION

Wave CAIPI SWI phase images offer a non-inferior alternative to conventional SWI for differentiating between intracranial hemorrhage and calcification that can be acquired within less than 1/4th of the scan time.

R5B-SPNR-17 Aberrant Spontaneous Brain Activity in Patients with Dysthyroid Optic Neuropathy: A Resting-State Functional MRI Study

Participants
Ping Liu, MS, (*Presenter*) Nothing to Disclose

PURPOSE

Increasing evidence indicated that DON is not only a disease limited to the visual system, it is an eye-brain disease involves multiple brain regions. The purpose of the study was to investigate the brain functional alteration in patients with DON by evaluating the spontaneous neural activity changes using resting-state functional magnetic resonance imaging (rs-fMRI) with the regional homogeneity (ReHo).

METHODS AND MATERIALS

Forty-seven TAO patients, including 20 with neuropathy (DON) and 27 without neuropathy, and 28 healthy controls (HCs) were recruited, matched for weight, height, age, sex, and educational level. All participants underwent resting-state functional nuclear resonance imaging, and the characteristics of spontaneous brain activity were evaluated employing the regional homogeneity (ReHo) method. Each patient with dysthyroid optic neuropathy also completed the ophthalmopathy examination. The ReHo values were compared among groups. Correlations between ReHo values and clinical metrics were assessed.

RESULTS

Compared with TAOs, DON showed significantly decreased ReHo values in the left insula and right superior temporal gyrus, and increased ReHo values in left posterior cingulum and left precentral cuneus. Compared with HCs, TAOs also showed significantly decreased ReHo values in the left posterior cingulum. Additionally, the changed ReHo values were correlated visual acuity, mean deviation (MD) and pattern standard deviation (PSD) of visual field, and he amplitude and absolute latency of P100 of the visual-evoked potentials (VEPs).

CONCLUSION

s DON patients had altered spontaneous brain activities in the left insula, right superior temporal gyrus, left posterior cingulum and left precentral cuneus. And these brain functional abnormalities associated with the visual function.

CLINICAL RELEVANCE/APPLICATION

The abnormal spontaneous brain activities may be related to the pathological mechanism of DON, which may provide a valuable basis for further research on the clinical management of DON. Moreover, regional homogeneity has the potential for early diagnosis and prevent DON.

R5B-SPNR-18 Identification of Autism Spectrum Disorder (ASD) Patients Using Functional MRI - Nonlinear, Directed, Multivariate Brain Connectivity Analysis by Non-Linear Large-scale Granger Causality (lsNGC)

Participants
Ali Vosoughi, Rochester, NY (*Presenter*) Nothing to Disclose

PURPOSE

To develop and evaluate a novel machine learning method for identifying patients with Autism Spectrum Disorder (ASD) using large-scale Nonlinear Granger Causality (lsNGC) by capturing connectivity differences in resting-state functional MRI (rsfMRI).

METHODS AND MATERIALS

We included the subset of all 93 rsfMRI data sets acquired from ASD patients and healthy controls from two institutions (36 from Olin, Institute of Living at Hartford Hospital, and 57 from University of Pittsburgh School of Medicine: Longitudinal Sample) represented in the publicly available preprocessed Autism Brain Imaging Data Exchange I (ABIDE I) data repository. For calculating directed functional connectivity between brain regions, we have recently developed the large-scale Nonlinear Granger Causality (lsNGC) algorithm [Citation blinded for review] that leverages radial basis function kernel transformation for causal modeling in high-dimensional fMRI time series. A 100-iteration cross-validation approach with 80%/20% train/test ratio was applied, where feature selection was performed on each training set using Kendall's tau rank correlation, followed by support vector machine classification. To quantitatively evaluate diagnostic accuracy of lsNGC for correctly classifying ASD patients and normal controls, we compare its performance with both a recent state-of-the-art causal discovery method (PCMCI, [Runge et al., Science, 2019]), and the current clinical fMRI analysis standard of cross-correlation (CC), reporting accuracy, area under ROC curve (AUC), and f1-score.

RESULTS

The lsNGC rsfMRI analysis method significantly outperformed both PCMCI and the clinical standard CC techniques at classifying ASD patients from healthy subjects, with accuracy/AUC/f1 score of 100%/1.0/100% for lsNGC, 75.4%/0.69/70.0% for PCMCI, and 65.8%/0.61/62.4% for CC, respectively.

CONCLUSION

s Our results suggest that lsNGC significantly improves the diagnostic accuracy of correctly identifying patients with ASD from rsfMRI neuroimaging. We conclude that, when compared to both conventional CC analysis and state-of-the-art PCMCI, lsNGC is better suited to capture disease-related brain network connectivity changes in ASD patients.

CLINICAL RELEVANCE/APPLICATION

The lsNGC method classifies Autism Spectrum Disorder (ASD) patients and controls by identifying relevant changes in fMRI connectivity, suggesting its potential usefulness as a novel diagnostic imaging biomarker for neurologic disease.

R5B-SPNR-19 Three-vessel Selective Pseudo-continuous Arterial Spin Labeling Using Designed Metal Artifacts: A Feasibility Study

Participants
Keizo Tanitame, MD, Hiroshima, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Arterial spin labeling (ASL) of magnetic resonance (MR) imaging is a noninvasive evaluation method for assessing cerebral perfusion, and delineation of individual perfusion territories of cerebral arteries can help in the evaluation of the collateral pathway development in cerebrovascular disease patients. We evaluated the feasibility of three-vessel selective pseudo-continuous ASL (pCASL) using designed metal artifacts.

METHODS AND MATERIALS

We recruited fifteen healthy volunteers, and firstly obtained MR angiography of the brain and whole brain perfusion maps of all the cerebral arteries using three-dimensional pCASL. Then while confirming the anatomical location of common carotid arteries (CCAs), we placed one or two small insulated metals on the skin surface near the right, left or bilateral CCAs at the labeling plane, and performed vessel-selective pCASL using three different kinds of local labeling suppression. From analysis of the perfusion maps of all the cerebral arteries, the right CCA and vertebrobasilar artery (VBA), the left CCA and VBA, and only the VBA, two independent observers inferred and drew the cerebral arterial atlases, and another assessed the coincidence of the schematic atlas and MRA image in each subject.

RESULTS

Three-vessel selective pCASL imaging could be performed in all subjects, and no subjects complained of local heat sensation related to the insulated metals. The coincidence rate of inferred cerebral arterial atlases and MRA images was 86.7% in each observer. In five subjects with incomplete circle of Willis, contralateral routes from well-developed communicating arteries could be inferred from the vessel-selective pCASL images. In a subject with an aberrant branch of the left posterior artery, the perfusion territory of the branch was shown in the vessel-selective pCASL images. Interobserver agreement was 100%. In two subjects, two observers independently suspected anterior to posterior circulation through well-developed bilateral posterior communicating arteries from the vessel-selective pCASL images, but MRA showed that the arteries were absent. These misunderstandings were thought to be due to unexpected suppression effect of the metals on VBA labeling.

CONCLUSION

s We presented a three-vessel selective pCASL using designed metal artifacts. The perfusion territories of individual cerebral arteries could be delineated differently, but attention is needed for the depth of the vertebral arteries.

CLINICAL RELEVANCE/APPLICATION

Three-vessel selective pseudo-continuous arterial spin labeling using designed metal artifacts can be used to obtain individual perfusion maps of bilateral carotid and vertebrobasilar arteries.

R5B-SPNR-2 Feasibility of Ultrashort Echo Time Quantitative Susceptibility Mapping (UTE-QSM) With a 3D Cones Trajectory in the Human Brain

Participants
Sam Sedaghat, MD, La Jolla, CA (*Presenter*) Nothing to Disclose

PURPOSE

Over the past decade, quantitative susceptibility mapping (QSM) has emerged as a promising quantitative MR imaging technique to assess the microenvironment in the brain. In literatures, many new QSM techniques have been proposed, but non-Cartesian ultrashort echo time (UTE) sequences have not been explored. In this study, the feasibility of UTE-QSM based on a 3D spiral cones trajectory is demonstrated in the brain.

METHODS AND MATERIALS

The UTE-QSM sequence based on a 3D cones trajectory was implemented on a 3T clinical MRI scanner (MR 750, GE Healthcare). To show the feasibility, an ex vivo experiment was performed on 3 fresh human brain samples using an 8-ch head coil with the following imaging parameters: TR = 50 ms, TE = 0.032, 4.4, 8.8, 13.2, 17.6, and 22 ms, FA = 20°, FOV = 220x220x80 mm3, matrix = 256x256x80, and readout bandwidth = 166.6 kHz. The scan was repeated with 8 different stretching factors (SFs) of the 3D cones spiral arms: 1.0, 1.1, 1.2, 1.3, 1.4, 1.5, 1.6, and 1.7 with the corresponding scan times of 1383, 1229, 1099, 1005, 920, 857, 794, and 745 sec (acceleration factors (AFs) of 1.00, 1.13, 1.26, 1.38, 1.50, 1.62, 1.74, and 1.86), respectively. An in vivo UTE-QSM was performed on five healthy volunteers (37.6 ± 6.7 years old) using the same imaging protocol except for: matrix = 220x220x80, FOV = 220x220x160 mm3, SF = 1.7 (AF = 1.86), and scan time = 645 sec. The reconstructed complex MR images were processed with a UTE-QSM pipeline established based on a MEDI toolbox.

RESULTS

In the ex vivo experiment, a very high correlation in pixelwise QSM values (i.e., susceptibility) was found between SF of 1.0 and SFs from 1.1 to 1.7: Pearson's correlation 0.987, 0.981, 0.976, 0.972, 0.970, 0.962, and 0.953, respectively with all p-values < 0.05. In the in vivo experiment, the measured QSM values in cortical gray matter, juxtacortical white matter, corpus callosum, caudate, and putamen were 25.4 ± 4.0, -21.8 ± 3.2, -22.6 ± 10.0, 77.5 ± 18.8, and 53.8 ± 7.1 ppb in five volunteers, which correspond well with the values reported in literatures.

CONCLUSION

s In this study, we demonstrated the clinical feasibility of 3D UTE-QSM in the brain for the first time. UTE-QSM with a stretched cones trajectory (i.e., acceleration up to 1.86x) showed reliable estimation of susceptibility in the brain.

CLINICAL RELEVANCE/APPLICATION

The proposed UTE-QSM technique based on an efficient cones trajectory allows whole brain susceptibility mapping in a clinically feasible scan time of ~11 min. UTE-QSM is likely to provide more accurate assessment of calcification, hemorrhage, iron overload, and tumor vascularization as UTE acquisition allows direct imaging of short T2 tissues and robust mapping of their susceptibilities. Moreover, the non-Cartesian UTE-QSM is likely to be more robust to patient motion.

R5B-SPNR-20 The Value of Deep Learning Reconstruction Algorithm in CT Whole Brain Perfusion in Patients with Ischemic Stroke

Participants
Limin Lei, Zhengzhou, China (*Presenter*) Nothing to Disclose

PURPOSE

To compare deep learning-based image reconstruction (DLIR) algorithm and adaptive statistical iterative reconstruction-Veo (ASIR-V) algorithm on the image quality and brain perfusion parameters of whole brain CT perfusion scanning in patients with ischemic stroke due to large vessel occlusion.

METHODS AND MATERIALS

A total of 27 patients with ischemic stroke due to large vessel occlusion were collected prospectively in this study, including 15 cases of acute and 12 cases of chronic, consisted of 22 males and 5 females with a median age of 54(range 30-79 years). All patients underwent whole brain perfusion imaging using latest-generation 16 cm detector coverage CT scanner (APEX CT, GE Healthcare). CT datasets were reconstructed using ASIR-V at a level of 80% (80%ASIR-V) and DLIR with high reconstruction strength level (DLIR-H) with 1.25-mm slice thickness. The volumetric CT dose index (CTDIvol) and dose length product (DLP) for each patient scan were recorded. Objective parameters including CT values and standard deviation (SD) in frontotemporal lobe, gray matter nucleus (caudate lobe, lenticular, thalamus) and posterior limb of internal capsule on the contralateral side, as well as the signal-to-noise ratio (SNR) and contrast-to-noise ratio (CNR) of gray matter nucleus were compared. we performed brain perfusion analysis based on CT Perfusion 4D package and calculated the perfusion parameters such as CBF, CBV, MTT and TTP at the same site as the CT values were measured. Moreover, the functional analysis of ipsilateral cerebral infarction including the brain tissue volume, Tmax average value, CBV average value were conducted with the threshold as CBV beyond 1ml/100g while Tmax within 6 seconds. Differences between continuous data were tested using paired t test or Wilcoxon rank test.

RESULTS

DLIR-H had a lower image noise in frontotemporal lobe, gray matter nucleus and posterior limb of internal capsule than 80% ASIR-V (all $P < 0.001$), while higher SNR and CNR of gray matter nucleus(all $P < 0.001$) without changing the CT values. Moreover, there was no significant difference between DLIR-H and 80% ASIR-V in the perfusion parameters including CBF, CBV, MTT and TTP of gray matter and white matter as well as the Tmax average value, CBV average value with the threshold as CBV beyond 1ml/100g while Tmax within 6 seconds.

CONCLUSION

s In cerebral perfusion scan of patients with ischemic stroke, DLIR-H reconstruction algorithm can effectively improve image quality without changing perfusion parameters and functional parameters.

CLINICAL RELEVANCE/APPLICATION

Deep learning reconstruction algorithm can reduce image noise without changing the vital diagnostic parameters, which throws light on low-dose CT acquisition protocol of clinical cerebral perfusion scans.

R5B-SPNR-3 Label-Free Spectral X-Ray Method for Non-invasively Quantifying Amyloid Burden in the Human Brain

Participants
Eshan Dahal, (*Presenter*) Nothing to Disclose

PURPOSE

To describe a spectral x-ray method based on the small-angle elastic scattering of photons for measuring amyloid burden in the human brain.

METHODS AND MATERIALS

We built a prototype system capable of probing an intact human head using a polychromatic x-ray source with tungsten anode in the diagnostic x-ray energy range and a 2D spectroscopic photon-counting detector (80 x 80, 250-micron pixels) with a 1-mm cadmium telluride (HEXITEC) to record energy (in 1-keV bins) and location of each scattered photons. An energy-dependent transmission correction factor was calculated using spectroscopic measurements of the primary beam. The x-ray beam was pinhole collimated to create a 2-mm pencil beam to irradiate the human head phantom with and without embedded targets. We used a commercially available tissue-mimicking (brain and skull) phantom with slabs and an anthropomorphic human head phantom to assess the recovery of the scattering signature for targets with varying concentrations. By comparing the scattering profiles for areas with and without targets, we report amyloid burden as the area-under-the-peak for the characteristic target peaks which correlates with the mass fraction of amyloid plaques.

RESULTS

Measurements of the head phantom with embedded caffeine targets show well-defined characteristic Bragg peaks at momentum transfer of 8.4 and 18.7 nm-1. We recovered the characteristic peaks with exposure times as low as 60 s. Measurements investigating the effect of sample thickness up to 16 cm and spectral x-ray energies from 30 to 120 keV was evaluated to maximize the scattering signal from the targets.

CONCLUSION

s The findings of the study suggest that the spectral x-ray-based method for non-invasively detecting and quantifying amyloid-like targets embedded within a human head has promise.

CLINICAL RELEVANCE/APPLICATION

Amyloid burden can be used to monitor onset and progression of Alzheimer's disease. The spectral small-angle method described in this study has potential to facilitate more efficient therapeutic clinical trials by providing a fast and label-free amyloid plaque quantification tool as an alternative to amyloid-specific positron emission tomography.

R5B-SPNR-4 How Confident Are You - Contrast-Enhanced T1-weighted SPACE Versus 3D FLASH Sequences for the Detection of Brain Metastases

Participants
Maria Gule-Monroe, MD, Houston, TX (*Presenter*) Nothing to Disclose

PURPOSE

This study aimed to evaluate the utility of contrast-enhanced (CE) T1-weighted 3D fast spin-echo-based SPACE sequence, by comparing to the gradient-echo-based 3D-FLASH sequence (without inversion recovery, IR) for the detection of brain metastases at 3T.

METHODS AND MATERIALS

220 patients at a single institution who were scheduled for brain MRI underwent optimized CE T1-weighted SPACE and 3D-FLASH sequences at 3T as part of a practice quality improvement project. Each scan took approximately 4 minutes, and the order of the two sequences was balanced among the patients. The medical records were retrospectively reviewed, and 79 patients found to have brain metastases at the time of imaging were included. Images were evaluated by 5 CAQ certified neuroradiologists, with at least 2-week separation between scoring sequences for the same patient and 20 patients scored by 2 radiologists. Parameters evaluated included number of metastatic lesions, number of indeterminate lesions, visual assessment of lesion margin, visual assessment of contrast to noise ratio (CNR), presence of image artifact, and overall image quality. In addition, CNR was quantified for solidly enhancing lesions greater than 1 cm.

RESULTS

SPACE detected more lesions than 3D-FLASH in 35 patients, while 3D-FLASH detected more lesions in 10 patients. A greater number of indeterminate lesions were seen on 3D-FLASH (27 patients) vs SPACE (9 patients), mostly related to presence of vascular enhancement seen in 3D-FLASH images. When rating overall image quality, lesion margin and CNR on a Likert scale, SPACE performed better than 3D-FLASH with more image artifact seen on 3D-FLASH. Higher quantitative CNR was found in SPACE than 3D FLASH images (mean=26.9 vs. 19.8, respectively, n=16, p=0.054).

CONCLUSION

s This is the first study to date comparing the performance of CE T1-weighted SPACE to non-IR 3D-FLASH sequence for the detection of brain metastases. The SPACE sequence detects a greater number of metastatic lesions and is rated higher for image quality, lesion margin and CNR with less artifact. Gradient Echo are the most commonly used sequences for detection and radiation treatment planning of brain metastases. Superiority of SPACE for lesion detection and confidence has implications across the diagnostic and therapeutic imaging journey.

CLINICAL RELEVANCE/APPLICATION

This is the first study to date evaluating the performance of CE T1-weighted SPACE to non-IR 3D-FLASH for the detection of brain metastases. Superiority of SPACE for lesion detection and confidence has implications across the diagnostic and therapeutic imaging journey.

R5B-SPNR-5 Characterization of Lenticulostriate Arteries by Combining High Resolution Black-blood T1-weighted with Variable Flip Angles Compressed Sensitivity Encoding at 3.0 Tesla

Participants
Yukun Zhang, Dalian, China (*Presenter*) Nothing to Disclose

PURPOSE

To visualize and characterize lenticulostriate arteries (LSAs) in a short period time on a 3.0T MR scanner, we investigated the feasibility of high resolution black-blood T1-weighted with variable flip angles (T1w TSE-VFA) accelerated by compressed sensitivity encoding (CS-T1w TSE-VFA) and further identify the optimal acceleration factors (AFs) for clinical use.

METHODS AND MATERIALS

14 healthy volunteers (6 males, mean age 29.57±6.17 years) and 7 patients with cerebral infarction (4 males, mean age 50.06±20.13 yeas) were prospectively included and divided into the volunteer group and patient group. T1w TSE-VFA images with different AFs (Parallel imaging (PI) AF=3, CS AF=3,4,5,6) (Table 1) were acquired on a 3.0T scanner (uMR Omega, Imaging Healthcare, Shanghai, China). For objective evaluation, the regions of interest (ROIs) of the middle cerebral artery (MCA), the longest LSA, and corresponding white matter on the original or reformatted images were delineated (Fig.1 a-b). Then the signal intensity (SI) and standard deviation (SD) were measured and contrast-to-noise ratio (CNR): (SILSA/MCA-SIWM)/SDWM was further calculated. For subjective evaluation, the the number and length of LSAs of T1w (Fig.1 c) and subjective scoring (Fig.1 d-f) of T1w TSE-VFA with different AFs were measured. Paired t-test were used to compare CNR of MCA and LSA, number and length of LSAs, and image quality between T1w TSE-VFA with PI AF=3 and with CS AF=3 to 6.

RESULTS

For the volunteer group, when CS AF=6, the number of LSAs were significantly different from that of PI-T1w TSE-VFA ($p<0.05$); when CS AF=5, the length of LSAs and subjective scoring were significantly different from PI-T1w TSE-VFA ($p<0.05$)(Table.3 , Figs.2 and 4). For the patient group, when CS AF=6, the CNR of LSA and subjective scoring were significantly different from PI-T1w TSE-VFA ($p<0.05$); when CS AF=5, length and number of LSAs were significantly different from PI-T1w TSE-VFA ($p<0.05$)(Table 2, Figs. 3 and 4).

CONCLUSION

s CS-T1w TSE-VFA with AF of 3 can provide a better LSA display but time longer; with AF of 4 can balance visualization of LSAs and acquisition time. These sequences had the potential to be used in clinical to provide diagnostic information for preventive medicine at 3 Tesla.

CLINICAL RELEVANCE/APPLICATION

CS-T1w TSE-VFA can be used as a non-invasive head microvasculature examination in asymptomatic subjects and patients with cerebrovascular disease, which will be an important asset in preventive medicine.

R5B-SPNR-6 Reproducible Brain MRI Radiomics Features Achieving Test-Retest, Multi-Scanner, and Computational Reproducibility: A Phantom Study

Participants
Yunhwa Roh, (*Presenter*) Nothing to Disclose

PURPOSE

The image biomarker standardization initiative helped improving computational reproducibility of radiomics features on CT. Nonetheless, reproducible multiparametric MRI sequences across multi-scanner and different algorithms are yet to be standardized. We aimed to determine reproducible radiomic features in multiparametric sequences with multi-scanner and computational methods setting.

METHODS AND MATERIALS

A phantom was scanned twice on a clinical 3 T system (Philips, Siemens, and GE) with T1-weighted (T1w), T2-weighted (T2w), and diffusion-weighted imaging (DWI) sequences. Radiomic features were extracted using pyradiomics (110 features) and MITK (the Medical Imaging Interaction Toolkit) (364 features) from each test-retest and multi-scanner setting. Stable radiomics features were calculated when maintaining 5% cut-off of averaging features among different imaging methods (test-retest and multi-scanner) and computational methods. The stable features were calculated concordance- and intraclass correlation coefficients (CCC and ICC) and compared among sequences.

RESULTS

The number of robust features (CCC = 0.90) was higher for features calculated from DWI than from T1w and T2w images in test-retest analysis. From imaging reproducibility, a total of 79 (23.9%) of 330 features from pyradiomics and 473 (43.3%) of 1092 MITK features showed excellent robustness (ICC = 0.90. Applying both imaging and computational reproducibility cut-off, total 58 (17.5% from pyradiomics and 5.3% from MITK) features showed robustness across test-retest, multi-scanner, and computational methods. DWI images provided the highest percentage of robust features (23 out of 58, 39.6%), followed by T2w (19 out of 58, 32.7%) and T1w (16 out of 58, 27.6%).

CONCLUSION

s Only between 5.3% and 17.5% radiomics features from multiparametric MRI showed excellent robustness from both imaging with computational reproducibility. Diffusion-weighted imaging showed best robustness, and care must be taken in the interpretation of clinical studies using non-robust features.

CLINICAL RELEVANCE/APPLICATION

A recent multi-center study from the image biomarker standardization initiative (IBSI) helped improving computational reproducibility of radiomics features on CT. Nonetheless, reproducible multiparametric MRI sequences across multi-scanner and different algorithms are yet to be standardized. In this study, we found only between 5.3% and 17.5% radiomics features from multiparametric MRI showed excellent robustness from both imaging with computational reproducibility. Diffusion-weighted imaging showed best robustness, and care must be taken in the interpretation of clinical studies using non-robust features.

R5B-SPNR-7 Novel Technique of Simultaneous Non-contrast MR Angiography and Multi-contrast Vessel Wall Imaging (Simul-MRA+VWI) Using Multi-Shot Gradient-echo EPI (MSG-EPI) for Carotid Artery Evaluation

Participants
Yasuhiro Nagai, RT, Osaka, Japan (*Presenter*) Nothing to Disclose

PURPOSE

MRI for carotid artery has been widely used to assess the luminal stenosis and plaque characterization. However, separate acquisition of MR Angiography (MRA) and vessel wall imaging (VWI) require the long scan time and cause the misregistration. The hybrid of multi-shot gradient-echo EPI with modification of Look-Locker method enable to obtain the Simultaneous MRA and VWI (Simul-MRA+VWI) in a single scan. This study aims to compare the qualitative and quantitative image analysis for carotid artery between Simul-MRA+VWI and conventional scans.

METHODS AND MATERIALS

We obtained the carotid artery MRI with Simul-MRA+VWI and conventional sequences (TOF and IR-GRE) in 10 healthy volunteers using 3T-MRI. The phantom of simulated plaque (blueberry jam:T1=300msec) was scanned together with volunteers. Simul-MRA-VWI provide multi-contrast images with different inversion time (TI) after IR pulse. Images with short TI yield MRA as bright blood imaging and images with null TI of blood yield VWI as dark blood T1 weighted images.The image quality of MRA and VWI were evaluated using the 4-point scale.In MRA, SNR of blood and contrast ratio (CR) between blood and muscle were measured. In VWI, CR between blood and muscle and CR between plaque and muscle were measured. Then, we compared these parameters between Simul-MRA-VWI and conventional sequences.

RESULTS

The mean acquisition time of Simul-MRA-VWI sequence was 213sec, which was 60.7% shorter than the conventional two scans.There were no significant differences in image quality of MRA and VWI betweenSimul-MRA-VWI and conventional scans. In MRA, Simul-MRA-VWI had slightly higher SNR of blood and significantly higher CR between blood and muscle compared with TOF. In VWI, CR between blood and muscle (as black blood effect) tended to be higher in Simul-MRA-VWI than in IR-GRE but showed the no significant difference.CR between plaque and muscle (T1 contrast) was significantly higher in Simul-MRA-VWI than in IR-GRE with moderate correlation between two methods (r=0.78)

CONCLUSION

s Simul-MRA-VWI is a promising technique for shortening scan time with equivalent image quality to conventional sequences and

s Simul-MRA-VWI is a promising technique for shortening scan time with equivalent image quality to conventional sequences and yielding higher contrast MRA and VWI of carotid artery.

CLINICAL RELEVANCE/APPLICATION

Simul-MRA-VWI enable the simultaneous imaging of both carotid artery lumen and vessel wall with equivalent image quality to conventional methods. Our proposed method is practical approach for the reduction of scan time and the integrated assessment of both MRA and VWI without misregistration due to separate acquisition. Further, MRA and VWI obtained by this method can provide the higher contrast and permit the optimal contrast by determination from multiple TI images.

R5B-SPNR-8 Real Time Augmented Reality (AR) Navigation Technology From Medical Images: Toward Medical Metaverse Era

Participants
Yun-Sik Dho, Cheonju, Korea, Republic Of (*Presenter*) Stock options, Medical IP Co, Ltd

PURPOSE

Augmented reality is the essential underlying technology for metaverse implementation. Concomitant with the significant advances in computing technology, the novel concept of augmented reality (AR) registration and tracking have become possible. We introduce our newly developed real-time inside-out (RTIO) tracking AR navigation system.

METHODS AND MATERIALS

We developed RTIO tracking based on visual inertial odometry and a visual inertial simultaneous localization and mapping algorithm. The cube quick response (QR) marker and depth data obtained from light detection and ranging (LiDAR) sensors are used for continuous tracking. The registration accuracy was validated by both the intuitive method through visualization by the virtual 3-dimensional (3D) patient model for AR and the life-size 3D-printed patient model, and the quantitative method of identifying coordinates by matching errors. For depth realization, order-independent transparency (OIT), clipping, and annotation and measurement functions were developed. To validate depth realization technology, the AR model of a brain tumor patient was applied to its life-size 3D printed model.

RESULTS

By using RTIO tracking, we confirmed that the AR model remained consistent with the 3D-printed patient model without flutter, regardless of the movement of the visualization device. The red fiducial markers of the AR and the blue fiducial markers of the 3D-printed model were superimposed precisely at all locations. The registration accuracy was quantified using coordinates, and the average moving errors of the X-axis and Y-axis before and after the movement of visualization device were 0.34±0.21 and 0.04±0.08 mm (before) and 0.39±0.22 and 0.05±0.09 mm (after), respectively. Further, the application of OIT with multi-layer alpha blending (MLAB) and filtered alpha composites (FAC) improved the perception of overlapping internal brain structures. Clipping and annotation and measurement functions were also developed to aid depth perception, and worked perfectly during real-time coordination. We named this system METAMEDIP navigation.

CONCLUSION

s With these novel technologies developed for continuous tracking and depth perception in AR environments, we are able to overcome the critical obstacles in the development of clinically applicable AR neuronavigation in the metaverse era.

CLINICAL RELEVANCE/APPLICATION

It is verified augmented reality navigation can be used for brain tumor surgery planning and surgery and can be performed while checking anatomical structures intuitively compare to MRI-based neuro-navigation.

R5B-SPNR-9 Association of Brain Viscoelastic Properties With Age and Glymphatic Function in Neurologically Normal Subjects: An Exploratory Study of MR Elastography Using a Novel Transducer

Participants
Bio Joo, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Magnetic resonance elastography (MRE) can image viscoelastic properties of tissues by measuring propagation of mechanical waves generated by a MRE transducer. The purpose of this study was to investigate the relationship between viscoelastic properties of the brain measured by MRE with a novel MRE transducer and normal aging and glymphatic function in neurologically normal subjects.

METHODS AND MATERIALS

A total of 52 neurologically normal subjects (mean age: 48.1 ± 15.5 years, age range: 23 - 74, male:female = 23:29) were enrolled in this prospective study. MRE was conducted by using a transducer based on a rotational eccentric mass. Viscoelastic parameters, including storage modulus G′, loss modulus G″, magnitude of the complex shear modulus |G*|, and phase angle ?, were assessed in the centrum semiovale region. Glymphatic function was assessed using Diffusion Tensor Image Analysis Along the Perivascular Space index (ALPS-index). The viscoelastic parameters were compared with age and ALPS-index by Pearson correlation coefficient (r).

RESULTS

All the viscoelastic parameters showed significantly negative correlations with age (G′: r=-0.44, P<0.01; G″: r=-0.44, P<0.01; |G*|: r=-0.33, P=0.02; ?: r=-0.29, P=0.04). ALPS-index showed significantly positive correlations with G′ (r=0.35, P=0.02), G″ (r=0.37, P=0.02), and |G*| (r=0.37, P=0.01), but not with ? (r=0.25, P=0.11).

CONCLUSION

s This study demonstrated the applicability of the brain MRE using a novel transducer and the relationship between brain viscoelastic properties and glymphatic function in healthy subjects over a wide range of age. The brain MRE with the gravitational transducer can potentially play a role in various neurological conditions by providing additional information of the brain.

CLINICAL RELEVANCE/APPLICATION

MRE using a gravitational transducer can assess brain viscoelastic properties, which may be associated with normal aging as well as glymphatic function.

Effective Atomic Number as a Quantitative CT Marker for Myelin Content: A Validation Study Using Synthetic MRI

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Tomohito Hasegawa, Kagoshima, Japan (*Presenter*) Nothing to Disclose

PURPOSE

The effective atomic number (Zeff) reflects the elemental composition in biological tissues. Our purpose was to validate Zeff as a quantitative CT marker for myelin content in vivo.

METHODS AND MATERIALS

Fifteen patients (5 males and 10 females, age range from 35 to 84 years) with apparently normal cerebral parenchyma who underwent MRI scan and spectral detector CT scan within 1 month were included in this retrospective study. Images of myelin volume fraction (Vmy) were generated from synthetic MRI data using the multiparametric model based on the longitudinal and transverse relaxation rates and proton density. Whole brain spectral detector CT scans were performed using a dual-layer CT system, and images of the conventional CT value (CTconv), electron density (ED), and Zeff were obtained. The CT images were coregistered to the corresponding MR images using SPM12. Two independent observers placed elliptical ROIs in 12 gray matter (GM) and 12 white matter (WM) regions in each brain. Correlations between Vmy and CT parameters were evaluated using the Spearman's rank correlation coefficient for GM, WM, and altogether (GM+WM). The interobserver agreement was evaluated using the intraclass correlation coefficient (ICC).

RESULTS

The Vmy ranged from 0.881% to 32.06% in GM and from 25.34% to 48.32% in WM. CTconv, Zeff, and ED were significantly negatively correlated with Vmy for GM+WM. Zeff showed a strong negative correlation with Vmy (?=-0.783, P<0.001), which was stronger than CTconv (?=-0.715, P<0.001). ED showed only a moderate negative correlation with Vmy (?=-0.448, P<0.001). Only Zeff showed significant correlation with Vmy both in GM (?=-0.407, P<0.001) and WM (?=-0.215, P=0.004). The interobserver agreement was excellent for all measurement (ICC ranged from 0.897 to 0.984).

CONCLUSION

s Myelin content was more strongly reflected in Zeff than ED and CTconv. The negative correlation between Zeff and Vmy may be related to elemental composition of WM which is characterized by higher carbon and lower oxygen mass fractions than GM. The Zeff may serve as a quantitative CT marker for myelin content.

CLINICAL RELEVANCE/APPLICATION

The effective atomic number may serve as a quantitative CT marker for myelin content.

R5B-SPNR-10

Investigation on Pre ASiR-v on Image Quality and Radiation Dose of Non Spectral Scanning: A Phantom Study

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Yaoxing Ma, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the influence of different pre adaptative statistical iterative reconstruction - Veo (ASiR-V) level on the image quality and radiation dose of non spectral scanning.

METHODS AND MATERIALS

A polypropylene cylindrical phantom (QSP Phantom) with nine tubes containing different concentrations of iodine (0, 2.5, 5, 10, 20 mgI/ml) was scanned in using spectral CT (Revolution, GE Healthcare) gemstone spectral imaging (GSI) mode using fast kV switch (80/140 kV) ,the tube current was 485mA, the layer thickness was 1.25mm, the collimation width was 80mm, ,noise index (NI) 5HU, pitch 0.992:1. Three groups of pre-ASiR-V level (30%, 40%, 50%) was used for spectral CT scanning. Eleven groups of images were selected from the scan center and five layers above and below. CT value and the area of ROI were measured. The CT dose index (CTDI) of different pre ASiR-V level scans was recorded. The dose length product (DLP), CT value and noise (SD) of the tube were recorded. Signal noise ratio (SNR) and contrast to noise ratio (CNR) of tubes was calculated. The DLP across three groups were analyzed by simple linear regression analysis. SD, SNR and CNR across three groups were analyzed by one-way ANOVA.

RESULTS

With the increase of pre-selected ASiR-V level, DLP showed decreasing trend. There was significant difference in DLP among groups (9.24mSv, 7.55mSv,6.00mSv for 30%,40%,50%pre-ASiR-V, respectively. $P<0.05$). There were no significant differences in SD among groups (10.85±0.80(I20),8.38±0.29(I10),8.10±0.41(H2O), for 30% pre-ASiR-V ,10.86±0.74(I20),8.42±0.29(I10),8.05±0.46(H2O)40% pre-ASiR-V ,11.36±0.76(I20),7.97±0.29(I10),7.76±0.34(H2O),50% pre-ASiR-V , $F=2.130$, $p > 0.05$).

CONCLUSION

s With the increase of pre-ASiR-V from 30%,40%,50%, radiation dose was reduced effectively, while the image quality was not changed significantly.

CLINICAL RELEVANCE/APPLICATION

Radiation dose is reduced with the increase of pre-ASiR-V and image quality keeps no change. Correlation of clinical application: through the basic research of phantom, compared with conventional kVp scanning, energy spectrum CT scanning can provide the same image quality scanning radiation dose, at the same time, energy spectrum CT scanning can provide different levels (40-140kev) of single energy and effective atomic number, and more energy spectrum information of base material than conventional kVp scanning, This study has guiding significance for the application of energy spectrum scanning in different clinical scenarios.

R5B-SPNR-13

Effects of Different Weighted Iterative Reconstruction on the Image Quality of Head and Neck CTA

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Deng Jie, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the effect of adaptative statistical iterative reconstructionveo (ASIR-V) algorithm on image quality and application value of head and neck CTA scanning.

METHODS AND MATERIALS

A total of 88 patients underwent head and neck CTA. Image reconstruction was performed using Filtered Back Projection (FBP), 20% ASIR-V algorithm, 40% ASIR-V algorithm, 60% ASIR-V algorithm and 80% ASIR-V algorithm, and perform volume projection and maximum density projection processing on the five groups of images. The effects of different reconstruction methods on the image quality of head and neck CTA were evaluated from the two aspects of objective measurement and subjective score.

RESULTS

Comparison of five groups of different reconstruction methods (filtered back projection method) FBP, 20% ASIR, 40% ASIR, 60% ASIR and 80% ASIR in the blood vessels of the head and neck (aortic arch, left common carotid artery, right common carotid artery) Artery, left middle cerebral artery, right middle cerebral artery, left vertebral artery, right vertebral artery, basilar artery) image quality parameter comparison, there is no statistical difference in CT value and SD value among the five groups of images among each blood vessel (P>0.05); when comparing SNR and CNR, the blood vessels in the eight groups were 80%ASIR>60%ASIR>40%ASIR>20%ASIR>FBP (P<0.05). The Kappa value of the subjective rating of quality is 0.75, with strong consistency. The subjective scores were (4.13±1.669), (4.30±2.607), and (4.93±2.640), respectively, and there was no significant difference in the subjective scores among the three groups (F=0.876, P>0.05).

CONCLUSION

s With the gradual increase of the pre-ASIR-V weight, the CT value did not change significantly, and the image noise gradually increased. At the pre-ASIR-V level of 0~40%, the subjective image score was basically stable, and there was no significant difference in image quality. 60%~80% of the pre-ASIR-V level, the subjective scores in each group showed a gradually decreasing trend, and the image quality decreased obviously and gradually.

CLINICAL RELEVANCE/APPLICATION

When the ASIR value of different weights applied to head and neck CTA scans is 40%, the image quality is the best, which can be used in clinical practice.

Description of Magnetic Resonance Fingerprinting in Patients with Amyotrophic Lateral Sclerosis

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Philipp Moser, MD, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

Applicability of 3T Magnetic Resonance Fingerprinting (MRF) T1 and T2 mapping for quantitative analysis of the capsula interna in patients with amyotrophic lateral sclerosis (ALS)

METHODS AND MATERIALS

3T single-step MRF T1 and MRF T2 map data acquisition in addition to conventional multi-step MRI image acquisition was performed in patients diagnosed with ALS. In addition, DTI (b-values 0-2500) was analyzed in seven patients. A ROI-based analysis of relaxation times of the left and right capsula interna was performed. Interclass correlation (ICC, 3 repeats) and Pearson correlation coefficient were done for statistical analysis. Data presented as mean +/- SD.

RESULTS

Eighteen patients (mean age 63.712.7 years, male 61%) were included. We found excellent intra-observer ICC values for MRF T1R 0.985 (0.98-0.99, CI 95%) and MRF T2R 0.998 (0.99-1.0, CI 95%). The mean relaxation time of MRF T1R was 103634.1 ms and of MRF T2R was 2742308 ms. We observed a correlation between the MRF T1R values of the left and right capsula interna (R=0.65, p=0.003) and the MRF T2R values of the left and right capsula interna (R=0.96, p<0.0001). In addition, we found a correlation between MRF T1R and DTI values (R= -0.54, p=0.044) but no correlation between MRF T1R and ADC nor between MRF T2R and ADC or DTI.

CONCLUSION

s MRF T1 and T2 mapping of the capsula interna was successfully performed in patients with ALS and quantitative assessment may provide additional support in the diagnosis of upper motoneuron involvement.

CLINICAL RELEVANCE/APPLICATION

MRF may assist in the assessment of upper motoneuron involvement and disease progression in patients with ALS.

R5B-SPNR-15

A Clinical Application of 3D High-Resolution Contrast Enhanced MR Neurography With Precise Fat Suppression in Lumbosacral Plexus

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Xiangchuang Kong, Wuhan, China (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this study was to investigate the clinical application of precise fat suppression for 3D high-resolution contrast-enhanced MR neurography of lumbosacral plexus.

METHODS AND MATERIALS

32 patients were prospectively selected: 14 patients (group A) with preset TI, and 22 patients (group B) with accurately calculated TI values. All patients were scanned using a 3.0 T MR scanner (Ingenia CX, Philips Healthcare, the Netherlands) with a 32-element phased-array coil. After intravenous injection of Gd-DTPA (0.15mmol/kg), patients were scanned using the 3D NerveView sequence: TI=220ms in group A and calculated TI in group B by a low resolution and fast 3D NerveView scanning with different TI values (TI=180 200 220 230 250 260 270 280 300 320 ms, TR=2200ms). Images were reconstructed on the scanner by the vendor-supplied software package (Compressed SENSE, Philips Healthcare). The signal intensity of fat, and nerve was measured on the original graph and the MIP graph respectively and the signal intensity ratio of nerve to fat was calculated for evaluation of fat suppression. Then the nerve/fat signal ratio (NFR) was calculated. The IBM SPSS22.0 software was used for statistical analysis, and NFR between the two groups was compared by unpaired sample t-test. $P<0.05$ indicated a statistically significant difference.

RESULTS

1. The proposed TI scout method could improve fat suppression in MRN dramatically. The calculated NFR (precise fat suppression) (13.26±5.47) was about 425.4% higher than that in the preset TI situation (220ms) (2.39±0.55). The difference between the two groups was statistically significant ($t=26.495$, $P<0.05$).2. The detection rates of nerve roots and trunks by the two methods were 100% (18/18,14/14); The detection rates of the nerve tracts and branches in precise fat-suppression sequence were 94.4% (17/18) and 83.3% (15/18), respectively. The detection rates of nerve tracts and branches in the preset method were 92.9% (13/14) and 71.4% (10/14), respectively. There was no statistically significant difference between the two methods in the detection rate of nerve tracts and branches ($P=1.00$, 0.67).

CONCLUSION

s A fast and easy TI scout-based strategy was proposed to improve the fat suppression in 3D MRN of the lumbosacral plexus, which enhanced the image quality significantly. The NFR was increased by about 425.4% more than that in the vendor-provided preset TI scheme.

CLINICAL RELEVANCE/APPLICATION

A fast and easy TI scout-based strategy was proposed to improve the fat suppression in 3D MR neurography of lumbosacral plexus, which enhanced the image quality significantly. The nerve fat signal intensity ratio was increased by about 425.4% than that in vendor-provided preset TI scheme.

R5B-SPNR-16

Rapid Susceptibility-Weighted Imaging using Wave CAIPI for Differentiation of Diamagnetic and Paramagnetic Signal

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Parker Lawson, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Susceptibility-weighted imaging (SWI) is primarily used for the detection of paramagnetic and diamagnetic substances, typically hemorrhage and calcifications respectively. Differentiation between the two can be difficult on post-processed SWI images as both create a similar magnitude of susceptibility and appearance; however, SWI phase imaging can often distinguish the two as their phase shifts and resultant signals are opposite of each other. Unfortunately, differentiation is not always achievable for larger lesions. Wave CAIPI SWI has been recently developed as an alternative to conventional SWI with reduced scan times. Prior to this investigation, Wave CAIPI SWI phase had not been evaluated for its ability to differentiate between paramagnetic and diamagnetic susceptibility.

METHODS AND MATERIALS

126 Brain MRI studies were prospectively selected with the inclusion of a Wave CAIPI SWI sequence at 1.5T and 3T MR units. The images were evaluated by two radiologists for presence and characterization of susceptibility on both conventional SWI (scan time: 4.8 minutes) and Wave CAIPI (scan time: 1.14 minutes) phase and confirmed with head CTs.

RESULTS

Of the 126 studies, 64 demonstrated a focus of susceptibility on conventional SWI and Wave CAIPI SWI. All 64 were identifiable as diamagnetic or paramagnetic on Wave CAIPI phase with homogeneous black or white signal. There were a total of 31 cases in which larger lesions demonstrated heterogeneous or dipole signal on conventional SWI phase, making interpretation difficult; however, Wave CAIPI SWI phase demonstrated homogenous signal facilitating interpretation that was confirmed by CT.

CONCLUSION

s Wave CAIPI SWI phase is a non-inferior alternative to conventional SWI phase in differentiating between paramagnetic and diamagnetic signal and aids interpretation of larger lesions. The findings of this study, coupled with reduced scan times, support the inclusion of Wave CAIPI SWI sequences into routine brain imaging.

CLINICAL RELEVANCE/APPLICATION

Wave CAIPI SWI phase images offer a non-inferior alternative to conventional SWI for differentiating between intracranial hemorrhage and calcification that can be acquired within less than 1/4th of the scan time.

R5B-SPNR-17

Aberrant Spontaneous Brain Activity in Patients with Dysthyroid Optic Neuropathy: A Resting-State Functional MRI Study

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Ping Liu, MS, (*Presenter*) Nothing to Disclose

PURPOSE

Increasing evidence indicated that DON is not only a disease limited to the visual system, it is an eye-brain disease involves multiple brain regions. The purpose of the study was to investigate the brain functional alteration in patients with DON by evaluating the spontaneous neural activity changes using resting-state functional magnetic resonance imaging (rs-fMRI) with the regional homogeneity (ReHo).

METHODS AND MATERIALS

Forty-seven TAO patients, including 20 with neuropathy (DON) and 27 without neuropathy, and 28 healthy controls (HCs) were recruited, matched for weight, height, age, sex, and educational level. All participants underwent resting-state functional nuclear resonance imaging, and the characteristics of spontaneous brain activity were evaluated employing the regional homogeneity (ReHo) method. Each patient with dysthyroid optic neuropathy also completed the ophthalmopathy examination. The ReHo values were compared among groups. Correlations between ReHo values and clinical metrics were assessed.

RESULTS

Compared with TAOs, DON showed significantly decreased ReHo values in the left insula and right superior temporal gyrus, and increased ReHo values in left posterior cingulum and left precentral cuneus. Compared with HCs, TAOs also showed significantly decreased ReHo values in the left posterior cingulum. Additionally, the changed ReHo values were correlated visual acuity, mean deviation (MD) and pattern standard deviation (PSD) of visual field, and he amplitude and absolute latency of P100 of the visual-evoked potentials (VEPs).

CONCLUSION

s DON patients had altered spontaneous brain activities in the left insula, right superior temporal gyrus, left posterior cingulum and left precentral cuneus. And these brain functional abnormalities associated with the visual function.

CLINICAL RELEVANCE/APPLICATION

The abnormal spontaneous brain activities may be related to the pathological mechanism of DON, which may provide a valuable basis for further research on the clinical management of DON. Moreover, regional homogeneity has the potential for early diagnosis and prevent DON.

R5B-SPNR-18

Identification of Autism Spectrum Disorder (ASD) Patients Using Functional MRI - Nonlinear, Directed, Multivariate Brain Connectivity Analysis by Non-Linear Large-scale Granger Causality (lsNGC)

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Ali Vosoughi, Rochester, NY (*Presenter*) Nothing to Disclose

PURPOSE

To develop and evaluate a novel machine learning method for identifying patients with Autism Spectrum Disorder (ASD) using large-scale Nonlinear Granger Causality (lsNGC) by capturing connectivity differences in resting-state functional MRI (rsfMRI).

METHODS AND MATERIALS

We included the subset of all 93 rsfMRI data sets acquired from ASD patients and healthy controls from two institutions (36 from Olin, Institute of Living at Hartford Hospital, and 57 from University of Pittsburgh School of Medicine: Longitudinal Sample) represented in the publicly available preprocessed Autism Brain Imaging Data Exchange I (ABIDE I) data repository. For calculating directed functional connectivity between brain regions, we have recently developed the large-scale Nonlinear Granger Causality (lsNGC) algorithm [Citation blinded for review] that leverages radial basis function kernel transformation for causal modeling in high-dimensional fMRI time series. A 100-iteration cross-validation approach with 80%/20% train/test ratio was applied, where feature selection was performed on each training set using Kendall's tau rank correlation, followed by support vector machine classification. To quantitatively evaluate diagnostic accuracy of lsNGC for correctly classifying ASD patients and normal controls, we compare its performance with both a recent state-of-the-art causal discovery method (PCMCI, [Runge et al., Science, 2019]), and the current clinical fMRI analysis standard of cross-correlation (CC), reporting accuracy, area under ROC curve (AUC), and f1-score.

RESULTS

The lsNGC rsfMRI analysis method significantly outperformed both PCMCI and the clinical standard CC techniques at classifying ASD patients from healthy subjects, with accuracy/AUC/f1 score of 100%/1.0/100% for lsNGC, 75.4%/0.69/70.0% for PCMCI, and 65.8%/0.61/62.4% for CC, respectively.

CONCLUSION

s Our results suggest that lsNGC significantly improves the diagnostic accuracy of correctly identifying patients with ASD from rsfMRI neuroimaging. We conclude that, when compared to both conventional CC analysis and state-of-the-art PCMCI, lsNGC is better suited to capture disease-related brain network connectivity changes in ASD patients.

CLINICAL RELEVANCE/APPLICATION

The lsNGC method classifies Autism Spectrum Disorder (ASD) patients and controls by identifying relevant changes in fMRI connectivity, suggesting its potential usefulness as a novel diagnostic imaging biomarker for neurologic disease.

Three-vessel Selective Pseudo-continuous Arterial Spin Labeling Using Designed Metal Artifacts: A Feasibility Study

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Keizo Tanitame, MD, Hiroshima, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Arterial spin labeling (ASL) of magnetic resonance (MR) imaging is a noninvasive evaluation method for assessing cerebral perfusion, and delineation of individual perfusion territories of cerebral arteries can help in the evaluation of the collateral pathway development in cerebrovascular disease patients. We evaluated the feasibility of three-vessel selective pseudo-continuous ASL (pCASL) using designed metal artifacts.

METHODS AND MATERIALS

We recruited fifteen healthy volunteers, and firstly obtained MR angiography of the brain and whole brain perfusion maps of all the cerebral arteries using three-dimensional pCASL. Then while confirming the anatomical location of common carotid arteries (CCAs), we placed one or two small insulated metals on the skin surface near the right, left or bilateral CCAs at the labeling plane, and performed vessel-selective pCASL using three different kinds of local labeling suppression. From analysis of the perfusion maps of all the cerebral arteries, the right CCA and vertebrobasilar artery (VBA), the left CCA and VBA, and only the VBA, two independent observers inferred and drew the cerebral arterial atlases, and another assessed the coincidence of the schematic atlas and MRA image in each subject.

RESULTS

Three-vessel selective pCASL imaging could be performed in all subjects, and no subjects complained of local heat sensation related to the insulated metals. The coincidence rate of inferred cerebral arterial atlases and MRA images was 86.7% in each observer. In five subjects with incomplete circle of Willis, contralateral routes from well-developed communicating arteries could be inferred from the vessel-selective pCASL images. In a subject with an aberrant branch of the left posterior artery, the perfusion territory of the branch was shown in the vessel-selective pCASL images. Interobserver agreement was 100%. In two subjects, two observers independently suspected anterior to posterior circulation through well-developed bilateral posterior communicating arteries from the vessel-selective pCASL images, but MRA showed that the arteries were absent. These misunderstandings were thought to be due to unexpected suppression effect of the metals on VBA labeling.

CONCLUSION

s We presented a three-vessel selective pCASL using designed metal artifacts. The perfusion territories of individual cerebral arteries could be delineated differently, but attention is needed for the depth of the vertebral arteries.

CLINICAL RELEVANCE/APPLICATION

Three-vessel selective pseudo-continuous arterial spin labeling using designed metal artifacts can be used to obtain individual perfusion maps of bilateral carotid and vertebrobasilar arteries.

Feasibility of Ultrashort Echo Time Quantitative Susceptibility Mapping (UTE-QSM) With a 3D Cones Trajectory in the Human Brain

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Sam Sedaghat, MD, La Jolla, CA (*Presenter*) Nothing to Disclose

PURPOSE

Over the past decade, quantitative susceptibility mapping (QSM) has emerged as a promising quantitative MR imaging technique to assess the microenvironment in the brain. In literatures, many new QSM techniques have been proposed, but non-Cartesian ultrashort echo time (UTE) sequences have not been explored. In this study, the feasibility of UTE-QSM based on a 3D spiral cones trajectory is demonstrated in the brain.

METHODS AND MATERIALS

The UTE-QSM sequence based on a 3D cones trajectory was implemented on a 3T clinical MRI scanner (MR 750, GE Healthcare). To show the feasibility, an ex vivo experiment was performed on 3 fresh human brain samples using an 8-ch head coil with the following imaging parameters: TR = 50 ms, TE = 0.032, 4.4, 8.8, 13.2, 17.6, and 22 ms, FA = 20°, FOV = 220x220x80 mm3, matrix = 256x256x80, and readout bandwidth = 166.6 kHz. The scan was repeated with 8 different stretching factors (SFs) of the 3D cones spiral arms: 1.0, 1.1, 1.2, 1.3, 1.4, 1.5, 1.6, and 1.7 with the corresponding scan times of 1383, 1229, 1099, 1005, 920, 857, 794, and 745 sec (acceleration factors (AFs) of 1.00, 1.13, 1.26, 1.38, 1.50, 1.62, 1.74, and 1.86), respectively. An in vivo UTE-QSM was performed on five healthy volunteers (37.6 ± 6.7 years old) using the same imaging protocol except for: matrix = 220x220x80, FOV = 220x220x160 mm3, SF = 1.7 (AF = 1.86), and scan time = 645 sec. The reconstructed complex MR images were processed with a UTE-QSM pipeline established based on a MEDI toolbox.

RESULTS

In the ex vivo experiment, a very high correlation in pixelwise QSM values (i.e., susceptibility) was found between SF of 1.0 and SFs from 1.1 to 1.7: Pearson's correlation 0.987, 0.981, 0.976, 0.972, 0.970, 0.962, and 0.953, respectively with all p-values < 0.05. In the in vivo experiment, the measured QSM values in cortical gray matter, juxtacortical white matter, corpus callosum, caudate, and putamen were 25.4 ± 4.0, -21.8 ± 3.2, -22.6 ± 10.0, 77.5 ± 18.8, and 53.8 ± 7.1 ppb in five volunteers, which correspond well with the values reported in literatures.

CONCLUSION

s In this study, we demonstrated the clinical feasibility of 3D UTE-QSM in the brain for the first time. UTE-QSM with a stretched cones trajectory (i.e., acceleration up to 1.86x) showed reliable estimation of susceptibility in the brain.

CLINICAL RELEVANCE/APPLICATION

The proposed UTE-QSM technique based on an efficient cones trajectory allows whole brain susceptibility mapping in a clinically feasible scan time of ~11 min. UTE-QSM is likely to provide more accurate assessment of calcification, hemorrhage, iron overload, and tumor vascularization as UTE acquisition allows direct imaging of short T2 tissues and robust mapping of their susceptibilities. Moreover, the non-Cartesian UTE-QSM is likely to be more robust to patient motion.

The Value of Deep Learning Reconstruction Algorithm in CT Whole Brain Perfusion in Patients with Ischemic Stroke

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Limin Lei, Zhengzhou, China (*Presenter*) Nothing to Disclose

PURPOSE

To compare deep learning-based image reconstruction (DLIR) algorithm and adaptive statistical iterative reconstruction-Veo (ASIR-V) algorithm on the image quality and brain perfusion parameters of whole brain CT perfusion scanning in patients with ischemic stroke due to large vessel occlusion.

METHODS AND MATERIALS

A total of 27 patients with ischemic stroke due to large vessel occlusion were collected prospectively in this study, including 15 cases of acute and 12 cases of chronic, consisted of 22 males and 5 females with a median age of 54(range 30-79 years). All patients underwent whole brain perfusion imaging using latest-generation 16 cm detector coverage CT scanner (APEX CT, GE Healthcare). CT datasets were reconstructed using ASIR-V at a level of 80% (80%ASIR-V) and DLIR with high reconstruction strength level (DLIR-H) with 1.25-mm slice thickness. The volumetric CT dose index (CTDIvol) and dose length product (DLP) for each patient scan were recorded. Objective parameters including CT values and standard deviation (SD) in frontotemporal lobe, gray matter nucleus (caudate lobe, lenticular, thalamus) and posterior limb of internal capsule on the contralateral side, as well as the signal-to-noise ratio (SNR) and contrast-to-noise ratio (CNR) of gray matter nucleus were compared. we performed brain perfusion analysis based on CT Perfusion 4D package and calculated the perfusion parameters such as CBF, CBV, MTT and TTP at the same site as the CT values were measured. Moreover, the functional analysis of ipsilateral cerebral infarction including the brain tissue volume, Tmax average value, CBV average value were conducted with the threshold as CBV beyond 1ml/100g while Tmax within 6 seconds. Differences between continuous data were tested using paired t test or Wilcoxon rank test.

RESULTS

DLIR-H had a lower image noise in frontotemporal lobe, gray matter nucleus and posterior limb of internal capsule than 80% ASIR-V (all $P < 0.001$), while higher SNR and CNR of gray matter nucleus(all $P < 0.001$) without changing the CT values. Moreover, there was no significant difference between DLIR-H and 80% ASIR-V in the perfusion parameters including CBF, CBV, MTT and TTP of gray matter and white matter as well as the Tmax average value, CBV average value with the threshold as CBV beyond 1ml/100g while Tmax within 6 seconds.

CONCLUSION

s In cerebral perfusion scan of patients with ischemic stroke, DLIR-H reconstruction algorithm can effectively improve image quality without changing perfusion parameters and functional parameters.

CLINICAL RELEVANCE/APPLICATION

Deep learning reconstruction algorithm can reduce image noise without changing the vital diagnostic parameters, which throws light on low-dose CT acquisition protocol of clinical cerebral perfusion scans.

Label-Free Spectral X-Ray Method for Non-invasively Quantifying Amyloid Burden in the Human Brain

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Eshan Dahal, (*Presenter*) Nothing to Disclose

PURPOSE

To describe a spectral x-ray method based on the small-angle elastic scattering of photons for measuring amyloid burden in the human brain.

METHODS AND MATERIALS

We built a prototype system capable of probing an intact human head using a polychromatic x-ray source with tungsten anode in the diagnostic x-ray energy range and a 2D spectroscopic photon-counting detector (80 x 80, 250-micron pixels) with a 1-mm cadmium telluride (HEXITEC) to record energy (in 1-keV bins) and location of each scattered photons. An energy-dependent transmission correction factor was calculated using spectroscopic measurements of the primary beam. The x-ray beam was pinhole collimated to create a 2-mm pencil beam to irradiate the human head phantom with and without embedded targets. We used a commercially available tissue-mimicking (brain and skull) phantom with slabs and an anthropomorphic human head phantom to assess the recovery of the scattering signature for targets with varying concentrations. By comparing the scattering profiles for areas with and without targets, we report amyloid burden as the area-under-the-peak for the characteristic target peaks which correlates with the mass fraction of amyloid plaques.

RESULTS

Measurements of the head phantom with embedded caffeine targets show well-defined characteristic Bragg peaks at momentum transfer of 8.4 and 18.7 nm-1. We recovered the characteristic peaks with exposure times as low as 60 s. Measurements investigating the effect of sample thickness up to 16 cm and spectral x-ray energies from 30 to 120 keV was evaluated to maximize the scattering signal from the targets.

CONCLUSION

s The findings of the study suggest that the spectral x-ray-based method for non-invasively detecting and quantifying amyloid-like targets embedded within a human head has promise.

CLINICAL RELEVANCE/APPLICATION

Amyloid burden can be used to monitor onset and progression of Alzheimer's disease. The spectral small-angle method described in this study has potential to facilitate more efficient therapeutic clinical trials by providing a fast and label-free amyloid plaque quantification tool as an alternative to amyloid-specific positron emission tomography.

How Confident Are You - Contrast-Enhanced T1-weighted SPACE Versus 3D FLASH Sequences for the Detection of Brain Metastases

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Maria Gule-Monroe, MD, Houston, TX (*Presenter*) Nothing to Disclose

PURPOSE

This study aimed to evaluate the utility of contrast-enhanced (CE) T1-weighted 3D fast spin-echo-based SPACE sequence, by comparing to the gradient-echo-based 3D-FLASH sequence (without inversion recovery, IR) for the detection of brain metastases at 3T.

METHODS AND MATERIALS

220 patients at a single institution who were scheduled for brain MRI underwent optimized CE T1-weighted SPACE and 3D-FLASH sequences at 3T as part of a practice quality improvement project. Each scan took approximately 4 minutes, and the order of the two sequences was balanced among the patients. The medical records were retrospectively reviewed, and 79 patients found to have brain metastases at the time of imaging were included. Images were evaluated by 5 CAQ certified neuroradiologists, with at least 2-week separation between scoring sequences for the same patient and 20 patients scored by 2 radiologists. Parameters evaluated included number of metastatic lesions, number of indeterminate lesions, visual assessment of lesion margin, visual assessment of contrast to noise ratio (CNR), presence of image artifact, and overall image quality. In addition, CNR was quantified for solidly enhancing lesions greater than 1 cm.

RESULTS

SPACE detected more lesions than 3D-FLASH in 35 patients, while 3D-FLASH detected more lesions in 10 patients. A greater number of indeterminate lesions were seen on 3D-FLASH (27 patients) vs SPACE (9 patients), mostly related to presence of vascular enhancement seen in 3D-FLASH images. When rating overall image quality, lesion margin and CNR on a Likert scale, SPACE performed better than 3D-FLASH with more image artifact seen on 3D-FLASH. Higher quantitative CNR was found in SPACE than 3D FLASH images (mean=26.9 vs. 19.8, respectively, n=16, p=0.054).

CONCLUSION

s This is the first study to date comparing the performance of CE T1-weighted SPACE to non-IR 3D-FLASH sequence for the detection of brain metastases. The SPACE sequence detects a greater number of metastatic lesions and is rated higher for image quality, lesion margin and CNR with less artifact. Gradient Echo are the most commonly used sequences for detection and radiation treatment planning of brain metastases. Superiority of SPACE for lesion detection and confidence has implications across the diagnostic and therapeutic imaging journey.

CLINICAL RELEVANCE/APPLICATION

This is the first study to date evaluating the performance of CE T1-weighted SPACE to non-IR 3D-FLASH for the detection of brain metastases. Superiority of SPACE for lesion detection and confidence has implications across the diagnostic and therapeutic imaging journey.

Characterization of Lenticulostriate Arteries by Combining High Resolution Black-blood T1-weighted with Variable Flip Angles Compressed Sensitivity Encoding at 3.0 Tesla

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Yukun Zhang, Dalian, China (*Presenter*) Nothing to Disclose

PURPOSE

To visualize and characterize lenticulostriate arteries (LSAs) in a short period time on a 3.0T MR scanner, we investigated the feasibility of high resolution black-blood T1-weighted with variable flip angles (T1w TSE-VFA) accelerated by compressed sensitivity encoding (CS-T1w TSE-VFA) and further identify the optimal acceleration factors (AFs) for clinical use.

METHODS AND MATERIALS

14 healthy volunteers (6 males, mean age 29.57±6.17 years) and 7 patients with cerebral infarction (4 males, mean age 50.06±20.13 yeas) were prospectively included and divided into the volunteer group and patient group. T1w TSE-VFA images with different AFs (Parallel imaging (PI) AF=3, CS AF=3,4,5,6) (Table 1) were acquired on a 3.0T scanner (uMR Omega, Imaging Healthcare, Shanghai, China). For objective evaluation, the regions of interest (ROIs) of the middle cerebral artery (MCA), the longest LSA, and corresponding white matter on the original or reformatted images were delineated (Fig.1 a-b). Then the signal intensity (SI) and standard deviation (SD) were measured and contrast-to-noise ratio (CNR): (SILSA/MCA-SIWM)/SDWM was further calculated. For subjective evaluation, the the number and length of LSAs of T1w (Fig.1 c) and subjective scoring (Fig.1 d-f) of T1w TSE-VFA with different AFs were measured. Paired t-test were used to compare CNR of MCA and LSA, number and length of LSAs, and image quality between T1w TSE-VFA with PI AF=3 and with CS AF=3 to 6.

RESULTS

For the volunteer group, when CS AF=6, the number of LSAs were significantly different from that of PI-T1w TSE-VFA ($p<0.05$); when CS AF=5, the length of LSAs and subjective scoring were significantly different from PI-T1w TSE-VFA ($p<0.05$)(Table.3 , Figs.2 and 4). For the patient group, when CS AF=6, the CNR of LSA and subjective scoring were significantly different from PI-T1w TSE-VFA ($p<0.05$); when CS AF=5, length and number of LSAs were significantly different from PI-T1w TSE-VFA ($p<0.05$)(Table 2, Figs. 3 and 4).

CONCLUSION

s CS-T1w TSE-VFA with AF of 3 can provide a better LSA display but time longer; with AF of 4 can balance visualization of LSAs and acquisition time. These sequences had the potential to be used in clinical to provide diagnostic information for preventive medicine at 3 Tesla.

CLINICAL RELEVANCE/APPLICATION

CS-T1w TSE-VFA can be used as a non-invasive head microvasculature examination in asymptomatic subjects and patients with cerebrovascular disease, which will be an important asset in preventive medicine.

Reproducible Brain MRI Radiomics Features Achieving Test-Retest, Multi-Scanner, and Computational Reproducibility: A Phantom Study

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Yunhwa Roh, (*Presenter*) Nothing to Disclose

PURPOSE

The image biomarker standardization initiative helped improving computational reproducibility of radiomics features on CT. Nonetheless, reproducible multiparametric MRI sequences across multi-scanner and different algorithms are yet to be standardized. We aimed to determine reproducible radiomic features in multiparametric sequences with multi-scanner and computational methods setting.

METHODS AND MATERIALS

A phantom was scanned twice on a clinical 3 T system (Philips, Siemens, and GE) with T1-weighted (T1w), T2-weighted (T2w), and diffusion-weighted imaging (DWI) sequences. Radiomic features were extracted using pyradiomics (110 features) and MITK (the Medical Imaging Interaction Toolkit) (364 features) from each test-retest and multi-scanner setting. Stable radiomics features were calculated when maintaining 5% cut-off of averaging features among different imaging methods (test-retest and multi-scanner) and computational methods. The stable features were calculated concordance- and intraclass correlation coefficients (CCC and ICC) and compared among sequences.

RESULTS

The number of robust features (CCC = 0.90) was higher for features calculated from DWI than from T1w and T2w images in test-retest analysis. From imaging reproducibility, a total of 79 (23.9%) of 330 features from pyradiomics and 473 (43.3%) of 1092 MITK features showed excellent robustness (ICC = 0.90. Applying both imaging and computational reproducibility cut-off, total 58 (17.5% from pyradiomics and 5.3% from MITK) features showed robustness across test-retest, multi-scanner, and computational methods. DWI images provided the highest percentage of robust features (23 out of 58, 39.6%), followed by T2w (19 out of 58, 32.7%) and T1w (16 out of 58, 27.6%).

CONCLUSION

s Only between 5.3% and 17.5% radiomics features from multiparametric MRI showed excellent robustness from both imaging with computational reproducibility. Diffusion-weighted imaging showed best robustness, and care must be taken in the interpretation of clinical studies using non-robust features.

CLINICAL RELEVANCE/APPLICATION

A recent multi-center study from the image biomarker standardization initiative (IBSI) helped improving computational reproducibility of radiomics features on CT. Nonetheless, reproducible multiparametric MRI sequences across multi-scanner and different algorithms are yet to be standardized. In this study, we found only between 5.3% and 17.5% radiomics features from multiparametric MRI showed excellent robustness from both imaging with computational reproducibility. Diffusion-weighted imaging showed best robustness, and care must be taken in the interpretation of clinical studies using non-robust features.

Novel Technique of Simultaneous Non-contrast MR Angiography and Multi-contrast Vessel Wall Imaging (Simul-MRA+VWI) Using Multi-Shot Gradient-echo EPI (MSG-EPI) for Carotid Artery Evaluation

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Yasuhiro Nagai, RT, Osaka, Japan (*Presenter*) Nothing to Disclose

PURPOSE

MRI for carotid artery has been widely used to assess the luminal stenosis and plaque characterization. However, separate acquisition of MR Angiography (MRA) and vessel wall imaging (VWI) require the long scan time and cause the misregistration. The hybrid of multi-shot gradient-echo EPI with modification of Look-Locker method enable to obtain the Simultaneous MRA and VWI (Simul-MRA+VWI) in a single scan. This study aims to compare the qualitative and quantitative image analysis for carotid artery between Simul-MRA+VWI and conventional scans.

METHODS AND MATERIALS

We obtained the carotid artery MRI with Simul-MRA+VWI and conventional sequences (TOF and IR-GRE) in 10 healthy volunteers using 3T-MRI. The phantom of simulated plaque (blueberry jam:T1=300msec) was scanned together with volunteers. Simul-MRA-VWI provide multi-contrast images with different inversion time (TI) after IR pulse. Images with short TI yield MRA as bright blood imaging and images with null TI of blood yield VWI as dark blood T1 weighted images.The image quality of MRA and VWI were evaluated using the 4-point scale.In MRA, SNR of blood and contrast ratio (CR) between blood and muscle were measured. In VWI, CR between blood and muscle and CR between plaque and muscle were measured. Then, we compared these parameters between Simul-MRA-VWI and conventional sequences.

RESULTS

The mean acquisition time of Simul-MRA-VWI sequence was 213sec, which was 60.7% shorter than the conventional two scans.There were no significant differences in image quality of MRA and VWI betweenSimul-MRA-VWI and conventional scans. In MRA, Simul-MRA-VWI had slightly higher SNR of blood and significantly higher CR between blood and muscle compared with TOF. In VWI, CR between blood and muscle (as black blood effect) tended to be higher in Simul-MRA-VWI than in IR-GRE but showed the no significant difference.CR between plaque and muscle (T1 contrast) was significantly higher in Simul-MRA-VWI than in IR-GRE with moderate correlation between two methods (r=0.78)

CONCLUSION

s Simul-MRA-VWI is a promising technique for shortening scan time with equivalent image quality to conventional sequences and yielding higher contrast MRA and VWI of carotid artery.

CLINICAL RELEVANCE/APPLICATION

Simul-MRA-VWI enable the simultaneous imaging of both carotid artery lumen and vessel wall with equivalent image quality to conventional methods. Our proposed method is practical approach for the reduction of scan time and the integrated assessment of both MRA and VWI without misregistration due to separate acquisition. Further, MRA and VWI obtained by this method can provide the higher contrast and permit the optimal contrast by determination from multiple TI images.

Real Time Augmented Reality (AR) Navigation Technology From Medical Images: Toward Medical Metaverse Era

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Yun-Sik Dho, Cheonju, Korea, Republic Of (*Presenter*) Stock options, Medical IP Co, Ltd

PURPOSE

Augmented reality is the essential underlying technology for metaverse implementation. Concomitant with the significant advances in computing technology, the novel concept of augmented reality (AR) registration and tracking have become possible. We introduce our newly developed real-time inside-out (RTIO) tracking AR navigation system.

METHODS AND MATERIALS

We developed RTIO tracking based on visual inertial odometry and a visual inertial simultaneous localization and mapping algorithm. The cube quick response (QR) marker and depth data obtained from light detection and ranging (LiDAR) sensors are used for continuous tracking. The registration accuracy was validated by both the intuitive method through visualization by the virtual 3-dimensional (3D) patient model for AR and the life-size 3D-printed patient model, and the quantitative method of identifying coordinates by matching errors. For depth realization, order-independent transparency (OIT), clipping, and annotation and measurement functions were developed. To validate depth realization technology, the AR model of a brain tumor patient was applied to its life-size 3D printed model.

RESULTS

By using RTIO tracking, we confirmed that the AR model remained consistent with the 3D-printed patient model without flutter, regardless of the movement of the visualization device. The red fiducial markers of the AR and the blue fiducial markers of the 3D-printed model were superimposed precisely at all locations. The registration accuracy was quantified using coordinates, and the average moving errors of the X-axis and Y-axis before and after the movement of visualization device were 0.34±0.21 and 0.04±0.08 mm (before) and 0.39±0.22 and 0.05±0.09 mm (after), respectively. Further, the application of OIT with multi-layer alpha blending (MLAB) and filtered alpha composites (FAC) improved the perception of overlapping internal brain structures. Clipping and annotation and measurement functions were also developed to aid depth perception, and worked perfectly during real-time coordination. We named this system METAMEDIP navigation.

CONCLUSION

s With these novel technologies developed for continuous tracking and depth perception in AR environments, we are able to overcome the critical obstacles in the development of clinically applicable AR neuronavigation in the metaverse era.

CLINICAL RELEVANCE/APPLICATION

It is verified augmented reality navigation can be used for brain tumor surgery planning and surgery and can be performed while checking anatomical structures intuitively compare to MRI-based neuro-navigation.

Association of Brain Viscoelastic Properties With Age and Glymphatic Function in Neurologically Normal Subjects: An Exploratory Study of MR Elastography Using a Novel Transducer

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Bio Joo, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Magnetic resonance elastography (MRE) can image viscoelastic properties of tissues by measuring propagation of mechanical waves generated by a MRE transducer. The purpose of this study was to investigate the relationship between viscoelastic properties of the brain measured by MRE with a novel MRE transducer and normal aging and glymphatic function in neurologically normal subjects.

METHODS AND MATERIALS

A total of 52 neurologically normal subjects (mean age: 48.1 ± 15.5 years, age range: 23 - 74, male:female = 23:29) were enrolled in this prospective study. MRE was conducted by using a transducer based on a rotational eccentric mass. Viscoelastic parameters, including storage modulus G′, loss modulus G″, magnitude of the complex shear modulus |G*|, and phase angle ?, were assessed in the centrum semiovale region. Glymphatic function was assessed using Diffusion Tensor Image Analysis Along the Perivascular Space index (ALPS-index). The viscoelastic parameters were compared with age and ALPS-index by Pearson correlation coefficient (r).

RESULTS

All the viscoelastic parameters showed significantly negative correlations with age (G′: r=-0.44, P<0.01; G″: r=-0.44, P<0.01; |G*|: r=-0.33, P=0.02; ?: r=-0.29, P=0.04). ALPS-index showed significantly positive correlations with G′ (r=0.35, P=0.02), G″ (r=0.37, P=0.02), and |G*| (r=0.37, P=0.01), but not with ? (r=0.25, P=0.11).

CONCLUSION

s This study demonstrated the applicability of the brain MRE using a novel transducer and the relationship between brain viscoelastic properties and glymphatic function in healthy subjects over a wide range of age. The brain MRE with the gravitational transducer can potentially play a role in various neurological conditions by providing additional information of the brain.

CLINICAL RELEVANCE/APPLICATION

MRE using a gravitational transducer can assess brain viscoelastic properties, which may be associated with normal aging as well as glymphatic function.

R5B-SPOB-1 Re-envisioning Pelvic Organ Prolapse (POP): Comparing Clinical and Imaging Assessments of Pelvic Organ Prolapse

Participants
Daniel Heller, BA, Lincolnwood, IL (*Presenter*) Nothing to Disclose

PURPOSE

To correlate Pelvic Organ Prolapse Quantification (POP-Q) clinical staging with MR defecography (MRD) assessment using correlative anatomical points, and compare staging using different reference line methods.

METHODS AND MATERIALS

IRB-approved, retrospective single-institution study of patients that underwent MRD and POP-Q staging by gynecologists from 2016 to 2022. Exclusion criteria: patients without POP-Q score, incomplete or poor quality MRD. POP-Q scores and clinical presenting complaints were documented. One fellowship-trained radiologist reviewed MRD and documented the following: H-line, and M-line at rest, and evacuation phase; different compartment POP grades based on pubococcygeal line (PCL) and mid pubic line (MPL), and POP-Q variables replicated on MRD. Statistical analysis was performed using weighted kappa tests.

RESULTS

A total of 116 patients with POP underwent MRD from 1/2016 to 4/2022, of which 24 met our inclusion criteria. Levator plate angle (LPA) was abnormal in 23/24 patients, and abnormal urethrovesical angle (UVA) in 19/24. Although PCL is more comparable to clinical staging of POP, both MPL and PCL were not comparable to clinical staging using weighted kappa analysis. MPL consistently overstaged POP, similar to literature. POP-Q variables replicated on MRD: better correlation with points D (16/20), Gh (14/19) and PB (13/20) with an allowed 2-3 cm difference between clinical and MR techniques. POP-Q clinical staging: stage 0 (1/24), stage 1 (8/24), stage 2 (13/24), stage 3 (2/24), stage 4 (0/24). POP staging by MRD was stage 0 (19/24); stage 1 (5/24). Although there is a better correlation of individual points, the overall score is underestimated by MRD. Limitations of the study include small sample size and a single radiologist review. The study can be improved with a multicenter trial, a prolonged study period, and additional radiologists reviewing the images with interreader agreement calculation in the future.

CONCLUSION

s Abnormal LPA and UVA measurements can serve as complementary tools to assess pelvic floor dysfunction. PCL had higher agreement than MPL with POP-Q clinic staging. We recommend a reassessment of the MPL staging criteria to avoid overstaging of POP and to better reflect clinical staging. Although overall POP-Q staging replication on MRD is not representative, individual measurement points can be replicated with confidence and help guide POP management.

CLINICAL RELEVANCE/APPLICATION

Diagnosis and management of pelvic organ prolapse (POP) requires a multidisciplinary approach with radiologists involvement. To date, there is limited radiographic and clinical concordance in POP staging.

MPL consistently overstaged POP, similar to literature. POP-Q variables replicated on MRD: better correlation with points D (16/20), Gh (14/19) and PB (13/20) with an allowed 2-3 cm difference between clinical and MR techniques. POP-Q clinical staging: stage 0 (1/24), stage 1 (8/24), stage 2 (13/24), stage 3 (2/24), stage 4 (0/24). POP staging by MRD was stage 0 (19/24); stage 1 (5/24). Although there is a better correlation of individual points, the overall score is underestimated by MRD. Limitations of the study include small sample size and a single radiologist review. The study can be improved with a multicenter trial, a prolonged study period, and additional radiologists reviewing the images with interreader agreement calculation in the future.

CONCLUSION

s Abnormal LPA and UVA measurements can serve as complementary tools to assess pelvic floor dysfunction. PCL had higher agreement than MPL with POP-Q clinic staging. We recommend a reassessment of the MPL staging criteria to avoid overstaging of POP and to better reflect clinical staging. Although overall POP-Q staging replication on MRD is not representative, individual measurement points can be replicated with confidence and help guide POP management.

CLINICAL RELEVANCE/APPLICATION

Diagnosis and management of pelvic organ prolapse (POP) requires a multidisciplinary approach with radiologists involvement. To date, there is limited radiographic and clinical concordance in POP staging.

R5B-SPPD-1 Comparison of Image Quality, Contrast Administration, and Radiation Dose of Pediatric Abdominal Dual-Energy CT in Actual Usage

Participants
Yeseul Kang, MD, Gyeonggi-do, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To compare the image quality, injected amount of iodine contrast and radiation dose of single-energy CT (SECT) and dual-energy CT (DECT) for pediatric abdominal CT.

METHODS AND MATERIALS

From April to December 2021, pediatric patients (=18 years old) who underwent abdominal SECT or DECT were retrospectively included in this study. Patients were classified into the SECT or DECT group after propensity-score matching. For the DECT group, the amount of iodine contrast was reduced to 10-30% of the routine dose. CT images were obtained at the hepatic venous phase with a routine reconstruction method (iDose4) and DECT was additionally reconstructed with a virtual monochromatic image (VMI) at 40 keV. To compare image quality quantitatively, the contrast-to-noise ratio (CNR) and signal-to-noise ratio (SNR) of the liver, pancreas, and portal vein were compared. The total amount of injected iodine contrast and radiation dose were compared using the Mann-Whitney U test.

RESULTS

Among 318 patients, 116 patients were included after propensity-score matching (median 16 years old, range 9-18 years, 58 patients in each group). Compared with the SECT group, CNR and SNR were significantly lower in the DECT group using the routine reconstruction method, but no significant differences were observed using VMI at 40 keV. The total amount of injected contrast was significantly lower in the DECT group (median 90 cc vs. 76 cc, p=0.007), with a 15.6% reduction from the routine dose. The CT dose index volume did not differ between the two groups (median 2.9 mGy vs. 2.8 mGy, p=0.714).

CONCLUSION

s Pediatric abdominal DECT can reduce the amount of iodine contrast, without significant difference in image quality and radiation dose compared to SECT in our study population of 9-18 years old.

CLINICAL RELEVANCE/APPLICATION

This study demonstrated actual clinical impact of DECT on pediatric abdominal CT and approved that DECT could be used for pediatric patients without degradation of image quality or increasing radiation dose, even with lower iodine contrast amount.

R5B-SPPH-1 Task-Based Image Quality Assessments of Super-Resolution Deep-Learning Reconstruction for Coronary CT Angiography

Participants
Yasunori Nagayama, MD, Kumamoto, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the task-based image quality of novel super-resolution deep-learning reconstruction (SR-DLR) designed for coronary CT angiography and compare it with those of hybrid iterative reconstruction (HIR), model-based iterative reconstruction (MBIR), and normal-resolution DLR (NR-DLR) algorithms.

METHODS AND MATERIALS

A cylindrical physical evaluation phantom (Catphan 700) was scanned on a 320-row scanner at seven tube currents (100-700 mA; CTDIvol, 1.9-10.2 mGy) with a tube voltage of 120 kVp and rotation time of 0.275 s. Raw data were reconstructed with HIR (AIDR 3D), MBIR (FIRST), NR-DLR (AiCE), and SR-DLR (PIQE) at 0.5-mm section thickness using dedicated cardiac parameters. Noise power spectrum (NPS) was evaluated on CTP712 homogeneous module; the noise magnitude and average NPS frequencies were quantified. The spatial resolution at given dose and contrast levels were evaluated with task-based transfer function (TTF) on CTP682 sensitometry module. The values of TTF at 50% (TTF50%) for Delrin (approximately 340 HU), polyethylene (approximately -30 HU), and Bone-50% (approximately 630 HU) inserts were quantified. The detectability index for the simulated coronary lumen (300 HU with a 2-mm diameter), soft plaque (40 HU with a 1-mm diameter), and calcified plaque (500 HU with a 1-mm diameter) were calculated by synthesizing the NPS and TTF outcomes. Five readers subjectively ranked the algorithms in terms of the visibility of fine high-contrast objects, delineation of small low-contrast objects, blooming artifact, noise magnitude, and noise texture on a 4-point scale.

RESULTS

Throughout the entire dose levels, SR-DLR yielded the lowest noise magnitude, highest average NPS frequency, and highest TTF50% for all inserts. The detectability index for all task objects were higher in SR-DLR than in HIR, MBIR, and NR-DLR. At each dose setting, the best subjective scores for all evaluation criteria were attained with SR-DLR.

CONCLUSION

s Compared with HIR, MBIR, and NR-DLR algorithms, newly introduced SR-DLR improved the task-based image quality and detectability for low- and high-contrast objects relevant to coronary CT angiography.

CLINICAL RELEVANCE/APPLICATION

SR-DLR provides CT images with excellent spatial resolution, preferable noise texture, and object detectability, potentially facilitating the interpretation of coronary artery diseases.

R5B-SPPH-3 Physical Properties of a New Deep Learning Reconstruction in Ultra-High-Resolution Images: Comparison with Model-Based Iterative Reconstruction

Participants
Shun Muramatsu, RT, Fukushima, Japan (*Presenter*) Nothing to Disclose

PURPOSE

In this study, we physically evaluated ultra-high resolution (U-HR) images reconstructed with model-based iterative reconstruction (MBIR) and deep learning reconstruction (DLR), and demonstrated the usefulness of U-HR images with DLR.

METHODS AND MATERIALS

The U-HRCT system used in this studywas Aquilion Precision (Canon Medical Systems, Otawara,Tochigi, Japan). This scanner is characterized by 0.25 mm collimation (160 detector rows) in the z axis, and 1792 channels (0.25 mm detectors in the x-y plane). The phantom was 180 mm in diameter and 250 mm in heightand consisted of a water-only part and a part in which fiverods (Wilmington, DE, USA) with different CT numberswere inserted into the water. The data acquired were reconstructed with forward-projected MBIR solution (FIRST), which was MBIR, and Advanced Intelligent Clear-IQ Engine (AiCE), which was DLR. Both images were reconstructed with a slice thickness of 0.25 mm and an image matrix size of 1024 × 1024 pixels. For physical evaluation, the modulation transfer function (MTF) and noise power spectrum (NPS) of MBIR and DLR were compared.

RESULTS

The MTFs of MBIR and DLR were comparable.The NPS of DLR was lower than that of MBIR. The NPS had less noise in DLR than MBIR in all frequency ranges. Therefore, DLR would be more useful than MBIR in termsof physical performance.

CONCLUSION

s There was no difference in the resolution characteristics of MBIR and DLR. DLR had better noise characteristics than MBIR. DLR is more useful than MBIR for with U-HR images.

CLINICAL RELEVANCE/APPLICATION

DLR would be more useful than MBIR for obtainingU-HR images. In contrast to a normal CTimages (matrix size: 512 × 512, slice thickness: 0.5 mm),a high-resolution images (matrix size: 1024 × 1024, slicethickness: 0.25 mm) has a smaller voxel size. Therefore, ifwe consider only the statistics of photon detection, the noisein the image is about four times larger. In other words,in order to achieve a noise level equivalent to that of a conventionalimage, the dose needs to be increased by a factorof 16. Fine sampling requires a combined image noisesuppression technique, and, as mentioned above, DLR maybe effective in reducing image noise. To achieve higher spatial resolution and less image noise, DLR would be more useful than MBIR.

R5B-SPPH-4 Combined digital twin and deep learning approach to scatter correction in head cone-beam CT: Use of MC-GPU and patient-derived head voxel phantom

Participants
AHYEONG LEE, BEng, (*Presenter*) Nothing to Disclose

PURPOSE

A digital twin refers to a digital replica of the physician system that could predict how the system will perform by making simulations. This study explores the potential of combined digital twin and deep learning approach in performance improvement of Cone-beam CT (CBCT).

METHODS AND MATERIALS

A digital twin CBCT platform was constructed by using a Monte Carlo-based CBCT simulator and patient-derived 3D voxel phantoms. From the publicly available CQ500 dataset of head scans, 20 sets of patient-derived 3D head voxel phantoms were generated that mimicked the patient's anatomy and material property of human tissues. MC-GPU was used for accurate simulation of CBCT imaging for the patient-derived voxel phantoms with an accelerated graphics processing unit (GPU) based computing speed including generation of synthetic radiographic images and reconstruction of CT scans reflecting the real-world hardware component and geometry of CBCT systems. Pairs of scattered and corresponding non-scattered images were generated by calculating the interaction of photon transport in voxel phantom through MC-GPU that reflected the real CBCT geometry. The projection images were reconstructed and then, a CNN-based deep learning model was trained to predict the non-scattered CT image from the input scattered CT image. The 20 simulated CT cases were divided into 15 training and 5 test set. The quality improvement with deep learning-based scatter correction was evaluated with cupping artifact index (CAI) and CT number uniformity index (CUI). CAI was defined as the difference between the average HU values in the peripheral area and middle area, while CUI was defined as the difference between maximum and minimum HU values on the homogeneous brain parenchyma.

RESULTS

CAI was 39.59 the scattered image, 5.03 in non-scattered image, and 8.15 in scatter-corrected image, respectively, showing about 90% reduction of cupping artifacts in the scatter-corrected image. CUI was 14.76 in scattered image, 6.26 in scatter-corrected image showing about 42% improved of CT number uniformity in the scatter-corrected image.

CONCLUSION

s Our combined digital twin with a deep learning model could reduce scatter artifacts and has a potential to improve the imaging performance of CBCT.

CLINICAL RELEVANCE/APPLICATION

Reconstructed images using digital twin phantom and MC-GPU are feasible with deep convolutional neural network for CBCT scatter correction, potentially applicable to real CBCT images.

R5B-SPPH-5 Evaluation of Zero TE Imaging for MR-only Catheter Detection in Interstitial Gynecologic HDR Brachytherapy

Participants
Habib Al Saleh, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

One of the main challenges for MR-only interstitial brachytherapy treatment planning is that the implanted plastic needles cannot be detected with acceptable accuracy using conventional MR T1 and T2 weighted images. While it might not also be clearly visible in CT images, our current workflow requires acquisition of CT images with marker-filled catheters for registration with MR images and needle reconstruction. Eventual changes between MR and CT scans could lead to registration errors and affect the calculated dose. In this work, the feasibility of using ZTE images for detection and reconstruction of interstitial needles as an alternative to CT approach was evaluated.

METHODS AND MATERIALS

Two ProGuide (Elekta Brachytherapy, Stockholm, Sweden) 6Fx294mm interstitial plastic needles (one rounded and one sharp) were inserted into a melon and scanned with and without CT marker in a 3.0T GE Signa Premier MRI system (GE Healthcare, Milwaukee, WI) and a Philips Brilliance Big Bore CT (Philips, Netherland). The rounded needle was slightly moved out of its first insertion to demonstrate the ability of detecting needle tip from scanned images. The phantom was CT scanned and subsequently coronal 3D MR images were acquired with MPRAGE T1W (TR/TE 2308/4 ms, FOV 200, matrix 288), CUBE T2W (TR/TE 3000/108 ms, FOV 200, matrix 288) and ZTE (TR/TE 647/0.016, FOV 200, matrix 288). Scan time was approximately identical for all MR sequences. MR images were registered to CT images for comparison.

RESULTS

T1w and T2w images demonstrate susceptibility-induced distortions around the empty needles, and the distortion increased in the presence of the CT-marker. ZTE image of empty needles showed clear depiction of the catheters with no artifacts. With CT marker, ZTE image present less artifact and a uniform distortion around the top part of the marker. ZTE-CT fusion showed very good positional agreement between top bright part of the marker in CT image with the metal-induced susceptibility artifact in the ZTE image.

CONCLUSION

s In this work we showed that ZTE sequence with near zero echo time has the potential to localize empty needles more accurately than T1 and T2 weighted images and can be used with CT-marker for catheter reconstruction in MR-only brachytherapy workflow. Future clinical investigation is required to confirm these initial results for clinical workflow.

CLINICAL RELEVANCE/APPLICATION

Magnetic Resonance Zero Echo Time (ZTE) imaging has the potential to improves interstitial gynecologic HDR brachytherapy dose estimation and MR-guided treatment planning workflow.

R5B-SPPH-6 Evaluation of Multi-Criteria Optimization for Improving RapidPlan Model Based Treatment Planning for Prostate Cancer

Participants
Vishruta Dumane, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the ability of multicriteria optimization (MCO) to improve the dosimetric sparing of the rectum and bladder in RapidPlan based plans for prostate cancer and to compare the results with clinical plans.

METHODS AND MATERIALS

A total of 93 patient plans treated at our institution with radiation using volumetric modulated arc therapy with 2-3coplanar arcs and 6 MV photons were used to build a dose volume histogram (DVH) estimation model for organs at risk (OARs, essentially the bladder, bladder wall, rectum, rectal wall, bowel and femoral heads). Prescription dose to the PTV was 45 Gy. Dose constraints for the rectal wall and the bladder wall were e V40Gy lt 30%, V30Gy lt 50%, bowel maximum lt 50Gy, femoral head maximum lt 45Gy and V30Gy lt 50%. Dose heterogeneity to the PTV was expected to be within 110% and the PTV D95 at least 98%. The model generated was tested on 10 patient cases that were not originally used in training or testing. After application of the RapidPlan model, MCO was utilized to explore tradeoffs to see if the organ at risk (OAR) sparing could be improved without compromising on the coverage or other OAR doses. Dosimetric parameters between the MCO + Rapidplan were compared to both the RapidPlan alone and the clinical plan. Parameters were compared using the Wilcoxon sign-rank test for statistical significance.

RESULTS

Compared to the clinical plan, combination of MCO and RapidPlan helped reduce the rectum V30Gy, V25Gy, V20Gy, V15Gy and V10Gy by 6.2%, 10.5%, 18.3%, 26.6% and 10.2% (p lt 0.01) respectively without a significant change in PTV D95 and V95 or the rectal wall maximum dose. The improvement in sparing of the rectum with MCO over RapidPlan alone for these dosimetric parameters was as much as 16.8% (p lt 0.01). Compared to the clinical plan, combination of MCO and RapidPlan was also reduced the bladder V30Gy, V25Gy, V20Gy, V15Gy and V10Gy by as much as 8.5%. MCO+RapidPlan did not significant improve bladder sparing compared to RapidPlan alone. The change in the maximum dose to the bladder wall was insignificant as a result of using MCO+RapidPlan

CONCLUSION

s Although both the clinical and the RapidPlan based plans can meet dose constraints, MCO can potentially significantly improve the sparing of OARs and has the potential to improve our RapidPlan model for intact prostate.

CLINICAL RELEVANCE/APPLICATION

Development of optimal treatment plans for patient specific anatomy requires a significant intervention from the treatment planner. This work shows not only the potential of MCO + RapidPlan to meet constraints but also significantly improve OAR sparing that could be clinically impactful.

R5B-SPPH-7 Carbon Nanotube-Based Wide-Slot Long-Length Tomosynthesis for Whole Body Skeletal Imaging

Participants
Diwash Thapa, BS, Wake Forest, NC (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this work is to demonstrate the feasibility of cone beam geometry-based reconstruction for long length tomosynthesis in a system comprising carbon nanotube (CNT) x-ray sources and to characterize the scatter and radiation associated with the system.

METHODS AND MATERIALS

CNT-based long length tomosynthesis or orthogonal tomosynthesis (OT) consists of a linear x-ray tube positioned orthogonally to a small field-of-view (FOV) area detector. Sources are collimated to a 5 X 30 cm2 rectangular strip on the detector and projections are acquired in a step-and-shoot scheme (figure 1 a). In preprocessing, all projections from a given source were stitched using weighted addition. Reconstructions were performed with two algorithms: simultaneous iterative reconstruction technique (SIRT) and simultaneous algebraic reconstruction technique (SART). Entrance dose at 100 cm source to detector distance was measured using the RaySafe X2 R/F sensor (figure 1 b) and the dose area product (DAP) within the FOV was calculated. Projection space scatter to primary ratio (S/P) and scatter degradation factor (SDF) was calculated.

RESULTS

Reconstruction images using SIRT and SART are displayed in figure 1 c, d. The compiled SIRT algorithm took 3.44 s while SART took

21.6 s for completion. Both reconstructions were found to be anatomically correct and provided good resolution of all osseous structures. With collimation, DAP was calculated to be 170.0 mGy whereas without collimation DAP was 207.1 mGy to image the 540 cm2 FOV of the chest phantom reconstructions. The average S/P and SDF with collimation across sources was 0.31 and 0.77 while the same was 0.69 and 0.59 respectively without collimation.

CONCLUSION

s This work demonstrates the feasibility of cone beam geometry based algebraic reconstruction for OT. Due to collimation, this system has significantly reduced scatter (> 50% decrease in S/P) and radiation (18% decrease in DAP) burden compared to conventional tomosynthesis.

CLINICAL RELEVANCE/APPLICATION

Conventional tomosynthesis is performed with specific anatomy within a limited FOV. Extended FOV tomosynthesis is beneficial for whole-body skeletal imaging in austere environments due to tomosynthesis' increased fracture detection sensitivity. Current research and commercial long-length tomosynthesis systems are built on large gantries making them unsuitable for mobile applications. The OT system presented here can be mounted on a single small unit and fits on the back of an ambulance or a helicopter. Patients could be scanned as they are loaded into the transport vehicle without the tube/detector ever moving. The reduced scatter and radiation hazard also makes OT suitable for repetitive use such as scoliosis imaging.

R5B-SPPH-8 Deep learning denoising and assessment of detectability of microcalcifications in digital breast tomosynthesis: A task-based image evaluation approach using CNN

Participants
Mingjie Gao, (*Presenter*) Nothing to Disclose

PURPOSE

Deep learning (DL) denoising for digital breast tomosynthesis (DBT) has the potential to reduce dose and improve microcalcification (MC) detection. This study proposed two convolutional neural network (CNN) models to assess image noise (CNN-ns) and MC detectability (CNN-mc) and guide the development of denoising techniques.

METHODS AND MATERIALS

For the CNN-ns for noise estimation, we extracted 52,526 128×128×3-pixel patches from virtual DBTs of a wide range of noise levels simulated by the VICTRE software as training set and calculated the root-mean-square variations of pixel values as training labels to fine-tune the ImageNet pre-trained ConvNeXt-T. For the CNN-mc for MC vs background classification, we collected with IRB approval 231 views of DBTs from 116 human subjects who had biopsy proven MCs and split the set by case into 127 views for training/validation and 104 views for testing. We reconstructed the DBTs with (1) simultaneous algebraic reconstruction technique (SART), (2) SART with DL-denoised projections, and (3) DL-denoiser regularized plug-and-play reconstruction. For each condition, we extracted 751 128×128×3-pixel MC patches (6,008 after flipping and rotation augmentation) and 6,305 MC-free patches as training/validation set, and 709 MC and 777 MC-free patches as test set. Maximum intensity projection of the 3 slices was applied to all patches to emphasize the MCs. We adopted a multi-stage transfer learning strategy of first fine-tuning the ConvNeXt-T to CNN-ns, which was then further fine-tuned to CNN-mc. We used the area under ROC curve (AUC) of the CNN-mc as an MC detectability measure.

RESULTS

Our DL denoising methods reduced image noise and improved AUC. The AUC increased with MC signal strengths when the CNN-ns estimated noise was comparable. DL-denoiser regularized reconstruction with additional post-reconstruction denoising resulted in the lowest CNN-ns estimated noise and highest AUC. The AUC and noise rankings matched our visual judgement on the images.

CONCLUSION

s The CNN-mc and CNN-ns provided task-based measures for image assessment, which may be useful for comparison of the detectability of clustered MCs in DBTs obtained with different denoising or reconstruction techniques.

CLINICAL RELEVANCE/APPLICATION

The CNN image assessment tools can help develop better DBT denoising or reconstruction methods, which may lead to lower dose and higher sensitivity and specificity for MC detection in screening.

Task-Based Image Quality Assessments of Super-Resolution Deep-Learning Reconstruction for Coronary CT Angiography

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - PH DPS

Participants
Yasunori Nagayama, MD, Kumamoto, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the task-based image quality of novel super-resolution deep-learning reconstruction (SR-DLR) designed for coronary CT angiography and compare it with those of hybrid iterative reconstruction (HIR), model-based iterative reconstruction (MBIR), and normal-resolution DLR (NR-DLR) algorithms.

METHODS AND MATERIALS

A cylindrical physical evaluation phantom (Catphan 700) was scanned on a 320-row scanner at seven tube currents (100-700 mA; CTDIvol, 1.9-10.2 mGy) with a tube voltage of 120 kVp and rotation time of 0.275 s. Raw data were reconstructed with HIR (AIDR 3D), MBIR (FIRST), NR-DLR (AiCE), and SR-DLR (PIQE) at 0.5-mm section thickness using dedicated cardiac parameters. Noise power spectrum (NPS) was evaluated on CTP712 homogeneous module; the noise magnitude and average NPS frequencies were quantified. The spatial resolution at given dose and contrast levels were evaluated with task-based transfer function (TTF) on CTP682 sensitometry module. The values of TTF at 50% (TTF50%) for Delrin (approximately 340 HU), polyethylene (approximately -30 HU), and Bone-50% (approximately 630 HU) inserts were quantified. The detectability index for the simulated coronary lumen (300 HU with a 2-mm diameter), soft plaque (40 HU with a 1-mm diameter), and calcified plaque (500 HU with a 1-mm diameter) were calculated by synthesizing the NPS and TTF outcomes. Five readers subjectively ranked the algorithms in terms of the visibility of fine high-contrast objects, delineation of small low-contrast objects, blooming artifact, noise magnitude, and noise texture on a 4-point scale.

RESULTS

Throughout the entire dose levels, SR-DLR yielded the lowest noise magnitude, highest average NPS frequency, and highest TTF50% for all inserts. The detectability index for all task objects were higher in SR-DLR than in HIR, MBIR, and NR-DLR. At each dose setting, the best subjective scores for all evaluation criteria were attained with SR-DLR.

CONCLUSION

s Compared with HIR, MBIR, and NR-DLR algorithms, newly introduced SR-DLR improved the task-based image quality and detectability for low- and high-contrast objects relevant to coronary CT angiography.

CLINICAL RELEVANCE/APPLICATION

SR-DLR provides CT images with excellent spatial resolution, preferable noise texture, and object detectability, potentially facilitating the interpretation of coronary artery diseases.

Physical Properties of a New Deep Learning Reconstruction in Ultra-High-Resolution Images: Comparison with Model-Based Iterative Reconstruction

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - PH DPS

Participants
Shun Muramatsu, RT, Fukushima, Japan (*Presenter*) Nothing to Disclose

PURPOSE

In this study, we physically evaluated ultra-high resolution (U-HR) images reconstructed with model-based iterative reconstruction (MBIR) and deep learning reconstruction (DLR), and demonstrated the usefulness of U-HR images with DLR.

METHODS AND MATERIALS

The U-HRCT system used in this studywas Aquilion Precision (Canon Medical Systems, Otawara,Tochigi, Japan). This scanner is characterized by 0.25 mm collimation (160 detector rows) in the z axis, and 1792 channels (0.25 mm detectors in the x-y plane). The phantom was 180 mm in diameter and 250 mm in heightand consisted of a water-only part and a part in which fiverods (Wilmington, DE, USA) with different CT numberswere inserted into the water. The data acquired were reconstructed with forward-projected MBIR solution (FIRST), which was MBIR, and Advanced Intelligent Clear-IQ Engine (AiCE), which was DLR. Both images were reconstructed with a slice thickness of 0.25 mm and an image matrix size of 1024 × 1024 pixels. For physical evaluation, the modulation transfer function (MTF) and noise power spectrum (NPS) of MBIR and DLR were compared.

RESULTS

The MTFs of MBIR and DLR were comparable.The NPS of DLR was lower than that of MBIR. The NPS had less noise in DLR than MBIR in all frequency ranges. Therefore, DLR would be more useful than MBIR in termsof physical performance.

CONCLUSION

s There was no difference in the resolution characteristics of MBIR and DLR. DLR had better noise characteristics than MBIR. DLR is more useful than MBIR for with U-HR images.

CLINICAL RELEVANCE/APPLICATION

DLR would be more useful than MBIR for obtainingU-HR images. In contrast to a normal CTimages (matrix size: 512 × 512, slice thickness: 0.5 mm),a high-resolution images (matrix size: 1024 × 1024, slicethickness: 0.25 mm) has a smaller voxel size. Therefore, ifwe consider only the statistics of photon detection, the noisein the image is about four times larger. In other words,in order to achieve a noise level equivalent to that of a conventionalimage, the dose needs to be increased by a factorof 16. Fine sampling requires a combined image noisesuppression technique, and, as mentioned above, DLR maybe effective in reducing image noise. To achieve higher spatial resolution and less image noise, DLR would be more useful than MBIR.

Combined digital twin and deep learning approach to scatter correction in head cone-beam CT: Use of MC-GPU and patient-derived head voxel phantom

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - PH DPS

Participants
AHYEONG LEE, BEng, (*Presenter*) Nothing to Disclose

PURPOSE

A digital twin refers to a digital replica of the physician system that could predict how the system will perform by making simulations. This study explores the potential of combined digital twin and deep learning approach in performance improvement of Cone-beam CT (CBCT).

METHODS AND MATERIALS

A digital twin CBCT platform was constructed by using a Monte Carlo-based CBCT simulator and patient-derived 3D voxel phantoms. From the publicly available CQ500 dataset of head scans, 20 sets of patient-derived 3D head voxel phantoms were generated that mimicked the patient's anatomy and material property of human tissues. MC-GPU was used for accurate simulation of CBCT imaging for the patient-derived voxel phantoms with an accelerated graphics processing unit (GPU) based computing speed including generation of synthetic radiographic images and reconstruction of CT scans reflecting the real-world hardware component and geometry of CBCT systems. Pairs of scattered and corresponding non-scattered images were generated by calculating the interaction of photon transport in voxel phantom through MC-GPU that reflected the real CBCT geometry. The projection images were reconstructed and then, a CNN-based deep learning model was trained to predict the non-scattered CT image from the input scattered CT image. The 20 simulated CT cases were divided into 15 training and 5 test set. The quality improvement with deep learning-based scatter correction was evaluated with cupping artifact index (CAI) and CT number uniformity index (CUI). CAI was defined as the difference between the average HU values in the peripheral area and middle area, while CUI was defined as the difference between maximum and minimum HU values on the homogeneous brain parenchyma.

RESULTS

CAI was 39.59 the scattered image, 5.03 in non-scattered image, and 8.15 in scatter-corrected image, respectively, showing about 90% reduction of cupping artifacts in the scatter-corrected image. CUI was 14.76 in scattered image, 6.26 in scatter-corrected image showing about 42% improved of CT number uniformity in the scatter-corrected image.

CONCLUSION

s Our combined digital twin with a deep learning model could reduce scatter artifacts and has a potential to improve the imaging performance of CBCT.

CLINICAL RELEVANCE/APPLICATION

Reconstructed images using digital twin phantom and MC-GPU are feasible with deep convolutional neural network for CBCT scatter correction, potentially applicable to real CBCT images.

Evaluation of Zero TE Imaging for MR-only Catheter Detection in Interstitial Gynecologic HDR Brachytherapy

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - PH DPS

Participants
Habib Al Saleh, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

One of the main challenges for MR-only interstitial brachytherapy treatment planning is that the implanted plastic needles cannot be detected with acceptable accuracy using conventional MR T1 and T2 weighted images. While it might not also be clearly visible in CT images, our current workflow requires acquisition of CT images with marker-filled catheters for registration with MR images and needle reconstruction. Eventual changes between MR and CT scans could lead to registration errors and affect the calculated dose. In this work, the feasibility of using ZTE images for detection and reconstruction of interstitial needles as an alternative to CT approach was evaluated.

METHODS AND MATERIALS

Two ProGuide (Elekta Brachytherapy, Stockholm, Sweden) 6Fx294mm interstitial plastic needles (one rounded and one sharp) were inserted into a melon and scanned with and without CT marker in a 3.0T GE Signa Premier MRI system (GE Healthcare, Milwaukee, WI) and a Philips Brilliance Big Bore CT (Philips, Netherland). The rounded needle was slightly moved out of its first insertion to demonstrate the ability of detecting needle tip from scanned images. The phantom was CT scanned and subsequently coronal 3D MR images were acquired with MPRAGE T1W (TR/TE 2308/4 ms, FOV 200, matrix 288), CUBE T2W (TR/TE 3000/108 ms, FOV 200, matrix 288) and ZTE (TR/TE 647/0.016, FOV 200, matrix 288). Scan time was approximately identical for all MR sequences. MR images were registered to CT images for comparison.

RESULTS

T1w and T2w images demonstrate susceptibility-induced distortions around the empty needles, and the distortion increased in the presence of the CT-marker. ZTE image of empty needles showed clear depiction of the catheters with no artifacts. With CT marker, ZTE image present less artifact and a uniform distortion around the top part of the marker. ZTE-CT fusion showed very good positional agreement between top bright part of the marker in CT image with the metal-induced susceptibility artifact in the ZTE image.

CONCLUSION

s In this work we showed that ZTE sequence with near zero echo time has the potential to localize empty needles more accurately than T1 and T2 weighted images and can be used with CT-marker for catheter reconstruction in MR-only brachytherapy workflow. Future clinical investigation is required to confirm these initial results for clinical workflow.

CLINICAL RELEVANCE/APPLICATION

Magnetic Resonance Zero Echo Time (ZTE) imaging has the potential to improves interstitial gynecologic HDR brachytherapy dose estimation and MR-guided treatment planning workflow.

Evaluation of Multi-Criteria Optimization for Improving RapidPlan Model Based Treatment Planning for Prostate Cancer

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - PH DPS

Participants
Vishruta Dumane, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the ability of multicriteria optimization (MCO) to improve the dosimetric sparing of the rectum and bladder in RapidPlan based plans for prostate cancer and to compare the results with clinical plans.

METHODS AND MATERIALS

A total of 93 patient plans treated at our institution with radiation using volumetric modulated arc therapy with 2-3coplanar arcs and 6 MV photons were used to build a dose volume histogram (DVH) estimation model for organs at risk (OARs, essentially the bladder, bladder wall, rectum, rectal wall, bowel and femoral heads). Prescription dose to the PTV was 45 Gy. Dose constraints for the rectal wall and the bladder wall were e V40Gy lt 30%, V30Gy lt 50%, bowel maximum lt 50Gy, femoral head maximum lt 45Gy and V30Gy lt 50%. Dose heterogeneity to the PTV was expected to be within 110% and the PTV D95 at least 98%. The model generated was tested on 10 patient cases that were not originally used in training or testing. After application of the RapidPlan model, MCO was utilized to explore tradeoffs to see if the organ at risk (OAR) sparing could be improved without compromising on the coverage or other OAR doses. Dosimetric parameters between the MCO + Rapidplan were compared to both the RapidPlan alone and the clinical plan. Parameters were compared using the Wilcoxon sign-rank test for statistical significance.

RESULTS

Compared to the clinical plan, combination of MCO and RapidPlan helped reduce the rectum V30Gy, V25Gy, V20Gy, V15Gy and V10Gy by 6.2%, 10.5%, 18.3%, 26.6% and 10.2% (p lt 0.01) respectively without a significant change in PTV D95 and V95 or the rectal wall maximum dose. The improvement in sparing of the rectum with MCO over RapidPlan alone for these dosimetric parameters was as much as 16.8% (p lt 0.01). Compared to the clinical plan, combination of MCO and RapidPlan was also reduced the bladder V30Gy, V25Gy, V20Gy, V15Gy and V10Gy by as much as 8.5%. MCO+RapidPlan did not significant improve bladder sparing compared to RapidPlan alone. The change in the maximum dose to the bladder wall was insignificant as a result of using MCO+RapidPlan

CONCLUSION

s Although both the clinical and the RapidPlan based plans can meet dose constraints, MCO can potentially significantly improve the sparing of OARs and has the potential to improve our RapidPlan model for intact prostate.

CLINICAL RELEVANCE/APPLICATION

Development of optimal treatment plans for patient specific anatomy requires a significant intervention from the treatment planner. This work shows not only the potential of MCO + RapidPlan to meet constraints but also significantly improve OAR sparing that could be clinically impactful.

Carbon Nanotube-Based Wide-Slot Long-Length Tomosynthesis for Whole Body Skeletal Imaging

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - PH DPS

Participants
Diwash Thapa, BS, Wake Forest, NC (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this work is to demonstrate the feasibility of cone beam geometry-based reconstruction for long length tomosynthesis in a system comprising carbon nanotube (CNT) x-ray sources and to characterize the scatter and radiation associated with the system.

METHODS AND MATERIALS

CNT-based long length tomosynthesis or orthogonal tomosynthesis (OT) consists of a linear x-ray tube positioned orthogonally to a small field-of-view (FOV) area detector. Sources are collimated to a 5 X 30 cm2 rectangular strip on the detector and projections are acquired in a step-and-shoot scheme (figure 1 a). In preprocessing, all projections from a given source were stitched using weighted addition. Reconstructions were performed with two algorithms: simultaneous iterative reconstruction technique (SIRT) and simultaneous algebraic reconstruction technique (SART). Entrance dose at 100 cm source to detector distance was measured using the RaySafe X2 R/F sensor (figure 1 b) and the dose area product (DAP) within the FOV was calculated. Projection space scatter to primary ratio (S/P) and scatter degradation factor (SDF) was calculated.

RESULTS

Reconstruction images using SIRT and SART are displayed in figure 1 c, d. The compiled SIRT algorithm took 3.44 s while SART took 21.6 s for completion. Both reconstructions were found to be anatomically correct and provided good resolution of all osseous structures. With collimation, DAP was calculated to be 170.0 mGy whereas without collimation DAP was 207.1 mGy to image the 540 cm2 FOV of the chest phantom reconstructions. The average S/P and SDF with collimation across sources was 0.31 and 0.77 while the same was 0.69 and 0.59 respectively without collimation.

CONCLUSION

s This work demonstrates the feasibility of cone beam geometry based algebraic reconstruction for OT. Due to collimation, this system has significantly reduced scatter (> 50% decrease in S/P) and radiation (18% decrease in DAP) burden compared to conventional tomosynthesis.

CLINICAL RELEVANCE/APPLICATION

Conventional tomosynthesis is performed with specific anatomy within a limited FOV. Extended FOV tomosynthesis is beneficial for whole-body skeletal imaging in austere environments due to tomosynthesis' increased fracture detection sensitivity. Current research and commercial long-length tomosynthesis systems are built on large gantries making them unsuitable for mobile applications. The OT system presented here can be mounted on a single small unit and fits on the back of an ambulance or a helicopter. Patients could be scanned as they are loaded into the transport vehicle without the tube/detector ever moving. The reduced scatter and radiation hazard also makes OT suitable for repetitive use such as scoliosis imaging.

Deep learning denoising and assessment of detectability of microcalcifications in digital breast tomosynthesis: A task-based image evaluation approach using CNN

Thursday, Dec. 1 12:45PM - 1:15PM Room: Learning Center - PH DPS

Participants
Mingjie Gao, (*Presenter*) Nothing to Disclose

PURPOSE

Deep learning (DL) denoising for digital breast tomosynthesis (DBT) has the potential to reduce dose and improve microcalcification (MC) detection. This study proposed two convolutional neural network (CNN) models to assess image noise (CNN-ns) and MC detectability (CNN-mc) and guide the development of denoising techniques.

METHODS AND MATERIALS

For the CNN-ns for noise estimation, we extracted 52,526 128×128×3-pixel patches from virtual DBTs of a wide range of noise levels simulated by the VICTRE software as training set and calculated the root-mean-square variations of pixel values as training labels to fine-tune the ImageNet pre-trained ConvNeXt-T. For the CNN-mc for MC vs background classification, we collected with IRB approval 231 views of DBTs from 116 human subjects who had biopsy proven MCs and split the set by case into 127 views for training/validation and 104 views for testing. We reconstructed the DBTs with (1) simultaneous algebraic reconstruction technique (SART), (2) SART with DL-denoised projections, and (3) DL-denoiser regularized plug-and-play reconstruction. For each condition, we extracted 751 128×128×3-pixel MC patches (6,008 after flipping and rotation augmentation) and 6,305 MC-free patches as training/validation set, and 709 MC and 777 MC-free patches as test set. Maximum intensity projection of the 3 slices was applied to all patches to emphasize the MCs. We adopted a multi-stage transfer learning strategy of first fine-tuning the ConvNeXt-T to CNN-ns, which was then further fine-tuned to CNN-mc. We used the area under ROC curve (AUC) of the CNN-mc as an MC detectability measure.

RESULTS

Our DL denoising methods reduced image noise and improved AUC. The AUC increased with MC signal strengths when the CNN-ns estimated noise was comparable. DL-denoiser regularized reconstruction with additional post-reconstruction denoising resulted in the lowest CNN-ns estimated noise and highest AUC. The AUC and noise rankings matched our visual judgement on the images.

CONCLUSION

s The CNN-mc and CNN-ns provided task-based measures for image assessment, which may be useful for comparison of the detectability of clustered MCs in DBTs obtained with different denoising or reconstruction techniques.

CLINICAL RELEVANCE/APPLICATION

The CNN image assessment tools can help develop better DBT denoising or reconstruction methods, which may lead to lower dose and higher sensitivity and specificity for MC detection in screening.

S3A-SPBR-1 Use of Artificial Intelligence in Women with Mammographic Abnormality Reduces Screening Recalls

Participants
Jung Min Chang, MD, Seoul, (*Presenter*) Research Consultant, Genoray Co, Ltd

PURPOSE

Potential benefit of using artificial intelligence (AI) in reducing screening mammography recalls has not been well investigated in the past. This study was to evaluate whether artificial intelligence (AI)-aided reviews of mammographic findings can reduce unnecessary recall while maintaining cancer detection ability in mammography screening.

METHODS AND MATERIALS

A retrospective reader study was performed with screening mammography from women who were recalled for mammography-detected abnormalities between January 2016 and December 2019 at two screening centers. Exams were sequentially interpreted in two sessions, with and without AI aid, by three radiologists providing their decision on whether it should be recalled. The area under the receiver operating characteristic curve (AUC), sensitivity, specificity, and recall rates were compared.

RESULTS

A total of 793 women (mean age ± standard deviation, 49.8 years ± 8.9), 54 cancer and 739 benign cases, were included. The AI standalone per-examination AUC was significantly higher than that of all three radiologists (0.94 [95% CI, 0.92-0.97] vs. 0.76 [95% CI, 0.69-0.83]; 0.80 [95% CI, 0.74-0.86]; 0.86 [95% CI, 0.82-0.91]; P <.001, respectively). The per-examination and per-lesion reader-averaged AUC improved after AI aid (0.80 [95% CI, 0.71-0.90] vs. 0.91 [95% CI, 0.83-0.99]; P =.02; 0.79 [95% CI, 0.70-0.89] vs. 0.89 [95% CI, 0.83-0.96]; P =.03). In both the per-examination and per-lesion analyses, average specificities of all radiologists improved after AI aid (41.9% [95% CI, 4.3%-79.5%] vs. 53.9% [95% CI, 27.1%-80.7%]; P =.04), whereas the sensitivities only improved for the least experienced radiologist with AI aid (79.6%, 43 of 54 [95% CI, 66.5%-89.4%] vs. 90.7%, 49 of 54 [95% CI, 79.7%-96.9%]; P =.03). With AI aid, the average recall rate decreased from 60.4% (95% CI, 23.9%-96.8%) to 49.5% (95% CI, 23.9%-75.0%) with marginal significance (P =.05).

CONCLUSION

s The use of an AI system in women with screening recalls reduces the need for supplemental mammographic views and improves the overall diagnostic performance.

CLINICAL RELEVANCE/APPLICATION

In women recalled for mammographic abnormalities, the use of an AI system could improve the diagnostic performance of screening mammography, and provide an efficient way of diagnosing negative cases, which ultimately leads to a reduction of unnecessary recall and the workload.

S3A-SPBR-2 Deep Learning-enabled Fully Automated Pipeline for Segmentation and Classification of Breast Lesions using Contrast Enhanced Mammography

Participants
Ning Mao, Yantai, China (*Presenter*) Nothing to Disclose

PURPOSE

We aimed to develop a deep learning - enabled fully automated pipeline for segmentation and classification of breast lesions using contrast enhanced mammography (CEM).

METHODS AND MATERIALS

In this study, we retrospectively collected 1710 preoperative CEM images of breast lesions from a hospital for the fully automated pipeline development and test. We adopted RefineNet and Xception as sub-networks of the pipeline system to perform segmentation and classification tasks, respectively. The segmentation performance was assessed using dice similarity coefficient (DSC) in test set. For classification task, we compared our system with the classification performance of four radiologists using the area under the receiver operating characteristic curve (AUROC). Finally, we also explored the performance of radiologists assisted by artificial intelligence (AI) and the changes in the amount of fine needle aspiration biopsy under the AI-assisted Breast Imaging Reporting and Data System (BI-RADS) category in view of clinical application.

RESULTS

The automated pipeline for tumor segmentation achieved a DSC 0.888 in test cohort, the classification task performed by the Xception yielded an AUC of 0.906 (95%CI=0.857-0.955) in the CC+MLO view on test set, which is higher than CC view (0.876, 95%CI=0.819-0.933) and MLO view (0.850, 95%CI=0.784-0.916). And it also was significantly higher than those of radiologists (0.846,95%CI=0.784-0.916). Furthermore, AI-assisted strategy improved the pooled AUC of the radiologists from 0.741(95%CI=0.657-0.855) when diagnosing without AI to 0.874 (95%CI=0.757-0.921) with AI for the performance of classification in test set. The number of fine needle aspiration biopsies also reduced from 162 to 120 in the case of AI assisting BI-RADS category in test set.

CONCLUSION

s Our fully automated pipeline system based on CEM demonstrated the potential for segmentation and classification of breast lesions, and also had good clinical applicability.

CLINICAL RELEVANCE/APPLICATION

The fully automated pipeline system that we developed can be well applied to the segmentation and classification of breast lesions as a non-invasive method, In addition, it also contributes greatly in assisting radiologists in making BI-RADS classification and reduces unnecessary biopsies, which could alleviate patient healthcare burden and promote the reallocation of healthcare resources.

S3A-SPBR-3 Artificial Intelligence (AI) for Ultrasound (US) MicroFlow Imaging (MFI) in Breast Cancer Diagnosis

Participants
Ji Hyun Youk, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To develop and evaluate AI algorithms for US MFI in breast cancer diagnosis

METHODS AND MATERIALS

We retrospectively collected a dataset consisting of 516 breast lesions (364 benign, 152 malignant) in 471 women who underwent B-mode US and MFI. BI-RADS category assigned by board-certified breast radiologists on B-mode US were noted. Pathology or at least 2-year follow up was used as the reference standard. To develop AI algorithms based on deep CNNs for MFI, the internal dataset was split on into training (n=410, 79%) and test dataset (n=106, 21%). AI algorithms were trained to provide malignancy risk (0-100%). The developed AI algorithms were further validated with an independent external dataset consisting of 238 breast lesions (208 benign, 27 malignant). To evaluate and compare the diagnostic performance of B-mode US, AI algorithms, or their combination, the area under the receiver operating characteristic curve (AUROC) was calculated. Logistic regression analysis was used to calculate the malignancy risk of lesions in combined B-mode US and AI algorithms.

RESULTS

The AUROC of developed three AI algorithms were 0.966, 0.964, and 0.955, respectively, and higher than that of B-mode US (0.842, P<.0001). AI algorithms had higher specificity (93-95% vs. 72%) and accuracy (93% vs. 79%) than B-mode US (P<.003). No significant difference was found in sensitivity between AI algorithms (88-91%) and B-mode US (97%). The performance metrics of the AI algorithms on the external validation dataset were similar to those of the test dataset (AUROC of 0.892-0.920, sensitivity of 82-89%, specificity of 92-98%, and accuracy of 91-96%). Among AI algorithms, no significant difference was found in all performance metrics with or without combination of B-mode US. Combined B-mode US and AI algorithms had higher performance than B-mode US (AUROC of 0.963-0.972, specificity of 96%, and accuracy of 94%, P=.0001) except sensitivity (91%). By combining B-mode US and AI algorithms, false-positive rate of BI-RADS category 4A lesions significantly decreased from 87% to 13% (P<.0001).

CONCLUSION

s AI-based MFI diagnosed breast cancers with better performance than B-mode US. Combined B-mode US and AI algorithm could eliminate 74% of false-positive diagnosis in BI-RADS category 4A lesions.

CLINICAL RELEVANCE/APPLICATION

AI-based MFI can improve diagnostic accuracy of breast US by decreasing false positives diagnosis, and thus reducing unnecessary biopsies of benign lesions.

S3A-SPBR-4 Detailed External Validation of A Commercial AI Algorithm for Breast Cancer Detection in The Setting of An Organized Population-based Breast Screening

Participants
Janette Sam, RT, Vancouver, BC (*Presenter*) Nothing to Disclose

PURPOSE

Evaluate the performance of a commercial Artificial Intelligence (AI) system for breast cancer detection using the digital mammograms from the BC Cancer Breast Screening Program

METHODS AND MATERIALS

Digital screening mammograms and associated outcomes, including mammographic findings (features), demographics, and risk factors were extracted for 136,700 women who underwent breast screening in British Columbia, Canada during the period February 1, 2019 - January 31, 2020. The outcome data were extracted on March 18, 2022. The images were de-identified and fed to the Lunit MMG AI algorithm version 1.1.2.0 running on a GeForce RTX 2080 GPU with 11 GB VRAM. The AI model performance was evaluated using Area Under the Curve (AUC) of Receiver Operating Characteristic (ROC) methodology.

RESULTS

The overall performance of the AI algorithm measured with AUC was 0.938 (CI: 0.927-0.949). However, once binary classification is performed using the 10% cut-off value used by the algorithm, the AUC dropped to 0.846 (0.836-0.856) compared to the

radiologists performance at 0.937 (0.929-0.944). The AI AUC for BIRAD breast density categories assigned by the radiologists were: A: 0.964 (0.934-0.993); B: 0.946 (0.932-0.961); C: 0.934 (0.916-0.952) and D: 0.831 (0.752-0.911). For women with family history of breast cancer, the AI AUC was 0.919 (0.895-0.943) whereas for women with no family history, 0.945 (0.933-0.957). The algorithm performance for cancers with any architectural distortion was 0.961 (0.944-0.978) whereas for cancers with any calcifications was 0.878 (0.855-0.900).

CONCLUSION

s The tested commercial AI algorithm is generalizable for a large external cohort from Canada. However, the performance of the AI algorithm fell short of that of the well-qualified screening program radiologists. Performance of the algorithm for women with family history of breast cancer and for cancers manifesting as calcifications was found to be weaker.

CLINICAL RELEVANCE/APPLICATION

Commercial AI algorithms well trained with datasets from multiple countries for breast cancer detection can be generalizable to cohorts in other countries. However, further improvements may be needed to match the performance of radiologists from well-organized population based breast screening programs.

S3A-SPBR-6 Investigating a Stand-alone AI System Prompt Accuracy for Interval Cancer Detection in Screening Mammography

Awards
Trainee Research Prize - Fellow

Participants
Sarah Hickman, MBBS, Cambridge, United Kingdom (*Presenter*) Research collaboration, Vara;Research collaboration, ScreenPoint Medical BV;Research collaboration, Lunit Inc;Research collaboration, Kheiron Medical Technologies Ltd;Research collaboration, Alphabet Inc;Research collaboration, Volpara Health Technologies Limited

PURPOSE

To evaluate the accuracy of prompts from a commercial artificial intelligence (AI) system in interval cancer detection.

METHODS AND MATERIALS

An enriched dataset of screening mammograms of 1548 normals and 514 interval cancers diagnosed between 2011 and 2018 was analyzed with a commercial AI algorithm. This provided a continuous per-lesion, per-image, per-breast and per-case score (0-10), and prompts for suspicious lesion location. A pre-defined threshold specificity of 96%, (prompt score 6.8) was used. Each case is assigned an overall risk score representing the highest per-lesion score. Interval cancers were classified as either true negatives, minimal signs, or false negatives by a consensus panel. The cancer cases were reviewed (radiologist, 7 years' experience) to determine the accuracy of prompt location (prompt within boundary of cancer) with consensus (two breast radiologists) for indeterminate cases. The ground truth was histopathology for cancers and a three yearly normal screen for normals.

RESULTS

The algorithm prompted 122/514 cancer cases, with an average prompt score of 8.5 (6.8-9.9) and correct localisation in 93/122 cases (76.2%). The highest prompt score was given for the cancer in 91/93 (97.8%) of the correctly localised cases. Overall interval cancer detection rate was 93/514 (18%). AI detected 12.6% of true negatives, 46% with minimal signs and 50% false negatives ($p<0.01$). There were 49 false positive prompts (0.09 per cancer case). For normal cases, the AI algorithm provided 61 false-positive recalls (3.9%) with an average prompt score of 8.1 (6.8-9.9). The overall sensitivity, specificity, and accuracy was 18%, 96%, and 76.6%, respectively. At alternative thresholds of 30% sensitivity and 90% specificity, the correct cancer localisation detection rate increased to 21.9%, and 25.4%, respectively. This corresponded to 7.5% and 9.6% false-positive recalls.

CONCLUSION

s Standalone AI set at the 96% specificity threshold can identify 23.7% of interval cancers with accurate localisation in three-quarters of cases.

CLINICAL RELEVANCE/APPLICATION

High accuracy of AI localisation prompts provides a layer of explainability, providing required information for cases not detected by human readers to target supplemental imaging or clinic assessment biopsy.

S3A-SPBR-7 AI-based Computer Assisted Diagnosis/Detection Systems Can Be Used for Upgrade Prediction of DCIS Diagnosed with Percutaneous Biopsy

Participants
Jung Hyun Yoon, MD, PhD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate whether mammographic features and the abnormality scores provided by artificial intelligence (AI)-based computer assisted detection/diagnosis (AI-CAD) system can be used in predicting upgrade in ductal carcinoma in situ (DCIS).

METHODS AND MATERIALS

This retrospective study had approval from our institutional review board (IRB). From Jan. 2015 to Dec. 2019, 440 DCIS diagnosed via percutaneous biopsy in 420 women (mean age, 52.8±10.6 years, range: 28-85) were included. Prebiopsy routine 4-view digital mammograms were analyzed using a commercially-available AI-CAD to obtain an abnormality score (range, 0-100%). Radiologic features were assessed according to mammographic features of the proven DCIS (negative, soft tissue lesions, calcifications with/without soft tissue lesions) and BI-RADS final assessment. Optimal cutoff for AI-CAD score was calculated using Youden J index. Uni-/mutivariable regression analysis was used to calculate the association between clinical, radiologic, and pathologic factors to DCIS upgrade after surgery.

RESULTS

Of the 440 DCIS, 117 (26.6%) were upgraded to invasive cancers. Mean AI-CAD score was significantly higher in those with upgrade (96.6% vs. 58.6%, P=0.0006). Optimal cutoff of AI-CAD score for DCIS upgrade was calculated as 82.87%. Among radiologic features, BI-RADS assessment, presence of calcifications, and AI-CAD score showed significance on univariable analysis (all P<0.05). BI-RADS 4c (OR: 2.509 (95% CI: 1.154-5.455), P=0.020) and 5 (OR: 5.266 (95% CI: 2.215-12.519), P=0.0002), presence of calcifications (OR: 2.198 (95% CI: 1.075-4.485), P=0.031), AI-CAD score (at cutoff of 82.87%) (OR: 2.272 (95% CI: 1.340-3.853), P=0.002), and vaccum-assisted biopsy for diagnosis (0.465 (95% CI: 0.248-0.871), P=0.016) were factors showing significance in multivariable analysis.

CONCLUSION

s Mammographic features assessed by radiologists and AI-CAD can be used as significant predictors of DCIS upgrade.

CLINICAL RELEVANCE/APPLICATION

Noninvasive imaging features including results from AI-based cancer detection and diagnosis system have the potential in predicting DCIS upgrade that may be beneficial in patient management including surgical extent.

Use of Artificial Intelligence in Women with Mammographic Abnormality Reduces Screening Recalls

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - BR DPS

Participants
Jung Min Chang, MD, Seoul, (*Presenter*) Research Consultant, Genoray Co, Ltd

PURPOSE

Potential benefit of using artificial intelligence (AI) in reducing screening mammography recalls has not been well investigated in the past. This study was to evaluate whether artificial intelligence (AI)-aided reviews of mammographic findings can reduce unnecessary recall while maintaining cancer detection ability in mammography screening.

METHODS AND MATERIALS

A retrospective reader study was performed with screening mammography from women who were recalled for mammography-detected abnormalities between January 2016 and December 2019 at two screening centers. Exams were sequentially interpreted in two sessions, with and without AI aid, by three radiologists providing their decision on whether it should be recalled. The area under the receiver operating characteristic curve (AUC), sensitivity, specificity, and recall rates were compared.

RESULTS

A total of 793 women (mean age ± standard deviation, 49.8 years ± 8.9), 54 cancer and 739 benign cases, were included. The AI standalone per-examination AUC was significantly higher than that of all three radiologists (0.94 [95% CI, 0.92-0.97] vs. 0.76 [95% CI, 0.69-0.83]; 0.80 [95% CI, 0.74-0.86]; 0.86 [95% CI, 0.82-0.91]; P <.001, respectively). The per-examination and per-lesion reader-averaged AUC improved after AI aid (0.80 [95% CI, 0.71-0.90] vs. 0.91 [95% CI, 0.83-0.99]; P =.02; 0.79 [95% CI, 0.70-0.89] vs. 0.89 [95% CI, 0.83-0.96]; P =.03). In both the per-examination and per-lesion analyses, average specificities of all radiologists improved after AI aid (41.9% [95% CI, 4.3%-79.5%] vs. 53.9% [95% CI, 27.1%-80.7%]; P =.04), whereas the sensitivities only improved for the least experienced radiologist with AI aid (79.6%, 43 of 54 [95% CI, 66.5%-89.4%] vs. 90.7%, 49 of 54 [95% CI, 79.7%-96.9%]; P =.03). With AI aid, the average recall rate decreased from 60.4% (95% CI, 23.9%-96.8%) to 49.5% (95% CI, 23.9%-75.0%) with marginal significance (P =.05).

CONCLUSION

s The use of an AI system in women with screening recalls reduces the need for supplemental mammographic views and improves the overall diagnostic performance.

CLINICAL RELEVANCE/APPLICATION

In women recalled for mammographic abnormalities, the use of an AI system could improve the diagnostic performance of screening mammography, and provide an efficient way of diagnosing negative cases, which ultimately leads to a reduction of unnecessary recall and the workload.

Deep Learning-enabled Fully Automated Pipeline for Segmentation and Classification of Breast Lesions using Contrast Enhanced Mammography

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - BR DPS

Participants
Ning Mao, Yantai, China (*Presenter*) Nothing to Disclose

PURPOSE

We aimed to develop a deep learning - enabled fully automated pipeline for segmentation and classification of breast lesions using contrast enhanced mammography (CEM).

METHODS AND MATERIALS

In this study, we retrospectively collected 1710 preoperative CEM images of breast lesions from a hospital for the fully automated pipeline development and test. We adopted RefineNet and Xception as sub-networks of the pipeline system to perform segmentation and classification tasks, respectively. The segmentation performance was assessed using dice similarity coefficient (DSC) in test set. For classification task, we compared our system with the classification performance of four radiologists using the area under the receiver operating characteristic curve (AUROC). Finally, we also explored the performance of radiologists assisted by artificial intelligence (AI) and the changes in the amount of fine needle aspiration biopsy under the AI-assisted Breast Imaging Reporting and Data System (BI-RADS) category in view of clinical application.

RESULTS

The automated pipeline for tumor segmentation achieved a DSC 0.888 in test cohort, the classification task performed by the Xception yielded an AUC of 0.906 (95%CI=0.857-0.955) in the CC+MLO view on test set, which is higher than CC view (0.876, 95%CI=0.819-0.933) and MLO view (0.850, 95%CI=0.784-0.916). And it also was significantly higher than those of radiologists (0.846,95%CI=0.784-0.916). Furthermore, AI-assisted strategy improved the pooled AUC of the radiologists from 0.741(95%CI=0.657-0.855) when diagnosing without AI to 0.874 (95%CI=0.757-0.921) with AI for the performance of classification in test set. The number of fine needle aspiration biopsies also reduced from 162 to 120 in the case of AI assisting BI-RADS category in test set.

CONCLUSION

s Our fully automated pipeline system based on CEM demonstrated the potential for segmentation and classification of breast lesions, and also had good clinical applicability.

CLINICAL RELEVANCE/APPLICATION

The fully automated pipeline system that we developed can be well applied to the segmentation and classification of breast lesions as a non-invasive method, In addition, it also contributes greatly in assisting radiologists in making BI-RADS classification and reduces unnecessary biopsies, which could alleviate patient healthcare burden and promote the reallocation of healthcare resources.

Artificial Intelligence (AI) for Ultrasound (US) MicroFlow Imaging (MFI) in Breast Cancer Diagnosis

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - BR DPS

Participants
Ji Hyun Youk, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To develop and evaluate AI algorithms for US MFI in breast cancer diagnosis

METHODS AND MATERIALS

We retrospectively collected a dataset consisting of 516 breast lesions (364 benign, 152 malignant) in 471 women who underwent B-mode US and MFI. BI-RADS category assigned by board-certified breast radiologists on B-mode US were noted. Pathology or at least 2-year follow up was used as the reference standard. To develop AI algorithms based on deep CNNs for MFI, the internal dataset was split on into training (n=410, 79%) and test dataset (n=106, 21%). AI algorithms were trained to provide malignancy risk (0-100%). The developed AI algorithms were further validated with an independent external dataset consisting of 238 breast lesions (208 benign, 27 malignant). To evaluate and compare the diagnostic performance of B-mode US, AI algorithms, or their combination, the area under the receiver operating characteristic curve (AUROC) was calculated. Logistic regression analysis was used to calculate the malignancy risk of lesions in combined B-mode US and AI algorithms.

RESULTS

The AUROC of developed three AI algorithms were 0.966, 0.964, and 0.955, respectively, and higher than that of B-mode US (0.842, P<.0001). AI algorithms had higher specificity (93-95% vs. 72%) and accuracy (93% vs. 79%) than B-mode US (P<.003). No significant difference was found in sensitivity between AI algorithms (88-91%) and B-mode US (97%). The performance metrics of the AI algorithms on the external validation dataset were similar to those of the test dataset (AUROC of 0.892-0.920, sensitivity of 82-89%, specificity of 92-98%, and accuracy of 91-96%). Among AI algorithms, no significant difference was found in all performance metrics with or without combination of B-mode US. Combined B-mode US and AI algorithms had higher performance than B-mode US (AUROC of 0.963-0.972, specificity of 96%, and accuracy of 94%, P=.0001) except sensitivity (91%). By combining B-mode US and AI algorithms, false-positive rate of BI-RADS category 4A lesions significantly decreased from 87% to 13% (P<.0001).

CONCLUSION

s AI-based MFI diagnosed breast cancers with better performance than B-mode US. Combined B-mode US and AI algorithm could eliminate 74% of false-positive diagnosis in BI-RADS category 4A lesions.

CLINICAL RELEVANCE/APPLICATION

AI-based MFI can improve diagnostic accuracy of breast US by decreasing false positives diagnosis, and thus reducing unnecessary biopsies of benign lesions.

S3A-SPBR-4

Detailed External Validation of A Commercial AI Algorithm for Breast Cancer Detection in The Setting of An Organized Population-based Breast Screening

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - BR DPS

Participants
Janette Sam, RT, Vancouver, BC (*Presenter*) Nothing to Disclose

PURPOSE

Evaluate the performance of a commercial Artificial Intelligence (AI) system for breast cancer detection using the digital mammograms from the BC Cancer Breast Screening Program

METHODS AND MATERIALS

Digital screening mammograms and associated outcomes, including mammographic findings (features), demographics, and risk factors were extracted for 136,700 women who underwent breast screening in British Columbia, Canada during the period February 1, 2019 - January 31, 2020. The outcome data were extracted on March 18, 2022. The images were de-identified and fed to the Lunit MMG AI algorithm version 1.1.2.0 running on a GeForce RTX 2080 GPU with 11 GB VRAM. The AI model performance was evaluated using Area Under the Curve (AUC) of Receiver Operating Characteristic (ROC) methodology.

RESULTS

The overall performance of the AI algorithm measured with AUC was 0.938 (CI: 0.927-0.949). However, once binary classification is performed using the 10% cut-off value used by the algorithm, the AUC dropped to 0.846 (0.836-0.856) compared to the radiologists performance at 0.937 (0.929-0.944). The AI AUC for BIRAD breast density categories assigned by the radiologists were: A: 0.964 (0.934-0.993); B: 0.946 (0.932-0.961); C: 0.934 (0.916-0.952) and D: 0.831 (0.752-0.911). For women with family history of breast cancer, the AI AUC was 0.919 (0.895-0.943) whereas for women with no family history, 0.945 (0.933-0.957). The algorithm performance for cancers with any architectural distortion was 0.961 (0.944-0.978) whereas for cancers with any calcifications was 0.878 (0.855-0.900).

CONCLUSION

s The tested commercial AI algorithm is generalizable for a large external cohort from Canada. However, the performance of the AI algorithm fell short of that of the well-qualified screening program radiologists. Performance of the algorithm for women with family history of breast cancer and for cancers manifesting as calcifications was found to be weaker.

CLINICAL RELEVANCE/APPLICATION

Commercial AI algorithms well trained with datasets from multiple countries for breast cancer detection can be generalizable to cohorts in other countries. However, further improvements may be needed to match the performance of radiologists from well-organized population based breast screening programs.

S3A-SPBR-6

Investigating a Stand-alone AI System Prompt Accuracy for Interval Cancer Detection in Screening Mammography

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - BR DPS

Awards
Trainee Research Prize - Fellow

Participants
Sarah Hickman, MBBS, Cambridge, United Kingdom (*Presenter*) Research collaboration, Vara;Research collaboration, ScreenPoint Medical BV;Research collaboration, Lunit Inc;Research collaboration, Kheiron Medical Technologies Ltd;Research collaboration, Alphabet Inc;Research collaboration, Volpara Health Technologies Limited

PURPOSE

To evaluate the accuracy of prompts from a commercial artificial intelligence (AI) system in interval cancer detection.

METHODS AND MATERIALS

An enriched dataset of screening mammograms of 1548 normals and 514 interval cancers diagnosed between 2011 and 2018 was analyzed with a commercial AI algorithm. This provided a continuous per-lesion, per-image, per-breast and per-case score (0-10), and prompts for suspicious lesion location. A pre-defined threshold specificity of 96%, (prompt score 6.8) was used. Each case is assigned an overall risk score representing the highest per-lesion score. Interval cancers were classified as either true negatives, minimal signs, or false negatives by a consensus panel. The cancer cases were reviewed (radiologist, 7 years' experience) to determine the accuracy of prompt location (prompt within boundary of cancer) with consensus (two breast radiologists) for indeterminate cases. The ground truth was histopathology for cancers and a three yearly normal screen for normals.

RESULTS

The algorithm prompted 122/514 cancer cases, with an average prompt score of 8.5 (6.8-9.9) and correct localisation in 93/122 cases (76.2%). The highest prompt score was given for the cancer in 91/93 (97.8%) of the correctly localised cases. Overall interval cancer detection rate was 93/514 (18%). AI detected 12.6% of true negatives, 46% with minimal signs and 50% false negatives ($p<0.01$). There were 49 false positive prompts (0.09 per cancer case). For normal cases, the AI algorithm provided 61 false-positive recalls (3.9%) with an average prompt score of 8.1 (6.8-9.9). The overall sensitivity, specificity, and accuracy was 18%, 96%, and 76.6%, respectively. At alternative thresholds of 30% sensitivity and 90% specificity, the correct cancer localisation detection rate increased to 21.9%, and 25.4%, respectively. This corresponded to 7.5% and 9.6% false-positive recalls.

CONCLUSION

s Standalone AI set at the 96% specificity threshold can identify 23.7% of interval cancers with accurate localisation in three-quarters of cases.

CLINICAL RELEVANCE/APPLICATION

High accuracy of AI localisation prompts provides a layer of explainability, providing required information for cases not detected by human readers to target supplemental imaging or clinic assessment biopsy.

AI-based Computer Assisted Diagnosis/Detection Systems Can Be Used for Upgrade Prediction of DCIS Diagnosed with Percutaneous Biopsy

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - BR DPS

Participants
Jung Hyun Yoon, MD, PhD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate whether mammographic features and the abnormality scores provided by artificial intelligence (AI)-based computer assisted detection/diagnosis (AI-CAD) system can be used in predicting upgrade in ductal carcinoma in situ (DCIS).

METHODS AND MATERIALS

This retrospective study had approval from our institutional review board (IRB). From Jan. 2015 to Dec. 2019, 440 DCIS diagnosed via percutaneous biopsy in 420 women (mean age, 52.8±10.6 years, range: 28-85) were included. Prebiopsy routine 4-view digital mammograms were analyzed using a commercially-available AI-CAD to obtain an abnormality score (range, 0-100%). Radiologic features were assessed according to mammographic features of the proven DCIS (negative, soft tissue lesions, calcifications with/without soft tissue lesions) and BI-RADS final assessment. Optimal cutoff for AI-CAD score was calculated using Youden J index. Uni-/mutivariable regression analysis was used to calculate the association between clinical, radiologic, and pathologic factors to DCIS upgrade after surgery.

RESULTS

Of the 440 DCIS, 117 (26.6%) were upgraded to invasive cancers. Mean AI-CAD score was significantly higher in those with upgrade (96.6% vs. 58.6%, P=0.0006). Optimal cutoff of AI-CAD score for DCIS upgrade was calculated as 82.87%. Among radiologic features, BI-RADS assessment, presence of calcifications, and AI-CAD score showed significance on univariable analysis (all P<0.05). BI-RADS 4c (OR: 2.509 (95% CI: 1.154-5.455), P=0.020) and 5 (OR: 5.266 (95% CI: 2.215-12.519), P=0.0002), presence of calcifications (OR: 2.198 (95% CI: 1.075-4.485), P=0.031), AI-CAD score (at cutoff of 82.87%) (OR: 2.272 (95% CI: 1.340-3.853), P=0.002), and vaccum-assisted biopsy for diagnosis (0.465 (95% CI: 0.248-0.871), P=0.016) were factors showing significance in multivariable analysis.

CONCLUSION

s Mammographic features assessed by radiologists and AI-CAD can be used as significant predictors of DCIS upgrade.

CLINICAL RELEVANCE/APPLICATION

Noninvasive imaging features including results from AI-based cancer detection and diagnosis system have the potential in predicting DCIS upgrade that may be beneficial in patient management including surgical extent.

Cardiac Sunday Poster Discussions - A

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - CA DPS

Sub-Events

S3A-SPCA-1 Improvement of Coronary Stent CT Imaging with Super-Resolution Deep-Learning Reconstruction: An Initial In Vivo Experience

Participants
Yasunori Nagayama, MD, Kumamoto, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the subjective and objective image qualities of novel super-resolution deep-learning reconstruction (SR-DLR) algorithm for in vivo coronary stents and compare them with those of iterative reconstruction (IR) and normal-resolution DLR (NR-DLR) algorithms.

METHODS AND MATERIALS

This retrospective study included 17 patients with 24 coronary stents who underwent ECG-gated coronary CT angiography on a 320-row scanner. Raw data were reconstructed with hybrid IR (HIR, AIDR 3D), model-based IR (MBIR, FIRST), NR-DLR (AiCE), and SR-DLR (PIQE) using dedicated cardiac parameters at a slice thickness of 0.5 mm. The external and internal diameters of the stents were measured to quantify the degree of blooming artifacts (defined as [measured external stent diameter - measured internal stent diameter]/measured external stent diameter). CT attenuation in the lumen of the stent (HUstent) and that of upstream coronary artery (HUcoronary) was measured. The stent-induced beam hardening artifacts were quantified as HUstent-HUcoronary. The image noise and contrast-to-noise ratio (CNR) of the coronary arteries were quantified. The delineation of the coronary wall before the stent, stent lumen, stent strut, calcifications surrounding the stent, beam-hardening artifacts, image noise, and overall quality were subjectively scored on a 5-point scale (1, inadequate; 5, excellent).

RESULTS

Among all reconstructions, SR-DLR images showed the largest internal diameters of the stents, for which blooming artifact was considerably reduced relative to HIR, MBIR, and NR-DLR images (all $p < 0.05$). SR-DLR also provided lower stent-induced beam hardening artifacts, lower image noise, and higher CNR that HIR, MBIR, and NR-DLR (all $p < 0.05$). In the subjective assessments, SR-DLR images received the best scores for all evaluation criteria (all $p < 0.05$).

CONCLUSION

s SR-DLR improves the objective and subjective qualities of coronary stent imaging compared with HIR, MBIR, and NR-DLR algorithms.

CLINICAL RELEVANCE/APPLICATION

Novel SR-DLR algorithm allows improvement of coronary stent evaluation because of excellent spatial resolution, lower blooming artifact, and stent-induced beam-hardening artifacts.

S3A-SPCA-2 High Fidelity Coronary CT Angiography Generated by Deep Learning Based Post Hoc Denoising Method Improved the Diagnostic Performance of the Coronary Perivascular Fat Attenuation Index

Participants
Tatsuya Nishii, MD, PhD, Suita, Japan (*Presenter*) Speakers Bureau, Guerbet SA;Speakers Bureau, General Electric Company;Speakers Bureau, Siemens AG;Research Grant, Canon Medical Systems Corporation

PURPOSE

Coronary inflammation related to vulnerable hemorrhagic plaques can be captured by the perivascular fat attenuation index (FAI) using coronary CT angiography (CCTA). Since FAI is susceptible to image noise, we believed that deep learning (DL) based post hoc noise reduction could improve diagnostic capability. We aimed to assess the diagnosis performance of FAI in DL-based denoised high fidelity CCTA images using coronary plaque MR imaging as a reference.

METHODS AND MATERIALS

We retrospectively reviewed 64 patients who examined standard CCTA and coronary plaque MR imaging (MPRAGE) within 2-month intervals from April 2017 to June 2019. Those examined with non-3T MRIs and those with stents or obstructions at proximal right coronary artery (RCA) were excluded. We generated the high fidelity CCTA images by denoising the standard CCTA images using a residual dense network supervised the denoising task by averaging CCTA images. In the original and denoised CCTA, we measured the FAIs as the mean CT value of all voxels (range of -190 to -30 HU) located within a radial distance from the outer proximal RCA wall using dedicated software. The diagnostic reference was defined using MRI with the consensus reading of 2 board-certified radiologists. We specified high-intensity plaques (HIP; vulnerable hemorrhagic plaque) as those with a plaque-to-myocardium signal ratio =1.4. The diagnostic performance of FAI in the original and denoised image was assessed using ROC analysis with regarded

presence of HIPs.

RESULTS

Of 45 cases (37 males, median 65 years), 12 cases had HIPs. The FAIs in the denoised CCTA image were correlated (r=0.97, P<.001) but were higher than those of the original (mean difference, 4.3 [95%CI 0.64-0.92], P< .001). FAI in the denoised CCTA improved the area under the ROC curve (0.87 [95%CI 0.77-0.98]) compared with FAI in the original image (0.78 [95%CI 0.64-0.92], P=.013). The optimal cutoff value for predicting HIPs in denoised CCTA was -69HU with 0.83 sensitivity, 0.79 specificities, and 0.80 accuracies.

CONCLUSION

s DL-based denoised high fidelity CCTA improved the diagnosis performance of FAI for predicting vulnerable hemorrhagic plaques.

CLINICAL RELEVANCE/APPLICATION

The DL-based post hoc denoising method, which does not require CT projection data nor additional radiation exposure, can improve the diagnostic performance of FAI for vulnerable hemorrhagic plaques in CCTA.

S3A-SPCA-3 Photon Counting Detector-CT Angiography of The Coronary Arteries: Intra-individual Comparison of Image Quality to Conventional Energy-integrating Detector-CT Angiography

Participants
Joseph Griffith III, Charleston, SC (*Presenter*) Nothing to Disclose

PURPOSE

The aim of this study was the intra-individual evaluation of objective image quality for CT angiography of the coronary arteries on a photon counting detector CT (PCD-CCTA) in comparison to a conventional energy-integrating detector CT (EID-CCTA).

METHODS AND MATERIALS

Twenty prospectively included patients (59.2±13.2 years, 65% male) with PCD- and EID-CCTA were examined at an interval of 9 ± 4 days. Contrast agent protocol and radiation dose were matched between PCD and EID CCTA. Polychromatic images were reconstructed for both EID and PCD CCTA (T3D). In addition, virtual monoenergetic images at 40, 50, 60, and 70 keV were reconstructed on the PCD-CT. Signal, contrast and noise were measured in the aorta, coronary arteries, and myocardium, and the contrast-to-noise ratio (CNR) was calculated for each anatomical structure. Differences were compared using a paired t-test and a Bonferroni-corrected p-value of 0.008 was considered significant.

RESULTS

The mean CNR of the left coronary artery was 13.3±5.4 for the EID-CCTA and 31.8±12.1, 28.4±9.7, 23.5±7.1, 21.2±6.7 and 21.9±6.7 for the PCD-CCTA at 40, 50, 60, 70 keV and T3D, respectively. CNR was significantly higher in all virtual monoenergetic reconstructions of PCD-CT than EID-CT (all P<0.008).

CONCLUSION

s PCD-CCTA with monoenergetic reconstructions leads to a significantly increased CNR compared to EID-CCTA.

CLINICAL RELEVANCE/APPLICATION

The improved image quality of PCD-CCTA may be translated into clinical advantages including low-dose scanning or improved detection of coronary artery disease.

S3A-SPCA-4 Super-Resolution Deep Learning Reconstruction for Cardiac CT: Comparison of Stenosis Evaluation Accuracy, Image Quality, Stenosis Confidence Level at Coronary Arteries and CAD-RADS Classification with Hybrid-Type and Model-Based Iterative Reconstructions and Deep Learning Reconstruction at In Vivo and In Vitro Studies

Participants
Yoshiharu Ohno, MD, PhD, Toyoake, Japan (*Presenter*) Research Grant, Canon Medical Systems Corporation;Research Grant, Daiichi Sankyo Co, Ltd;Research Grant, Ministry of Education, Culture, Sports, Science and Technology

PURPOSE

Super-resolution deep learning reconstruction (SR-DLR) for cardiac CT scans is recently set in routine clinical practice, which can maximize spatial resolution of area-detector CT (ADCT) (0.5mm×320 rows/896 channels) as super-high-resolution CT (0.25mm×160 rows/1792 channels) without reducing low-contrast detectability or increasing dose. The purpose of this study was to compare stenosis evaluation accuracy, image quality, stenosis confidence level and CAD-RADS classification on cardiac ADCT among hybrid-type and model-based iterative reconstructions (i.e. hybrid-type IR and MBIR), deep learning reconstruction (DLR) and SR-DLR at in vivo and in vitro studies.

METHODS AND MATERIALS

On in vitro study, a commercially available pulsating cardiac phantom with 3mm and 4 mm coronary artery phantoms, which had simulated 0, 25, 50 and 75% stenoses, were firstly scanned with standard protocol on a ADCT at five times and reconstructed with each method. Then, inner diameter of each coronary artery phantom was automatically measured. On in vivo study, 31 patients who suspected ischemic heart disease and underwent cardiac ADCT with standard protocol and coronary arteriography (CAG) were selected, and each cardiac ADCT data was also reconstructed with all methods. To compare stenosis evaluation accuracy among all methods, Spearman's correlations and Bland-Altman analyses were performed. To compare overall image quality, stenosis confidence level and CAD-RADS evaluations at all coronary arteries, each index was assessed by 5-points scoring systems and CAD-RADS classification and compared among all methods by Wilcoxon's signed rank test. Moreover, accuracy of CAD-RADS classification with standard reference generated from CAG by cardiologists were compared among all methods by McNemar's test.

RESULTS

On in vitro study, each methods showed excellent correlation (hybrid-type IR: ?=0.93, p<0.0001; others: ?=0.94, p<0.0001). The

limits of agreements for SR-DLR (0.7±0.4mm) and DLR (0.7±0.4mm) were smaller than those for hybrid-type IR (0.8±0.5mm) and MBIR (0.8±0.4mm). On in vivo study, overall image quality and stenosis confidence level of SR-DLR were significantly higher than those of others ($p<0.05$). Moreover, both indexes of DLR were significantly higher than those of hybrid-type IR ($p<0.05$). On the other hand, CAD-RADS classification accuracy had no significant difference among all methods ($p>0.05$).

CONCLUSION

s SR-DLR has a potential to improve stenosis evaluation accuracy, image quality and stenosis confidence level on cardiac CT than others at in vivo and in vitro studies.

CLINICAL RELEVANCE/APPLICATION

SR-DLR has a potential to improve stenosis evaluation accuracy, image quality and stenosis confidence level than others on cardiac ADCT.

Improvement of Coronary Stent CT Imaging with Super-Resolution Deep-Learning Reconstruction: An Initial In Vivo Experience

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - CA DPS

Participants
Yasunori Nagayama, MD, Kumamoto, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the subjective and objective image qualities of novel super-resolution deep-learning reconstruction (SR-DLR) algorithm for in vivo coronary stents and compare them with those of iterative reconstruction (IR) and normal-resolution DLR (NR-DLR) algorithms.

METHODS AND MATERIALS

This retrospective study included 17 patients with 24 coronary stents who underwent ECG-gated coronary CT angiography on a 320-row scanner. Raw data were reconstructed with hybrid IR (HIR, AIDR 3D), model-based IR (MBIR, FIRST), NR-DLR (AiCE), and SR-DLR (PIQE) using dedicated cardiac parameters at a slice thickness of 0.5 mm. The external and internal diameters of the stents were measured to quantify the degree of blooming artifacts (defined as [measured external stent diameter - measured internal stent diameter]/measured external stent diameter). CT attenuation in the lumen of the stent (HUstent) and that of upstream coronary artery (HUcoronary) was measured. The stent-induced beam hardening artifacts were quantified as HUstent-HUcoronary. The image noise and contrast-to-noise ratio (CNR) of the coronary arteries were quantified. The delineation of the coronary wall before the stent, stent lumen, stent strut, calcifications surrounding the stent, beam-hardening artifacts, image noise, and overall quality were subjectively scored on a 5-point scale (1, inadequate; 5, excellent).

RESULTS

Among all reconstructions, SR-DLR images showed the largest internal diameters of the stents, for which blooming artifact was considerably reduced relative to HIR, MBIR, and NR-DLR images (all $p < 0.05$). SR-DLR also provided lower stent-induced beam hardening artifacts, lower image noise, and higher CNR that HIR, MBIR, and NR-DLR (all $p < 0.05$). In the subjective assessments, SR-DLR images received the best scores for all evaluation criteria (all $p < 0.05$).

CONCLUSION

s SR-DLR improves the objective and subjective qualities of coronary stent imaging compared with HIR, MBIR, and NR-DLR algorithms.

CLINICAL RELEVANCE/APPLICATION

Novel SR-DLR algorithm allows improvement of coronary stent evaluation because of excellent spatial resolution, lower blooming artifact, and stent-induced beam-hardening artifacts.

High Fidelity Coronary CT Angiography Generated by Deep Learning Based Post Hoc Denoising Method Improved the Diagnostic Performance of the Coronary Perivascular Fat Attenuation Index

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - CA DPS

Participants
Tatsuya Nishii, MD, PhD, Suita, Japan (*Presenter*) Speakers Bureau, Guerbet SA;Speakers Bureau, General Electric Company;Speakers Bureau, Siemens AG;Research Grant, Canon Medical Systems Corporation

PURPOSE

Coronary inflammation related to vulnerable hemorrhagic plaques can be captured by the perivascular fat attenuation index (FAI) using coronary CT angiography (CCTA). Since FAI is susceptible to image noise, we believed that deep learning (DL) based post hoc noise reduction could improve diagnostic capability. We aimed to assess the diagnosis performance of FAI in DL-based denoised high fidelity CCTA images using coronary plaque MR imaging as a reference.

METHODS AND MATERIALS

We retrospectively reviewed 64 patients who examined standard CCTA and coronary plaque MR imaging (MPRAGE) within 2-month intervals from April 2017 to June 2019. Those examined with non-3T MRIs and those with stents or obstructions at proximal right coronary artery (RCA) were excluded. We generated the high fidelity CCTA images by denoising the standard CCTA images using a residual dense network supervised the denoising task by averaging CCTA images. In the original and denoised CCTA, we measured the FAIs as the mean CT value of all voxels (range of -190 to -30 HU) located within a radial distance from the outer proximal RCA wall using dedicated software. The diagnostic reference was defined using MRI with the consensus reading of 2 board-certified radiologists. We specified high-intensity plaques (HIP; vulnerable hemorrhagic plaque) as those with a plaque-to-myocardium signal ratio =1.4. The diagnostic performance of FAI in the original and denoised image was assessed using ROC analysis with regarded presence of HIPs.

RESULTS

Of 45 cases (37 males, median 65 years), 12 cases had HIPs. The FAIs in the denoised CCTA image were correlated (r=0.97, P<.001) but were higher than those of the original (mean difference, 4.3 [95%CI 0.64-0.92], P< .001). FAI in the denoised CCTA improved the area under the ROC curve (0.87 [95%CI 0.77-0.98]) compared with FAI in the original image (0.78 [95%CI 0.64-0.92], P=.013). The optimal cutoff value for predicting HIPs in denoised CCTA was -69HU with 0.83 sensitivity, 0.79 specificities, and 0.80 accuracies.

CONCLUSION

s DL-based denoised high fidelity CCTA improved the diagnosis performance of FAI for predicting vulnerable hemorrhagic plaques.

CLINICAL RELEVANCE/APPLICATION

The DL-based post hoc denoising method, which does not require CT projection data nor additional radiation exposure, can improve the diagnostic performance of FAI for vulnerable hemorrhagic plaques in CCTA.

Photon Counting Detector-CT Angiography of The Coronary Arteries: Intra-individual Comparison of Image Quality to Conventional Energy-integrating Detector-CT Angiography

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - CA DPS

Participants
Joseph Griffith III, Charleston, SC (*Presenter*) Nothing to Disclose

PURPOSE

The aim of this study was the intra-individual evaluation of objective image quality for CT angiography of the coronary arteries on a photon counting detector CT (PCD-CCTA) in comparison to a conventional energy-integrating detector CT (EID-CCTA).

METHODS AND MATERIALS

Twenty prospectively included patients (59.2±13.2 years, 65% male) with PCD- and EID-CCTA were examined at an interval of 9 ± 4 days. Contrast agent protocol and radiation dose were matched between PCD and EID CCTA. Polychromatic images were reconstructed for both EID and PCD CCTA (T3D). In addition, virtual monoenergetic images at 40, 50, 60, and 70 keV were reconstructed on the PCD-CT. Signal, contrast and noise were measured in the aorta, coronary arteries, and myocardium, and the contrast-to-noise ratio (CNR) was calculated for each anatomical structure. Differences were compared using a paired t-test and a Bonferroni-corrected p-value of 0.008 was considered significant.

RESULTS

The mean CNR of the left coronary artery was 13.3±5.4 for the EID-CCTA and 31.8±12.1, 28.4±9.7, 23.5±7.1, 21.2±6.7 and 21.9±6.7 for the PCD-CCTA at 40, 50, 60, 70 keV and T3D, respectively. CNR was significantly higher in all virtual monoenergetic reconstructions of PCD-CT than EID-CT (all P<0.008).

CONCLUSION

s PCD-CCTA with monoenergetic reconstructions leads to a significantly increased CNR compared to EID-CCTA.

CLINICAL RELEVANCE/APPLICATION

The improved image quality of PCD-CCTA may be translated into clinical advantages including low-dose scanning or improved detection of coronary artery disease.

Super-Resolution Deep Learning Reconstruction for Cardiac CT: Comparison of Stenosis Evaluation Accuracy, Image Quality, Stenosis Confidence Level at Coronary Arteries and CAD-RADS Classification with Hybrid-Type and Model-Based Iterative Reconstructions and Deep Learning Reconstruction at In Vivo and In Vitro Studies

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - CA DPS

Participants
Yoshiharu Ohno, MD, PhD, Toyoake, Japan (*Presenter*) Research Grant, Canon Medical Systems Corporation;Research Grant, Daiichi Sankyo Co, Ltd;Research Grant, Ministry of Education, Culture, Sports, Science and Technology

PURPOSE

Super-resolution deep learning reconstruction (SR-DLR) for cardiac CT scans is recently set in routine clinical practice, which can maximize spatial resolution of area-detector CT (ADCT) (0.5mm×320 rows/896 channels) as super-high-resolution CT (0.25mm×160 rows/1792 channels) without reducing low-contrast detectability or increasing dose. The purpose of this study was to compare stenosis evaluation accuracy, image quality, stenosis confidence level and CAD-RADS classification on cardiac ADCT among hybrid-type and model-based iterative reconstructions (i.e. hybrid-type IR and MBIR), deep learning reconstruction (DLR) and SR-DLR at in vivo and in vitro studies.

METHODS AND MATERIALS

On in vitro study, a commercially available pulsating cardiac phantom with 3mm and 4 mm coronary artery phantoms, which had simulated 0, 25, 50 and 75% stenoses, were firstly scanned with standard protocol on a ADCT at five times and reconstructed with each method. Then, inner diameter of each coronary artery phantom was automatically measured. On in vivo study, 31 patients who suspected ischemic heart disease and underwent cardiac ADCT with standard protocol and coronary arteriography (CAG) were selected, and each cardiac ADCT data was also reconstructed with all methods. To compare stenosis evaluation accuracy among all methods, Spearman's correlations and Bland-Altman analyses were performed. To compare overall image quality, stenosis confidence level and CAD-RADS evaluations at all coronary arteries, each index was assessed by 5-points scoring systems and CAD-RADS classification and compared among all methods by Wilcoxon's signed rank test. Moreover, accuracy of CAD-RADS classification with standard reference generated from CAG by cardiologists were compared among all methods by McNemar's test.

RESULTS

On in vitro study, each methods showed excellent correlation (hybrid-type IR: ?=0.93, p<0.0001; others: ?=0.94, p<0.0001). The limits of agreements for SR-DLR (0.7±0.4mm) and DLR (0.7±0.4mm) were smaller than those for hybrid-type IR (0.8±0.5mm) and MBIR (0.8±0.4mm). On in vivo study, overall image quality and stenosis confidence level of SR-DLR were significantly higher than those of others (p<0.05). Moreover, both indexes of DLR were significantly higher than those of hybrid-type IR (p<0.05). On the other hand, CAD-RADS classification accuracy had no significant difference among all methods (p>0.05).

CONCLUSION

s SR-DLR has a potential to improve stenosis evaluation accuracy, image quality and stenosis confidence level on cardiac CT than others at in vivo and in vitro studies.

CLINICAL RELEVANCE/APPLICATION

SR-DLR has a potential to improve stenosis evaluation accuracy, image quality and stenosis confidence level than others on cardiac ADCT.

S3A-SPCH-2 Clinical Value of Dual Layer Spectral Detector CT in Differential Diagnosis of Primary Malignant Chronic Lung Inflammation and Pulmonary Tuberculosis

Participants
Xiaoxia Zheng, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To explore the clinical value of dual-layer detector spectral CT (DLCT) in differential diagnosis of lung primary malignant tumor, chronic inflammation and pulmonary tuberculosis using conventional CT signs and spectral multi-parameters.

METHODS AND MATERIALS

From August 2020 to June 2021, 345 patients with pathologically confirmed of pulmonary diseases who underwent DLCT chest enhanced scan in our hospital were retrospective enrolled for this study. The patients were divided into three groups: primary lung malignant tumor group (n = 187, 88 adenocarcinoma, 51squamous cell carcinoma and 34 small cell lung cancer and 14 other malignant tumors), chronic inflammation group (n = 101) and tuberculosis group (n = 57) . The conventional CT signs and spectral CT parameters of the three groups were analyzed. Logistic regression analysis was performed for parameters with statistically significant differences, and conventional CT diagnostic model, spectral CT parameter diagnostic model and combined diagnostic model were established The diagnostic efficiency of each model was compared with the Area under the Receiver Operating characteristic (AUC).

RESULTS

In the three groups, the distance from pleura (P=0.009), morphology (P<0.001), density (P=0.001), separation from lung tissue (P=0.001), lobulation (P<0.001), liquefaction necrosis (P=0.003), vascular cluster sign (P<0.001), halo sign (P=0.003), satellite focus (P=0. 045), pleural effusion (P=0.002), Mediastinal lymph node enlargement(P<0.001),effective atomic number, iodine density, normalization iodine density, energy spectrum curve slope both in the arterial and venous phase,arterial enhancement fraction (P <0.001). The areas under ROC curve for the diagnosis of primary lung malignant tumor, chronic inflammation and pulmonary tuberculosis by conventional CT diagnostic model were 0.827, 0.753 and 0.770. The areas under ROC curve by spectral CT parameters were 0.905 0.824 and 0.909. The areas under ROC curve by combining conventional CT signs and spectral CT parameters were 0.929, 0.889 and 0.942.

CONCLUSION

s Spectral CT parameters combined with conventional CT signs can improve the differential diagnosis efficiency of pulmonary malignant tumor, chronic inflammation and pulmonary tuberculosis.

CLINICAL RELEVANCE/APPLICATION

Spectral CT parameters combined with conventional CT diagnosis can significantly improve the differential diagnosis efficiency of pulmonary primary malignant tumor, chronic inflammation and tuberculosis, which has high clinical application value. Reduce the probability of unnecessary surgery and biopsy for benign lesions due to difficulties in preoperative diagnosis.

S3A-SPCH-3 Dual-Source vs. Twin-Beam CT in Dual-Energy Lung Perfusion Assessment for Emphysema Patients

Participants
Quirin Strotzer, MD, Regensburg, Germany (*Presenter*) Nothing to Disclose

PURPOSE

This study is the first to compare dual-source dual-energy chest computed tomography (DECT) vs. twin-beam DECT to assess lung perfusion in emphysema patients with planned lung volume reduction therapy. Single-photon emission computed tomography (SPECT) was used as the gold standard.

METHODS AND MATERIALS

Sixty-two lung emphysema patients assessed for lung volume reduction therapy were included. All patients received a SPECT scan. Additionally, dual-source (two X-ray source/detector systems) DECT (thirty-two patients) or twin-beam (X-ray beam from a single source split with two filters into high and low energy spectra) DECT (thirty patients) was acquired. SPECT acquisitions were semi-

manually segmented, and the relative lung perfusion was calculated on a lobar level. On the DECTs, the lung lobes were automatically segmented using a U-Net, and segmentations were manually verified. The relative lung perfusion of each lobe was derived from iodine maps computed from the dual-energy data using a three-material decomposition algorithm.

RESULTS

Statistical analysis included the Pearson correlation coefficient to test the correlation between DECT and SPECT assessed lobar relative lung perfusion. While both methods showed a significant correlation with the SPECT acquisitions ($p < .001$), the correlation was higher for dual-source DECT ($r = .861$) than for twin-beam DECT ($r = .766$). Bland-Altman analysis showed a slightly better agreement for the dual-source data. No bias was observed.

CONCLUSION

s We conclude that both dual-source and twin-beam DECT are capable of assessing lung perfusion on a lobar level compared to SPECT. However, correlation and agreement are higher for dual-source DECT.

CLINICAL RELEVANCE/APPLICATION

Currently, patients undergoing assessment for lung volume reduction therapy require both structural computed tomography and evaluation of lung perfusion by single-photon emission computed tomography. With lung perfusion computed from dual-energy computed tomography data more readily available, the necessary information could be obtained from a single examination, saving time and money, and reducing the patients' radiation dose.

S3A-SPCH-4 Chest CT Angiography in Daily Practice With a Photon Counting CT Equipment: Comparison of Image Quality with Dual-source CT in 142 Patients

Participants
Martine J. Remy-Jardin, MD, PhD, Lille, France (*Presenter*) Research Grant, Siemens AG;Speaker, Siemens AG

PURPOSE

To compare the image quality of chest CT angiographic (CTA) examinations between photon-counting CT (PCCT) and dual-source CT (DSCT) in paired populations.

METHODS AND MATERIALS

The study population included 71 consecutive patients scanned with PCCT (Naeotom Alpha; Siemens Healthineers; Germany), compared to a paired population of 71 patients scanned with a 3rd-generation DSCT scanner (Somatom Force; Siemens Healthineers; Germany) selected on the basis of similar (a) injection protocols (80 mL of a 40% contrast agent; 4 mL/s); (b) age (± 5 years) and weight (± 5kg). The scanning parameters included (a) for DSCT (Group 1): collimation of 64x0.6x2 mm; pitch of 0.55; reconstruction of averaged images from both tubes; kernel: Br36; level of iterative reconstruction: ADMIRE 3; (b) for PCCT (Group 2): collimation of 144 x 0.4mm; pitch of 1.5; single-source acquisition; reconstruction of images at 70 keV; kernel: Br 36; level of iterative reconstruction: QIR 3. Comparative analysis of image quality of morphologic and perfusion images was undertaken.

RESULTS

Compared to Group 1: (a) the mean DLP of Group 2 acquisitions was significantly lower (172.6 ±55.14 vs 339.4 ±75.64 mGy.cm; $p<0.0001$) (52% dose reduction); (b) the duration of data acquisition in Group 2 was significantly shorter (0.93 ± 0.1s vs 3.98 ± 0.35s; $p<0.0001$). On mediastinal images, there was (a) no significant difference in the mean (±SD) attenuation value within central pulmonary arteries (Group 1: 420.0 ± 131.3 HU; Group 2: 398.0 ± 144.4 HU; $p=0.32$) nor at the level of the aorta (Group 1: 394.7 ± 92.34 HU; Group 2: 375.2 ± 90.34 HU; $p=0.15$); (b) a higher level of background noise, measured in the air around the patient (Group 2: 9.55 ± 1.86 HU; Group 1: 6.88 ±1.56 HU; $p<0.0001$). On perfusion images (a) the mean level of attenuation did not differ between the two groups (Group 1: 89.99 ± 28.86 HU; Group 2: 80.37 ± 30.07 HU; $p=0.05$) nor did the rating of subjective image noise (Group 1: mild: n=69; 97.2%, moderate: n=2; 2.8%; Group 2: mild: n=64; 90.1%, moderate: n=7; 9.9%; $p=0.16$); (b) the distribution of scores of fissure visualization significantly differed between the 2 groups ($p<0.0001$) with a higher proportion of fissures sharply delineated in Group 2 (n=60; 84.5%) than in Group 1 (n=26; 26.6%); (c) the rating of motion artifacts in the vicinity of the left ventricle differed between the 2 groups ($p<0.0001$) with a higher percentage of mild artifacts in Group 2 (n=69; 97.2%) than in Group 1 (n=19; 26.8%).

CONCLUSION

s PCCT acquisitions provided similar morphologic image quality and superior perfusion imaging at lower radiation dose.

CLINICAL RELEVANCE/APPLICATION

Photon-counting CT has the potential to improve perfusion imaging while maintaining morphologic image quality with a radiation dose reduced by 50%.

S3A-SPCH-6 Strain Analysis in Patients with Obstructive Ventilation Dysfunction Using Four It Dimensional Dynamic > Ventilation CT

Participants
Yanyan Xu, MD, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

To quantitatively identify abnormal lung motion in COPD using strain analysis, and further clarify the potential differences of deformation in COPD with different severity of airflow limitation.

METHODS AND MATERIALS

A total of 53 patients with suspected COPD were enrolled in this study. All CT examinations were performed on a 320 It row MDCT scanner, and dynamic It ventilation CT data was continuously reconstructed every 0.2 seconds (total 41 frames per patient). Strain measurement was performed using dynamic It ventilation CT data with a computational fluid dynamics analysis software (Micro Vec V3.6.2). The strain parameters derived from the whole expiration phase, the first 2s of expiration phase were divided respectively by the changes in lung volume to adjust for the degree of expiration. Spearman rank correlation analysis was used to evaluate associations between the adjusted strain parameters and various spirometric parameters. Comparisons of the strain

parameters between COPD and non It COPD patients, between GOLD I and GOLD II-IV were made using the Mann It Whitney U test. Then, receiver-operating characteristic (ROC) analysis was performed to evaluate the diagnostic performance of the adjusted strain parameters for COPD. P<0.05 was considered statistically significant.

RESULTS

Strain-related parameters were significantly correlated with forced expiratory volume in one second/forced vital capacity (?=0.450~0.687, P<0.001), maximum mid-expiratory flow rate (?=0.364~0.643, P<0.05), and peak expiratory flow (?=0.275~0.456, P<0.05), suggesting that heterogeneity in lung motion are related to abnormal spirometric results, and patients with obstructive ventilation dysfunction demonstrated lower strain values (P<0.001). According to the ROC curve, the strain-related parameters showed moderate diagnostic significance with the AUC values range from 0.821 to 0.894. The strain parameters derived from the whole expiration phase (PSmax-all,Speedmax-all) showed statistical differences between GOLD I and GOLD II-IV patients (z=-2.782, P=0.005; z=-2.053, P=0.04).

CONCLUSION

s Strain parameters basing on dynamic It ventilation CT data associated with lung function impairment in COPD, reflecting the severity of airflow limitation in some degree, even though its utility in severe COPD patients remains to be investigated.

CLINICAL RELEVANCE/APPLICATION

Strain measurements provides a promisingly quantitative method for monitoring disease progression in COPD.

S3A-SPCH-7 Dynamic Contrast-Enhanced Whole-Lung Perfusion Area-Detector CT: Capability for Lung Structure Change and Pulmonary Functional Loss Evaluations in Operated Stage I Lung Cancer Patients

Participants
Yoshiharu Ohno, MD, PhD, Toyoake, Japan (*Presenter*) Research Grant, Canon Medical Systems Corporation;Research Grant, Daiichi Sankyo Co, Ltd;Research Grant, Ministry of Education, Culture, Sports, Science and Technology

PURPOSE

To determine the capability of dynamic contrast-enhanced (CE-) whole-lung perfusion area-detector CT (ADCT) for pathological change and pulmonary functional loss evaluations in operated Stage I lung cancer patients.

METHODS AND MATERIALS

Sixty-three consecutive stage I lung cancer patients underwent dynamic CE-perfusion ADCT performed at two or three different positions as single examination, pulmonary function test, surgical treatment, and pathological examination. From perfusion ADCT data in each patient, whole lung total perfusion (TP), pulmonary arterial perfusion (PAP) and systemic arterial perfusion (SAP) maps were computationally generated based on dual-input maximum slope method by pixel-by-pixel analyses with commercially available software. Then, ROIs were placed within operated lung based on pathological examination results. In this study, all ROIs within operated lung were divided into following four structure groups: normal lung, emphysema, fibrotic changes without honeycombing (non-honeycombing), and honeycombing. To determine the capability of each perfusion parameter for pulmonary functional loss, Pearson's correlation was performed. To compare each perfusion parameter among all structure groups, Tukey's HSD test was performed. Finally, discrimination accuracy for structure change evaluation was compared among all perfusion parameters by McNemar's test.

RESULTS

%FEV1, %VC and %DLCO/VA had significant correlations with TP (0.47<r<0.60, p<0.0001) and PAP (0.43<r<0.58, p<0.0001). All perfusion parameters had significant differences between normal lung and other groups (p<0.05), between emphysema and non-honeycombing groups (p<0.0001) and between emphysema and honeycombing groups (p<0.0001). Moreover, SAP had significant difference between non-honeycombing and honeycombing groups (p<0.0001). Finally, discrimination accuracy of TP (71.0%) was significantly higher than that of others (PAP: 45.8%, p<0.0001, SAP: 52.4%, p<0.0001).

CONCLUSION

s Whole-lung dynamic first-pass CE-perfusion ADCT is useful for pathological change and pulmonary functional loss evaluations in operated stage I lung cancer patients.

CLINICAL RELEVANCE/APPLICATION

Whole-lung dynamic first-pass CE-perfusion ADCT is useful for pathological change and pulmonary functional loss evaluations in operated stage I lung cancer patients.

S3A-SPCH-8 Diagnostic Performance of Extracellular Volume Fraction (ECV) Measured by Dual-Energy CT: Prediction for Programmed Death-ligand 1 (PD-L1) Expression in Invasive Pulmonary Adenocarcinoma

Participants
Masahiro Yanagawa, MD, PhD, Suita, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To examine the association between quantitative data measured by dual-energy CT and expression of programmed death-ligand 1 (PD-L1) using immunostaining methods.

METHODS AND MATERIALS

37 patients with invasive pulmonary adenocarcinoma were scanned by dual-energy CT (Revolution CT; GE) with fast kV (80- and 140-kVp) switching mode for examining solitary pulmonary nodules. Enhanced dual-energy CT images in the 180s late phase were obtained with 1.25 mm thickness, 20 cm field of view and 512×512 matrix using a standard kernel and 30% adaptive statistical iterative reconstruction. The dose of contrast material (IOHEXOL300mgI) per patient was decided on the basis of 2 ml per weight. Volume of interest on three dimensional (3D) iodine density mapping was set in each nodule and aorta as large as possible. Extracellular volume fraction (ECV) was calculated using the following formula: ECV = (1-hematocrit) × (iodine density in each

nodule / iodine density in each aorta). 3D iodine density histogram texture analysis was performed for each nodule: 7 texture features (max, min, median, average, standard deviation, skewness, and kurtosis) were also obtained. A pathologist evaluated a tumor proportion score (TPS, %) using PD-L1 immunostaining: PD-L1 strong positive (TPS =50 %) (first line criteria for immune checkpoint inhibitors). Associations between expression of PD-L1(TPS =50%) and 8 parameters were evaluated using univariate and multivariate logistic regression analyses. Diagnostic performance was evaluated by sensitivity, specificity, and an area under the receiver operator characteristic curve (AUC). P values < 0.05 were considered significant.

RESULTS

Volume of 37 nodules (15 part-solid and 22 solid) showed 5.46 cc ±16.33 (mean ± SD). The number of PD-L1(TPS =50 %) was 11. Univariate logistic regression analysis revealed that the average >1.39 mg/cc, skewness =-2.28, kurtosis >6.17, and ECV >21.23 % were significant indicators ($p < 0.032$). Multivariate logistic regression analysis revealed that skewness =-2.28 and ECV >21.23% were independent indicators associated with PD-L1(TPS =50 %) (odds ratio, 7.11 and 6.57; 95% confidence interval, 1.11-45.6 and 1.12-38.4; $p = 0.039$ and 0.037, respectively). The diagnostic performance of these two findings combined were as follows: sensitivity of 64 % (7/11) specificity of 86 % (25/26) and AUC of 0.83.

CONCLUSION

s Skewness and ECV from dual-energy CT in the 180s late phase may predict high expression of PD-L1 in invasive pulmonary adenocarcinoma.

CLINICAL RELEVANCE/APPLICATION

Dual-energy CT may be a noninvasive method for chemotherapy strategy such as immune checkpoint inhibitors in invasive adenocarcinoma.

Clinical Value of Dual Layer Spectral Detector CT in Differential Diagnosis of Primary Malignant Chronic Lung Inflammation and Pulmonary Tuberculosis

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - CH DPS

Participants
Xiaoxia Zheng, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To explore the clinical value of dual-layer detector spectral CT (DLCT) in differential diagnosis of lung primary malignant tumor, chronic inflammation and pulmonary tuberculosis using conventional CT signs and spectral multi-parameters.

METHODS AND MATERIALS

From August 2020 to June 2021, 345 patients with pathologically confirmed of pulmonary diseases who underwent DLCT chest enhanced scan in our hospital were retrospective enrolled for this study. The patients were divided into three groups: primary lung malignant tumor group (n = 187, 88 adenocarcinoma, 51squamous cell carcinoma and 34 small cell lung cancer and 14 other malignant tumors), chronic inflammation group (n = 101) and tuberculosis group (n = 57) . The conventional CT signs and spectral CT parameters of the three groups were analyzed. Logistic regression analysis was performed for parameters with statistically significant differences, and conventional CT diagnostic model, spectral CT parameter diagnostic model and combined diagnostic model were established The diagnostic efficiency of each model was compared with the Area under the Receiver Operating characteristic (AUC).

RESULTS

In the three groups, the distance from pleura (P=0.009), morphology (P<0.001), density (P=0.001), separation from lung tissue (P=0.001), lobulation (P<0.001), liquefaction necrosis (P=0.003), vascular cluster sign (P<0.001), halo sign (P=0.003), satellite focus (P=0. 045), pleural effusion (P=0.002), Mediastinal lymph node enlargement(P<0.001),effective atomic number, iodine density, normalization iodine density, energy spectrum curve slope both in the arterial and venous phase,arterial enhancement fraction (P <0.001). The areas under ROC curve for the diagnosis of primary lung malignant tumor, chronic inflammation and pulmonary tuberculosis by conventional CT diagnostic model were 0.827, 0.753 and 0.770. The areas under ROC curve by spectral CT parameters were 0.905 0.824 and 0.909. The areas under ROC curve by combining conventional CT signs and spectral CT parameters were 0.929, 0.889 and 0.942.

CONCLUSION

s Spectral CT parameters combined with conventional CT signs can improve the differential diagnosis efficiency of pulmonary malignant tumor, chronic inflammation and pulmonary tuberculosis.

CLINICAL RELEVANCE/APPLICATION

Spectral CT parameters combined with conventional CT diagnosis can significantly improve the differential diagnosis efficiency of pulmonary primary malignant tumor, chronic inflammation and tuberculosis, which has high clinical application value. Reduce the probability of unnecessary surgery and biopsy for benign lesions due to difficulties in preoperative diagnosis.

S3A-SPCH-3

Dual-Source vs. Twin-Beam CT in Dual-Energy Lung Perfusion Assessment for Emphysema Patients

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - CH DPS

Participants
Quirin Strotzer, MD, Regensburg, Germany (*Presenter*) Nothing to Disclose

PURPOSE

This study is the first to compare dual-source dual-energy chest computed tomography (DECT) vs. twin-beam DECT to assess lung perfusion in emphysema patients with planned lung volume reduction therapy. Single-photon emission computed tomography (SPECT) was used as the gold standard.

METHODS AND MATERIALS

Sixty-two lung emphysema patients assessed for lung volume reduction therapy were included. All patients received a SPECT scan. Additionally, dual-source (two X-ray source/detector systems) DECT (thirty-two patients) or twin-beam (X-ray beam from a single source split with two filters into high and low energy spectra) DECT (thirty patients) was acquired. SPECT acquisitions were semi-manually segmented, and the relative lung perfusion was calculated on a lobar level. On the DECTs, the lung lobes were automatically segmented using a U-Net, and segmentations were manually verified. The relative lung perfusion of each lobe was derived from iodine maps computed from the dual-energy data using a three-material decomposition algorithm.

RESULTS

Statistical analysis included the Pearson correlation coefficient to test the correlation between DECT and SPECT assessed lobar relative lung perfusion. While both methods showed a significant correlation with the SPECT acquisitions ($p < .001$), the correlation was higher for dual-source DECT ($r = .861$) than for twin-beam DECT ($r = .766$). Bland-Altman analysis showed a slightly better agreement for the dual-source data. No bias was observed.

CONCLUSION

s We conclude that both dual-source and twin-beam DECT are capable of assessing lung perfusion on a lobar level compared to SPECT. However, correlation and agreement are higher for dual-source DECT.

CLINICAL RELEVANCE/APPLICATION

Currently, patients undergoing assessment for lung volume reduction therapy require both structural computed tomography and evaluation of lung perfusion by single-photon emission computed tomography. With lung perfusion computed from dual-energy computed tomography data more readily available, the necessary information could be obtained from a single examination, saving time and money, and reducing the patients' radiation dose.

Chest CT Angiography in Daily Practice With a Photon Counting CT Equipment: Comparison of Image Quality with Dual-source CT in 142 Patients

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - CH DPS

Participants
Martine J. Remy-Jardin, MD, PhD, Lille, France (*Presenter*) Research Grant, Siemens AG;Speaker, Siemens AG

PURPOSE

To compare the image quality of chest CT angiographic (CTA) examinations between photon-counting CT (PCCT) and dual-source CT (DSCT) in paired populations.

METHODS AND MATERIALS

The study population included 71 consecutive patients scanned with PCCT (Naeotom Alpha; Siemens Healthineers; Germany), compared to a paired population of 71 patients scanned with a 3rd-generation DSCT scanner (Somatom Force; Siemens Healthineers; Germany) selected on the basis of similar (a) injection protocols (80 mL of a 40% contrast agent; 4 mL/s); (b) age (± 5 years) and weight (± 5kg). The scanning parameters included (a) for DSCT (Group 1): collimation of 64x0.6x2 mm; pitch of 0.55; reconstruction of averaged images from both tubes; kernel: Br36; level of iterative reconstruction: ADMIRE 3; (b) for PCCT (Group 2): collimation of 144 x 0.4mm; pitch of 1.5; single-source acquisition; reconstruction of images at 70 keV; kernel: Br 36; level of iterative reconstruction: QIR 3. Comparative analysis of image quality of morphologic and perfusion images was undertaken.

RESULTS

Compared to Group 1: (a) the mean DLP of Group 2 acquisitions was significantly lower (172.6 ±55.14 vs 339.4 ±75.64 mGy.cm; p<0.0001) (52% dose reduction); (b) the duration of data acquisition in Group 2 was significantly shorter (0.93 ± 0.1s vs 3.98 ± 0.35s; p<0.0001). On mediastinal images, there was (a) no significant difference in the mean (±SD) attenuation value within central pulmonary arteries (Group 1: 420.0 ± 131.3 HU; Group 2: 398.0 ± 144.4 HU; p=0.32) nor at the level of the aorta (Group 1: 394.7 ± 92.34 HU; Group 2: 375.2 ± 90.34 HU; p=0.15); (b) a higher level of background noise, measured in the air around the patient (Group 2: 9.55 ± 1.86 HU; Group 1: 6.88 ±1.56 HU; p<0.0001). On perfusion images (a) the mean level of attenuation did not differ between the two groups (Group 1: 89.99 ± 28.86 HU; Group 2: 80.37 ± 30.07 HU; p=0.05) nor did the rating of subjective image noise (Group 1: mild: n=69; 97.2%, moderate: n=2; 2.8%; Group 2: mild: n=64; 90.1%, moderate: n=7; 9.9%; p=0.16); (b) the distribution of scores of fissure visualization significantly differed between the 2 groups (p<0.0001) with a higher proportion of fissures sharply delineated in Group 2 (n=60; 84.5%) than in Group 1 (n=26; 26.6%); (c) the rating of motion artifacts in the vicinity of the left ventricle differed between the 2 groups (p<0.0001) with a higher percentage of mild artifacts in Group 2 (n=69; 97.2%) than in Group 1 (n=19; 26.8%).

CONCLUSION

s PCCT acquisitions provided similar morphologic image quality and superior perfusion imaging at lower radiation dose.

CLINICAL RELEVANCE/APPLICATION

Photon-counting CT has the potential to improve perfusion imaging while maintaining morphologic image quality with a radiation dose reduced by 50%.

Strain Analysis in Patients with Obstructive Ventilation Dysfunction Using Four It Dimensional Dynamic > Ventilation CT

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - CH DPS

Participants
Yanyan Xu, MD, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

To quantitatively identify abnormal lung motion in COPD using strain analysis, and further clarify the potential differences of deformation in COPD with different severity of airflow limitation.

METHODS AND MATERIALS

A total of 53 patients with suspected COPD were enrolled in this study. All CT examinations were performed on a 320 It row MDCT scanner, and dynamic It ventilation CT data was continuously reconstructed every 0.2 seconds (total 41 frames per patient). Strain measurement was performed using dynamic It ventilation CT data with a computational fluid dynamics analysis software (Micro Vec V3.6.2). The strain parameters derived from the whole expiration phase, the first 2s of expiration phase were divided respectively by the changes in lung volume to adjust for the degree of expiration. Spearman rank correlation analysis was used to evaluate associations between the adjusted strain parameters and various spirometric parameters. Comparisons of the strain parameters between COPD and non It COPD patients, between GOLD I and GOLD II-IV were made using the Mann It Whitney U test. Then, receiver-operating characteristic (ROC) analysis was performed to evaluate the diagnostic performance of the adjusted strain parameters for COPD. $P<0.05$ was considered statistically significant.

RESULTS

Strain-related parameters were significantly correlated with forced expiratory volume in one second/forced vital capacity (?=0.450~0.687, $P<0.001$), maximum mid-expiratory flow rate (?=0.364~0.643, $P<0.05$), and peak expiratory flow (?=0.275~0.456, $P<0.05$), suggesting that heterogeneity in lung motion are related to abnormal spirometric results, and patients with obstructive ventilation dysfunction demonstrated lower strain values ($P<0.001$). According to the ROC curve, the strain-related parameters showed moderate diagnostic significance with the AUC values range from 0.821 to 0.894. The strain parameters derived from the whole expiration phase (PSmax-all,Speedmax-all) showed statistical differences between GOLD I and GOLD II-IV patients ($z=-2.782$, $P=0.005$; $z=-2.053$, $P=0.04$).

CONCLUSION

s Strain parameters basing on dynamic It ventilation CT data associated with lung function impairment in COPD, reflecting the severity of airflow limitation in some degree, even though its utility in severe COPD patients remains to be investigated.

CLINICAL RELEVANCE/APPLICATION

Strain measurements provides a promisingly quantitative method for monitoring disease progression in COPD.

Dynamic Contrast-Enhanced Whole-Lung Perfusion Area-Detector CT: Capability for Lung Structure Change and Pulmonary Functional Loss Evaluations in Operated Stage I Lung Cancer Patients

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - CH DPS

Participants
Yoshiharu Ohno, MD, PhD, Toyoake, Japan (*Presenter*) Research Grant, Canon Medical Systems Corporation;Research Grant, Daiichi Sankyo Co, Ltd;Research Grant, Ministry of Education, Culture, Sports, Science and Technology

PURPOSE

To determine the capability of dynamic contrast-enhanced (CE-) whole-lung perfusion area-detector CT (ADCT) for pathological change and pulmonary functional loss evaluations in operated Stage I lung cancer patients.

METHODS AND MATERIALS

Sixty-three consecutive stage I lung cancer patients underwent dynamic CE-perfusion ADCT performed at two or three different positions as single examination, pulmonary function test, surgical treatment, and pathological examination. From perfusion ADCT data in each patient, whole lung total perfusion (TP), pulmonary arterial perfusion (PAP) and systemic arterial perfusion (SAP) maps were computationally generated based on dual-input maximum slope method by pixel-by-pixel analyses with commercially available software. Then, ROIs were placed within operated lung based on pathological examination results. In this study, all ROIs within operated lung were divided into following four structure groups: normal lung, emphysema, fibrotic changes without honeycombing (non-honeycombing), and honeycombing. To determine the capability of each perfusion parameter for pulmonary functional loss, Pearson's correlation was performed. To compare each perfusion parameter among all structure groups, Tukey's HSD test was performed. Finally, discrimination accuracy for structure change evaluation was compared among all perfusion parameters by McNemar's test.

RESULTS

%FEV1, %VC and %DLCO/VA had significant correlations with TP ($0.47<r<0.60$, $p<0.0001$) and PAP ($0.43<r<0.58$, $p<0.0001$). All perfusion parameters had significant differences between normal lung and other groups ($p<0.05$), between emphysema and non-honeycombing groups ($p<0.0001$) and between emphysema and honeycombing groups ($p<0.0001$). Moreover, SAP had significant difference between non-honeycombing and honeycombing groups ($p<0.0001$). Finally, discrimination accuracy of TP (71.0%) was significantly higher than that of others (PAP: 45.8%, $p<0.0001$, SAP: 52.4%, $p<0.0001$).

CONCLUSION

s Whole-lung dynamic first-pass CE-perfusion ADCT is useful for pathological change and pulmonary functional loss evaluations in operated stage I lung cancer patients.

CLINICAL RELEVANCE/APPLICATION

Whole-lung dynamic first-pass CE-perfusion ADCT is useful for pathological change and pulmonary functional loss evaluations in operated stage I lung cancer patients.

Diagnostic Performance of Extracellular Volume Fraction (ECV) Measured by Dual-Energy CT: Prediction for Programmed Death-ligand 1 (PD-L1) Expression in Invasive Pulmonary Adenocarcinoma

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - CH DPS

Participants
Masahiro Yanagawa, MD, PhD, Suita, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To examine the association between quantitative data measured by dual-energy CT and expression of programmed death-ligand 1 (PD-L1) using immunostaining methods.

METHODS AND MATERIALS

37 patients with invasive pulmonary adenocarcinoma were scanned by dual-energy CT (Revolution CT; GE) with fast kV (80- and 140-kVp) switching mode for examining solitary pulmonary nodules. Enhanced dual-energy CT images in the 180s late phase were obtained with 1.25 mm thickness, 20 cm field of view and 512×512 matrix using a standard kernel and 30% adaptive statistical iterative reconstruction. The dose of contrast material (IOHEXOL300mgI) per patient was decided on the basis of 2 ml per weight. Volume of interest on three dimensional (3D) iodine density mapping was set in each nodule and aorta as large as possible. Extracellular volume fraction (ECV) was calculated using the following formula: ECV = (1-hematocrit) × (iodine density in each nodule / iodine density in each aorta). 3D iodine density histogram texture analysis was performed for each nodule: 7 texture features (max, min, median, average, standard deviation, skewness, and kurtosis) were also obtained. A pathologist evaluated a tumor proportion score (TPS, %) using PD-L1 immunostaining: PD-L1 strong positive (TPS =50 %) (first line criteria for immune checkpoint inhibitors). Associations between expression of PD-L1(TPS =50%) and 8 parameters were evaluated using univariate and multivariate logistic regression analyses. Diagnostic performance was evaluated by sensitivity, specificity, and an area under the receiver operator characteristic curve (AUC). P values < 0.05 were considered significant.

RESULTS

Volume of 37 nodules (15 part-solid and 22 solid) showed 5.46 cc ±16.33 (mean ± SD). The number of PD-L1(TPS =50 %) was 11. Univariate logistic regression analysis revealed that the average >1.39 mg/cc, skewness =-2.28, kurtosis >6.17, and ECV >21.23 % were significant indicators ($p < 0.032$). Multivariate logistic regression analysis revealed that skewness =-2.28 and ECV >21.23% were independent indicators associated with PD-L1(TPS =50 %) (odds ratio, 7.11 and 6.57; 95% confidence interval, 1.11-45.6 and 1.12-38.4; $p = 0.039$ and 0.037, respectively). The diagnostic performance of these two findings combined were as follows: sensitivity of 64 % (7/11) specificity of 86 % (25/26) and AUC of 0.83.

CONCLUSION

s Skewness and ECV from dual-energy CT in the 180s late phase may predict high expression of PD-L1 in invasive pulmonary adenocarcinoma.

CLINICAL RELEVANCE/APPLICATION

Dual-energy CT may be a noninvasive method for chemotherapy strategy such as immune checkpoint inhibitors in invasive adenocarcinoma.

S3A-SPER-1 Jointly Optimized Deep Neural Networks to Synthesize Monoenergetic Images from CT Angiography for Improving Classification of Pulmonary Embolism

Participants
Matthias Fink, MD, BSc, Heidelberg, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To develop a jointly optimized deep learning framework based on dual-energy CT pulmonary angiography (DE-CTPA) data to generate synthetic monoenergetic images (SMI) for improving automatic pulmonary embolism (PE) detection in single-energy CTPA scans.

METHODS AND MATERIALS

We used two data sets: our institutional DE-CTPA data set D1 comprising polyenergetic arterial series and the corresponding VMI at low-energy levels (40 keV) with 7,892 image pairs, and a 10% subset of the 2020 RSNA Pulmonary Embolism Detection Challenge data set D2, which consisted of 161,253 polyenergetic images with binary slice-wise annotations (PE/no PE). We trained a fully convolutional encoder-decoder on D1 to generate SMI from single-energy CTPA scans of D2, which were then fed into a ResNet50 network for training of the downstream PE classification task. We evaluated our VMI reconstruction results in terms of Peak-Signal-to-Noise-Ratio (PSNR) and Structural Similarity Index Measure (SSIM). For PE identification, we performed a binary classification on slice level and report the area under the curve (AUC).

RESULTS

The quantitative results on the reconstruction ability of our framework revealed high-quality visual SMI predictions with reconstruction results of 0.984 ± 0.002 (structural similarity) and 41.706 ± 0.547 dB (peak-signal-to-noise ratio). PE classification resulted in an AUC of 0.84 for our model, which achieved improved performance compared to other naïve approaches with AUCs up to 0.81.

CONCLUSION

s Using joint optimization strategies for deep learning algorithms allows training of translating polyenergetic into monoenergetic images without losing features necessary for automatic PE classification. Our model hereby improves noticeably over straight forward classification while outperforming existing methods.

CLINICAL RELEVANCE/APPLICATION

The proposed pipeline may prove to be beneficial for computer-aided detection systems and could help rescue CTPA studies with suboptimal contrast attenuation of the pulmonary arteries from single-energy CT scanners.

S3A-SPGI-1 PACS-integrated Artificial Intelligence-based Analysis of Body Composition in Exocrine Pancreatic Cancer: Skeletal Muscle Index and Sarcopenia Predict Survival

Participants
Nick Beetz, MD, Berlin, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Worldwide, pancreatic cancer is the seventh leading cause of cancer death in both sexes. Because of its poor prognosis, pancreatic cancer accounts for almost as many deaths as cases even if curative intended surgery is performed. The aim of this study is to analyze baseline CT body composition using artificial intelligence (AI)-based tissue segmentation to identify possible imaging predictors of survival.

METHODS AND MATERIALS

We retrospectively included 103 patients with exocrine pancreatic cancer for whom baseline CT imaging datasets were available. Body composition at the third lumbar vertebra level was analyzed using an AI-based software tool. Patient and survival data were obtained from medical records. Forty-six patients underwent surgery. First, presence of surgical treatment and cut-off values for sarcopenia and obesity served as independent variates. Second, presence of surgery, skeletal muscle index (SMI), visceral adipose tissue (VAT), and subcutaneous adipose tissue (SAT) served as independent variates. Cox regression analysis was performed for 1-year, 2-year, and 3-year survival after baseline CT. Additionally, possible differences between patients undergoing surgical versus nonsurgical treatment were analyzed.

RESULTS

Presence of surgery significantly predicted 1-year, 2-year, and 3-year survival (p=0.01, <0.001, and <0.001, respectively). Across the follow-up periods of 1-year, 2-year, and 3-year survival, the presence of sarcopenia became an equally important predictor of survival (p=0.2, 1.66, and <0.001, respectively). Additionally, increased VAT predicted 2-year and 3-year survival (p=0.02 and 0.04, respectively). The impact of sarcopenia on 3-year survival was higher in the surgical treatment group (p=0.02 and OR=2.61) compared to the nonsurgical treatment group (p=0.05 and OR=1.85). Fittingly, a lower SMI significantly affected 3-year survival only in patients who underwent surgery (p=0.02).

CONCLUSION

s This study for the first time uses a PACS-integrated AI-based body composition analysis tool to predict survival in patients with pancreatic cancer. Besides the already known influence of sarcopenia on survival, our results provide evidence that increased visceral fat is a negative predictor of survival. Moreover, we show that sarcopenia has a greater impact in patients who undergo surgery compared to patients undergoing nonsurgical treatment only.

CLINICAL RELEVANCE/APPLICATION

AI-based body composition analysis in pancreatic cancer provides important metabolic information for predicting patient survival. Especially if surgery is performed, sarcopenia and reduced muscle mass are unfavorable imaging predictors and should warrant additional special care to improve survival.

S3A-SPGI-2 Development and Validation of Deep Learning-based Automatic Detection and Grading of Motion-related Artifacts on Gadoxetic Acid-enhanced Liver MRI

Participants
Dong Wook Kim, MD, PhD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To develop and validate deep learning algorithm (DLA) for automatic detection and grading of motion-related artifact on arterial phase of gadoxetic acid-enhanced liver MRI

METHODS AND MATERIALS

Multi-step DLA for detection and grading of motion-related artifact, based on modified ResNet-101 and U-net, were trained using 336 arterial-phase images of gadoxetic acid-enhanced liver MRI obtained in 2017 (development dataset; 68.6-years [range, 18-95]; 254 men). Motion-related artifact was evaluated in 4 different MRI slices using 3-tier grading systems. In the validation datasets, 313 from the same institution obtained in 2018 (internal validation dataset; 67.2-years [range, 21-87], 228 men) and 329 from

three different institutions (external validation dataset; 64.0-years [range, 23-90], 214 men), per-slice and per-exam diagnostic performances for detection of motion-related artifact were evaluated.

RESULTS

Per-slice sensitivity and specificity for detecting grade 3 motion-related artifact were 91.5% (97/106) and 96.8% (1134/1172) in the internal validation dataset, and were 93.3% (265/284) and 91.6% (948/1035) in the external validation dataset. Per-exam sensitivity and specificity were 92.0% (23/25) and 99.7% (287/288) in the internal validation dataset, and were 90.0% (72/80) and 96.0% (239/249) in the external validation dataset. The average processing time of DLA for automatic grading of motion-related artifact was 4.15 seconds per MRI examination.

CONCLUSION

s DLA enables automatic and instant detection and grading of the motion-related artifact on arterial-phase gadoxetic acid-enhanced liver MRI.

CLINICAL RELEVANCE/APPLICATION

Implementation of DLA in liver MRI examination would potentially reduce repeat examination and additional cost caused by nondiagnostic image from motion-related artifact.

S3A-SPGI-3 Predicting tumor deposits in rectal cancer: A combined deep learning model using T2WI-MR imaging< and gtclinical features

Participants
Jin Yumei, (*Presenter*) Nothing to Disclose

PURPOSE

To develop and validate a deep learning (DL)based combined model incorporating T2-MR image and clinical factors for preoperatively predicting tumor deposits (TDs) in rectal cancer (RC) patients.

METHODS AND MATERIALS

A total of 327 RC patients from December 2017 to July 2021 was retrospectively collected and the TDs status was pathologically confirmed. Both tumoral and peritumoral regions were labeled on the preoperative T2-MR images. Patients were randomly divided into a development dataset (143 non-TDs and 103 TDs) and an independent testing set (47 non-TDs and 34 TDs). Three DL models were proposed: a single-channel deep learning (single-DL) model using only the tumoral regions as input, a multi-channel deep learning (multi-DL) model using both the tumoral and peri-tumoral regions as input, and a hybrid deep learning (hybrid-DL) model that incorporating both tumoral and peri-tumoral regions as well as the selected clinical variables. A clinical model was also constructed via multivariate logistic regression analysis. The performance of these predictive models was evaluated with respect to discrimination, calibration and clinical usefulness.

RESULTS

The AUCs of the clinical, single-DL, multi-DL and hybrid-DL models were 0.734 (95% CI, 0.674-0.788), 0.710 (95% CI, 0.649-0.766), 0.767 (95% CI, 0.710-0.819) and 0.857 (95% CI, 0.807-0.898) in the development dataset, respectively. Similar performance of these models was observed in the testing dataset with AUCs achieving 0.726 (95% CI, 0.615-0.819), 0.676 (95% CI, 0.563-0.776), 0.738 (95% CI, 0.628-0.829) and 0.839 (95% CI, 0.741-0.911), respectively. Delong's test indicated the hybrid-DL model showed improved performance than the clinical model ($p = 0.134$), single-DL model ($p=0.028$) and multi-DL model ($p = 0.066$) in the testing dataset. All models showed good calibration, and decision curve analysis confirmed net benefit of the hybrid-DL model was higher than other models across majority range of threshold probabilities

CONCLUSION

s The proposed hybrid-DL model incorporating T2-MR images and clinical risk factors achieved good predictive efficacy and could be used to predict tumor deposits in rectal cancer.

CLINICAL RELEVANCE/APPLICATION

We developed a deep learning model based on both T2-MR images and clinical risk factors with favorable performance, which could be used for preoperative prediction of tumor deposits in rectal cancer.

S3A-SPGI-4 Prognostic value of preoperative CT-based radiomics in grade 1-2 pancreatic neuroendocrine tumors: a multi-institutional study

Participants
Subin Heo, MD, Suwon, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To develop and validate a radiomics-based model for predicting postsurgical outcomes using preoperative CT in patients with grade 1-2 pancreatic neuroendocrine tumors (PNETs), and to evaluate the incremental prognostic value of radiomics analysis to the current staging system.

METHODS AND MATERIALS

This multicenter retrospective study included patients who underwent dynamic CT and subsequent curative resection for grade 1-2 PNETs. In the training cohort (441 patients from one institution), radiomics features were extracted from the segmented tumor of the arterial and portal-venous phase images. A radiomics score (R-score) for predicting recurrence-free survival (RFS) was built using the least absolute shrinkage and selection operator-Cox regression analysis. A model consisting of age and the 8th American Joint Committee on Cancer staging system (AJCC)-based tumor stage, and another model combining the R-score, age and AJCC stage were built to predict RFS and overall survival (OS) using the multivariable Cox regression analysis. Models were tested in an external cohort (159 patients from another institution) using Harrell's C-index. The incremental difference of the models was evaluated using the net reclassification improvement (NRI) and integrated discrimination improvement (IDI).

RESULTS

In the training cohort, 63 patients (14.3 %) experienced recurrence, and 35 (7.9 %) died. In the test cohort, recurrence occurred in 19 (11.9 %) and 12 (7.5 %) died. The median follow-up was 68.3 and 59.7 months in training and test cohort, respectively. In the test cohort, R-score had C-index of 0.716 for RFS and 0.674 for OS. The combined model outperformed the model without R-score in predicting outcomes in the test cohort (for RFS, C-index, 0.73 vs 0.66, p = 0.01; for OS, 0.78 vs 0.68, p = 0.04). By integrating the R-score, the combined model achieved improvement in classification and discrimination in predicting RFS at 3 years (NRI, 0.33; IDI, 0.07 [p < 0.001 for both]).

CONCLUSION

s Radiomics analysis adds incremental value beyond current tumor staging system in predicting RFS and OS in resected grade 1-2 PNETs.

CLINICAL RELEVANCE/APPLICATION

CT radiomics analysis improves prognostic performance when added to the current staging system in grade 1-2 PNETs, thus enables better patient assessment and individualized treatment decision-making.

S3A-SPGI-5 Multi-scale sampling method adapted for the detection of small hepatic lesions on gadoxetic acid-enhanced hepatobiliary phase MR images

Participants
Tatsuya Yamaguchi, Kawasaki-Shi, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Gadoxetic acid-enhanced hepatobiliary phase (HBP) magnetic resonance (MR) images are highly sensitive for the detection of liver lesions. However, small lesions, especially those near hepatic vessels, may be missed because they and the vessels are low signal intense on HBP images. Our new multi-scale sampling method is adapted for their detection. We investigated the feasibility of our method for the detection of small liver lesions on HBP images.

METHODS AND MATERIALS

We propose a new method based on multi-scale (6-, 12-, and 24 mm) sampling patch images. The patch images were converted from 3D- to 2D images via the minimum intensity projection of 3 orthogonal planes (axial, coronal, and sagittal). Areas harboring malignant hepatic tumors, hemangiomas, or cysts were sampled from the HBP images of 17 patients. A board-certified radiologist annotated 460 lesions. The VGG-16 convolutional neural network was used for their binary classification (hepatic lesion yes/no). Of the 460 lesions, 32 (7%) were used for evaluation and the other 328 for learning. True positive was recorded when the particle obtained by integrating the detection results acquired at each scale even partially overlapped the lesion. False positive was recorded when the particle showed no overlap. Free-response receiver operating characteristic (FROC) analysis was used to evaluate the performance of our method.

RESULTS

From FROC evaluation, the sensitivity of our method was 78% (25/32 lesions) at 9 false positives per volume (FP/vol); it was 80% (8/10 lesions) when limited to lesions less than 10 mm. Our method was more sensitive than single-scale methods used in related studies.

CONCLUSION

s Regardless of the target size, our multi-scale sampling method is highly sensitive for liver lesions on HBP images.

CLINICAL RELEVANCE/APPLICATION

Our multi-scale sampling method can detect small liver lesions with high sensitivity on HBP images regardless of the target size. Our method may be useful in patients with small, possibly metastatic hepatic lesions.

S3A-SPGI-6 Image Quality Improvement of Liver Ultrasound Using Unsupervised Deep Learning

Participants
Jaeyoung Huh, MS, Daejeon, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate image quality improvement of liver ultrasound (US) obtained by an old equipment through a deep learning approach.

METHODS AND MATERIALS

The neural network was trained using low-quality images as inputs and high-quality images as targets. Since there is no matched low-high quality paired dataset, unsupervised learning using cyclic consistency and adaptive instance normalization (AdaIN) was utilized. We consecutively enrolled and randomly selected liver US to prepared two categories of datasets for training our deep learning-based algorithm, i.e., 1) liver US obtained by an aged US machine more than 10 years served as inputs or students (All 500sets, training sets: test sets = 400:100); 2) liver us obtained by a high-end US machine manufactured within 5 years, served as targets or teacher (400 sets, all training sets). The image quality was evaluated by 5 categories by two reviewers, i.e., brightness, contrast, resolution, reverberation artifact and overall quality, using 5-scored system. Additionally, the reviewers assessed the presence of liver cirrhosis (LC), fatty liver, solid hepatic focal lesion detection, gallbladder polyp and gallstones in each US set. We use paired simple t test to assess five categories of image quality improvement and weighted kappa analysis for inter-reader agreement. To compare diagnostic performance, the Fisher exact test was used and inter-reader diagnostic difference was evaluated by McNemar test.

RESULTS

Liver US reconstructed by the proposed algorithm showed a significantly higher value in most categories such as brightness, contrast and overall quality ($p<0.0001$) by both reviewers. On the other hand, there was a slight increase in resolution and reverberation categories, but with no significant difference. The weighted kappa values of the image quality and diagnostic performance categories were calculated as 0.225 to 0.838, showing fair to almost perfect inter reader agreement. All reviewers called significantly more LC at post-processed sets and the diagnostic performance of LC increased at post-processed sets in both

reviewers (p<0.05), based on clinical diagnosis made by physicians with other imaging and laboratory studies.

CONCLUSION

s The proposed algorithm enhances the low-quality liver US images to high-quality, thereby helping early diagnosis and intervention for liver cirrhosis.

CLINICAL RELEVANCE/APPLICATION

The proposed algorithm enhances the low-quality liver US images to high-quality, thereby helping early diagnosis and intervention for liver cirrhosis.

S3A-SPGI-7 Concordance between fully automated Computed Tomography-based and bioimpedance-based analysis of body composition in a prospective study

Participants
Uli Fehrenbach, MD, Berlin, Germany (*Presenter*) Grant, Siemens AG;Grant, Bayer AG;Grant, Ipsen SA;Grant, Asahi Intecc Co, Ltd;Grant, ESGAR;Grant, General Electric Company

PURPOSE

Body composition is increasingly recognized as an important indicator of patient frailty. Apart from the established bioimpedance analysis (BIA), computed tomography (CT)-based body composition assessment is increasingly used to identify patients at risk. The aim of this prospective study was to compare body composition parameters obtained from BIA and CT using a fully automated artificial intelligence (AI)-based segmentation method.

METHODS AND MATERIALS

We prospectively included 210 randomly selected patients who underwent contrast-enhanced CT imaging of the abdomen at our institution. Immediately prior the CT scan, all patients underwent BIA (InBody 770, InBody Europe B.V.). CT body composition was assessed with an AI-based single-slice segmentation tool (Visage Imaging) at the level of the third lumbar vertebra with automated detection and segmentation. BIA-derived parameters, body fat mass (BFM) and skeletal muscle mass (SMM), as well as the CT parameters subcutaneous and visceral adipose tissue area (SATA and VATA) and skeletal muscle area (SMA) were obtained. Body Fat Percentage (BFP) and Skeletal Muscle Index (SMI) were calculated by normalizing the BIA and CT parameters to patient´s weight (BFP) or height (SMI). Pearson correlation coefficient was used to compare muscle and fat tissue parameters by sex. Linear regression models were used to analyse indices.

RESULTS

Fat and muscle tissue parameters, BIA-based BFM and CT-based SATA+VATA, as well as BIA-based SMM and CT-based SMA, showed strong correlations in female (fat: r=0.95; muscle: r=0.72; both p<0.001) and male (fat: r=0.91; muscle: r=0.71; both p<0.001) patients. Linear regression analysis was statistically significant and showed that BFPCT and LSMICT could predict BFPBIA and SMIBIA for female (BFP: b1=5.29; CI95 [4.62-5.95]; SMI: b1=0.11; CI95 [0.09-0.13]; both p<0.001) and male (BFP: b1=4.47; CI95 [3.97-4.97]; SMI: b1=0.09; CI95 [0.08-0.11]; both p<0.001) patients.

CONCLUSION

s Fully automated, AI-based CT body composition parameters strongly correlate with BIA measurements and allow quantification of body fat percentage and skeletal muscle index comparable to the measurements gleaned from the existing gold standard. Thus, an additional BIA appears unnecessary in patients who have received an abdominal CT scan as part of their clinical workup.

CLINICAL RELEVANCE/APPLICATION

The data obtained from CT-body composition analysis allows for assessment of patient frailty (e.g., sarcopenia). Our study shows that CT body composition is comparable to BIA and so it seems feasible that CT body composition assessment could replace BIA as the new standard in clinical practice.

S3A-SPGI-8 Can Deep Learning Reconstruction Effectively Reduce The Number Of Excitations In Fast Spin-Echo T2-Weighted MRI Of The Liver?

Participants
Takashi Ota, MD,PhD, Suita, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Deep leaning reconstruction (DLR) can reduce noise and allow number of excitations (NEX) to be reduced in MRI. However, it remains unknown if DLR can effectively reduce NEX in fast spin-echo T2-weighted imaging (FSE-T2WI) of the liver because reducing NEX might exacerbate motion artifacts. The purpose of this study was to intra-individually compare the image quality of liver FSE-T2WI obtained with NEX 1 along with DLR (NEX1-DLR) versus that with NEX 2 along with conventional reconstruction (NEX2-CR).

METHODS AND MATERIALS

Forty-seven patients were included in this study who were followed-up in our hospital and underwent liver MRI examinations before and after an introduction of DLR into our 3T-MR system. Respiratory-triggered FSE-T2WI was obtained with NEX2-CR and NEX1-DLR before and after the introduction of DLR, respectively. One radiologist measured the signal-to-noise-ratio (SNR) and the relative contrast. Two radiologists assessed the two sets of T2WI in a random order regarding noise, ghost artifacts, homogeneity, sharpness, liver conspicuity, lesion conspicuity, and overall image quality. After reviewing each image separately, they compared the two series side-to-side and selected better series considering the total visual quality. The results were compared using the paired t-test or Wilcoxon signed-rank test.

RESULTS

The mean acquisition time was 136 and 197 sec with NEX1-DLR and NEX2-CR, respectively. NEX1-DLR provided significantly higher SNR of the liver than NEX2-CR (mean, 10.13 and 8.60, respectively, p < .001). There was no significant difference in liver-to-focal liver lesion contrast between them. Qualitative analyses showed that the score of noise was significantly better with NEX1-DLR than with NEX2-CR in both reviewers (p < .001). There were no significant differences in the other evaluations except that one

reviewer rated significantly better scores for NEX2-CR than for NEX1-DLR regarding homogeneity. In the side-to-side comparisons, NEX1-DLR was preferred in 21 and 20 patients while NEX2-CR was preferred in 20 and 18 patients by the two reviewers.

CONCLUSION

s Liver FSE-T2WI with NEX1-DLR and NEX2-CR showed almost the same image quality.

CLINICAL RELEVANCE/APPLICATION

DLR can effectively reduce the scan time of liver FSE-T2WI by reducing NEX without diminishing the image quality.

S3A-SPGI-9 The Automatic diagnosis model for acute appendicitis in CT images based on deep learning

Participants
Kexin Wang, (*Presenter*) Nothing to Disclose

PURPOSE

To train a model based on 3D Residual Network for the triage of acute appendicitis with emergency CT images.

METHODS AND MATERIALS

991 sets of emergency plain CT scans from July 1st, 2019 to December 31st, 2020 were used. The clinical diagnosis was archived from the electronic medical recording system. 492 patients were diagnosed with acute appendicitis, and the other 499 patients were diagnosed without acute appendicitis. The images were allocated into three datasets. There was no overlap among the three datasets. In dataset 1, 100 of the images were annotated in the appendix area. A 3D UNet model (model 1) was trained to segment the area of the appendix. In dataset 2, 800 of the images were used to train a 3D ResNet (model 2) to classify acute appendicitis, within the predicted area of model 1. In dataset 3, 91 of the images were used to test the detection rate of acute appendicitis, sequentially by model 1 and model 2.

RESULTS

For model 1, the average Dice coefficient of the predicted appendix area was 0.87. For model 2, the accuracy, sensitivity, specificity, and F1-score of the classification of acute appendicitis were 0.82, 0.86, 0.88, and 0.81, respectively. In dataset 3, all the appendix areas were predicted by model 1 and the classification accuracy was 0.79 by model 2.

CONCLUSION

s It is possible to use deep learning models to establish a triage system for acute appendicitis in emergency radiology department.

CLINICAL RELEVANCE/APPLICATION

Automatic and rapid detection of patients with acute appendicitis after CT examinations in ER, facilitating patient management and improving safety.

PACS-integrated Artificial Intelligence-based Analysis of Body Composition in Exocrine Pancreatic Cancer: Skeletal Muscle Index and Sarcopenia Predict Survival

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - GI DPS

Participants
Nick Beetz, MD, Berlin, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Worldwide, pancreatic cancer is the seventh leading cause of cancer death in both sexes. Because of its poor prognosis, pancreatic cancer accounts for almost as many deaths as cases even if curative intended surgery is performed. The aim of this study is to analyze baseline CT body composition using artificial intelligence (AI)-based tissue segmentation to identify possible imaging predictors of survival.

METHODS AND MATERIALS

We retrospectively included 103 patients with exocrine pancreatic cancer for whom baseline CT imaging datasets were available. Body composition at the third lumbar vertebra level was analyzed using an AI-based software tool. Patient and survival data were obtained from medical records. Forty-six patients underwent surgery. First, presence of surgical treatment and cut-off values for sarcopenia and obesity served as independent variates. Second, presence of surgery, skeletal muscle index (SMI), visceral adipose tissue (VAT), and subcutaneous adipose tissue (SAT) served as independent variates. Cox regression analysis was performed for 1-year, 2-year, and 3-year survival after baseline CT. Additionally, possible differences between patients undergoing surgical versus nonsurgical treatment were analyzed.

RESULTS

Presence of surgery significantly predicted 1-year, 2-year, and 3-year survival ($p=0.01$, <0.001, and <0.001, respectively). Across the follow-up periods of 1-year, 2-year, and 3-year survival, the presence of sarcopenia became an equally important predictor of survival ($p=0.2$, 1.66, and <0.001, respectively). Additionally, increased VAT predicted 2-year and 3-year survival ($p=0.02$ and 0.04, respectively). The impact of sarcopenia on 3-year survival was higher in the surgical treatment group ($p=0.02$ and OR=2.61) compared to the nonsurgical treatment group ($p=0.05$ and OR=1.85). Fittingly, a lower SMI significantly affected 3-year survival only in patients who underwent surgery ($p=0.02$).

CONCLUSION

s This study for the first time uses a PACS-integrated AI-based body composition analysis tool to predict survival in patients with pancreatic cancer. Besides the already known influence of sarcopenia on survival, our results provide evidence that increased visceral fat is a negative predictor of survival. Moreover, we show that sarcopenia has a greater impact in patients who undergo surgery compared to patients undergoing nonsurgical treatment only.

CLINICAL RELEVANCE/APPLICATION

AI-based body composition analysis in pancreatic cancer provides important metabolic information for predicting patient survival. Especially if surgery is performed, sarcopenia and reduced muscle mass are unfavorable imaging predictors and should warrant additional special care to improve survival.

Development and Validation of Deep Learning-based Automatic Detection and Grading of Motion-related Artifacts on Gadoxetic Acid-enhanced Liver MRI

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - GI DPS

Participants
Dong Wook Kim, MD, PhD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To develop and validate deep learning algorithm (DLA) for automatic detection and grading of motion-related artifact on arterial phase of gadoxetic acid-enhanced liver MRI

METHODS AND MATERIALS

Multi-step DLA for detection and grading of motion-related artifact, based on modified ResNet-101 and U-net, were trained using 336 arterial-phase images of gadoxetic acid-enhanced liver MRI obtained in 2017 (development dataset; 68.6-years [range, 18-95]; 254 men). Motion-related artifact was evaluated in 4 different MRI slices using 3-tier grading systems. In the validation datasets, 313 from the same institution obtained in 2018 (internal validation dataset; 67.2-years [range, 21-87], 228 men) and 329 from three different institutions (external validation dataset; 64.0-years [range, 23-90], 214 men), per-slice and per-exam diagnostic performances for detection of motion-related artifact were evaluated.

RESULTS

Per-slice sensitivity and specificity for detecting grade 3 motion-related artifact were 91.5% (97/106) and 96.8% (1134/1172) in the internal validation dataset, and were 93.3% (265/284) and 91.6% (948/1035) in the external validation dataset. Per-exam sensitivity and specificity were 92.0% (23/25) and 99.7% (287/288) in the internal validation dataset, and were 90.0% (72/80) and 96.0% (239/249) in the external validation dataset. The average processing time of DLA for automatic grading of motion-related artifact was 4.15 seconds per MRI examination.

CONCLUSION

s DLA enables automatic and instant detection and grading of the motion-related artifact on arterial-phase gadoxetic acid-enhanced liver MRI.

CLINICAL RELEVANCE/APPLICATION

Implementation of DLA in liver MRI examination would potentially reduce repeat examination and additional cost caused by nondiagnostic image from motion-related artifact.

S3A-SPGI-3

Predicting tumor deposits in rectal cancer: A combined deep learning model using T2WI-MR imaging< and gtclinical features

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - GI DPS

Participants
Jin Yumei, (*Presenter*) Nothing to Disclose

PURPOSE

To develop and validate a deep learning (DL)based combined model incorporating T2-MR image and clinical factors for preoperatively predicting tumor deposits (TDs) in rectal cancer (RC) patients.

METHODS AND MATERIALS

A total of 327 RC patients from December 2017 to July 2021 was retrospectively collected and the TDs status was pathologically confirmed. Both tumoral and peritumoral regions were labeled on the preoperative T2-MR images. Patients were randomly divided into a development dataset (143 non-TDs and 103 TDs) and an independent testing set (47 non-TDs and 34 TDs). Three DL models were proposed: a single-channel deep learning (single-DL) model using only the tumoral regions as input, a multi-channel deep learning (multi-DL) model using both the tumoral and peri-tumoral regions as input, and a hybrid deep learning (hybrid-DL) model that incorporating both tumoral and peri-tumoral regions as well as the selected clinical variables. A clinical model was also constructed via multivariate logistic regression analysis. The performance of these predictive models was evaluated with respect to discrimination, calibration and clinical usefulness.

RESULTS

The AUCs of the clinical, single-DL, multi-DL and hybrid-DL models were 0.734 (95% CI, 0.674-0.788), 0.710 (95% CI, 0.649-0.766), 0.767 (95% CI, 0.710-0.819) and 0.857 (95% CI, 0.807-0.898) in the development dataset, respectively. Similar performance of these models was observed in the testing dataset with AUCs achieving 0.726 (95% CI, 0.615-0.819), 0.676 (95% CI, 0.563-0.776), 0.738 (95% CI, 0.628-0.829) and 0.839 (95% CI, 0.741-0.911), respectively. Delong's test indicated the hybrid-DL model showed improved performance than the clinical model (p = 0.134), single-DL model (p=0.028) and multi-DL model (p = 0.066) in the testing dataset. All models showed good calibration, and decision curve analysis confirmed net benefit of the hybrid-DL model was higher than other models across majority range of threshold probabilities

CONCLUSION

s The proposed hybrid-DL model incorporating T2-MR images and clinical risk factors achieved good predictive efficacy and could be used to predict tumor deposits in rectal cancer.

CLINICAL RELEVANCE/APPLICATION

We developed a deep learning model based on both T2-MR images and clinical risk factors with favorable performance, which could be used for preoperative prediction of tumor deposits in rectal cancer.

S3A-SPGI-4

Prognostic value of preoperative CT-based radiomics in grade 1-2 pancreatic neuroendocrine tumors: a multi-institutional study

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - GI DPS

Participants
Subin Heo, MD, Suwon, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To develop and validate a radiomics-based model for predicting postsurgical outcomes using preoperative CT in patients with grade 1-2 pancreatic neuroendocrine tumors (PNETs), and to evaluate the incremental prognostic value of radiomics analysis to the current staging system.

METHODS AND MATERIALS

This multicenter retrospective study included patients who underwent dynamic CT and subsequent curative resection for grade 1-2 PNETs. In the training cohort (441 patients from one institution), radiomics features were extracted from the segmented tumor of the arterial and portal-venous phase images. A radiomics score (R-score) for predicting recurrence-free survival (RFS) was built using the least absolute shrinkage and selection operator-Cox regression analysis. A model consisting of age and the 8th American Joint Committee on Cancer staging system (AJCC)-based tumor stage, and another model combining the R-score, age and AJCC stage were built to predict RFS and overall survival (OS) using the multivariable Cox regression analysis. Models were tested in an external cohort (159 patients from another institution) using Harrell's C-index. The incremental difference of the models was evaluated using the net reclassification improvement (NRI) and integrated discrimination improvement (IDI).

RESULTS

In the training cohort, 63 patients (14.3 %) experienced recurrence, and 35 (7.9 %) died. In the test cohort, recurrence occurred in 19 (11.9 %) and 12 (7.5 %) died. The median follow-up was 68.3 and 59.7 months in training and test cohort, respectively. In the test cohort, R-score had C-index of 0.716 for RFS and 0.674 for OS. The combined model outperformed the model without R-score in predicting outcomes in the test cohort (for RFS, C-index, 0.73 vs 0.66, p = 0.01; for OS, 0.78 vs 0.68, p = 0.04). By integrating the R-score, the combined model achieved improvement in classification and discrimination in predicting RFS at 3 years (NRI, 0.33; IDI, 0.07 [p < 0.001 for both]).

CONCLUSION

s Radiomics analysis adds incremental value beyond current tumor staging system in predicting RFS and OS in resected grade 1-2 PNETs.

CLINICAL RELEVANCE/APPLICATION

CT radiomics analysis improves prognostic performance when added to the current staging system in grade 1-2 PNETs, thus enables better patient assessment and individualized treatment decision-making.

Multi-scale sampling method adapted for the detection of small hepatic lesions on gadoxetic acid-enhanced hepatobiliary phase MR images

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - GI DPS

Participants
Tatsuya Yamaguchi, Kawasaki-Shi, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Gadoxetic acid-enhanced hepatobiliary phase (HBP) magnetic resonance (MR) images are highly sensitive for the detection of liver lesions. However, small lesions, especially those near hepatic vessels, may be missed because they and the vessels are low signal intense on HBP images. Our new multi-scale sampling method is adapted for their detection. We investigated the feasibility of our method for the detection of small liver lesions on HBP images.

METHODS AND MATERIALS

We propose a new method based on multi-scale (6-, 12-, and 24 mm) sampling patch images. The patch images were converted from 3D- to 2D images via the minimum intensity projection of 3 orthogonal planes (axial, coronal, and sagittal). Areas harboring malignant hepatic tumors, hemangiomas, or cysts were sampled from the HBP images of 17 patients. A board-certified radiologist annotated 460 lesions. The VGG-16 convolutional neural network was used for their binary classification (hepatic lesion yes/no). Of the 460 lesions, 32 (7%) were used for evaluation and the other 328 for learning. True positive was recorded when the particle obtained by integrating the detection results acquired at each scale even partially overlapped the lesion. False positive was recorded when the particle showed no overlap. Free-response receiver operating characteristic (FROC) analysis was used to evaluate the performance of our method.

RESULTS

From FROC evaluation, the sensitivity of our method was 78% (25/32 lesions) at 9 false positives per volume (FP/vol); it was 80% (8/10 lesions) when limited to lesions less than 10 mm. Our method was more sensitive than single-scale methods used in related studies.

CONCLUSION

s Regardless of the target size, our multi-scale sampling method is highly sensitive for liver lesions on HBP images.

CLINICAL RELEVANCE/APPLICATION

Our multi-scale sampling method can detect small liver lesions with high sensitivity on HBP images regardless of the target size. Our method may be useful in patients with small, possibly metastatic hepatic lesions.

Concordance between fully automated Computed Tomography-based and bioimpedance-based analysis of body composition in a prospective study

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - GI DPS

Participants
Uli Fehrenbach, MD, Berlin, Germany (*Presenter*) Grant, Siemens AG;Grant, Bayer AG;Grant, Ipsen SA;Grant, Asahi Intecc Co, Ltd;Grant, ESGAR;Grant, General Electric Company

PURPOSE

Body composition is increasingly recognized as an important indicator of patient frailty. Apart from the established bioimpedance analysis (BIA), computed tomography (CT)-based body composition assessment is increasingly used to identify patients at risk. The aim of this prospective study was to compare body composition parameters obtained from BIA and CT using a fully automated artificial intelligence (AI)-based segmentation method.

METHODS AND MATERIALS

We prospectively included 210 randomly selected patients who underwent contrast-enhanced CT imaging of the abdomen at our institution. Immediately prior the CT scan, all patients underwent BIA (InBody 770, InBody Europe B.V.). CT body composition was assessed with an AI-based single-slice segmentation tool (Visage Imaging) at the level of the third lumbar vertebra with automated detection and segmentation. BIA-derived parameters, body fat mass (BFM) and skeletal muscle mass (SMM), as well as the CT parameters subcutaneous and visceral adipose tissue area (SATA and VATA) and skeletal muscle area (SMA) were obtained. Body Fat Percentage (BFP) and Skeletal Muscle Index (SMI) were calculated by normalizing the BIA and CT parameters to patient´s weight (BFP) or height (SMI). Pearson correlation coefficient was used to compare muscle and fat tissue parameters by sex. Linear regression models were used to analyse indices.

RESULTS

Fat and muscle tissue parameters, BIA-based BFM and CT-based SATA+VATA, as well as BIA-based SMM and CT-based SMA, showed strong correlations in female (fat: r=0.95; muscle: r=0.72; both p<0.001) and male (fat: r=0.91; muscle: r=0.71; both p<0.001) patients. Linear regression analysis was statistically significant and showed that BFPCT and LSMICT could predict BFPBIA and SMIBIA for female (BFP: b1=5.29; CI95 [4.62-5.95]; SMI: b1=0.11; CI95 [0.09-0.13]; both p<0.001) and male (BFP: b1=4.47; CI95 [3.97-4.97]; SMI: b1=0.09; CI95 [0.08-0.11]; both p<0.001) patients.

CONCLUSION

s Fully automated, AI-based CT body composition parameters strongly correlate with BIA measurements and allow quantification of body fat percentage and skeletal muscle index comparable to the measurements gleaned from the existing gold standard. Thus, an additional BIA appears unnecessary in patients who have received an abdominal CT scan as part of their clinical workup.

CLINICAL RELEVANCE/APPLICATION

The data obtained from CT-body composition analysis allows for assessment of patient frailty (e.g., sarcopenia). Our study shows that CT body composition is comparable to BIA and so it seems feasible that CT body composition assessment could replace BIA as the new standard in clinical practice.

Can Deep Learning Reconstruction Effectively Reduce The Number Of Excitations In Fast Spin-Echo T2-Weighted MRI Of The Liver?

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - GI DPS

Participants
Takashi Ota, MD,PhD, Suita, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Deep leaning reconstruction (DLR) can reduce noise and allow number of excitations (NEX) to be reduced in MRI. However, it remains unknown if DLR can effectively reduce NEX in fast spin-echo T2-weighted imaging (FSE-T2WI) of the liver because reducing NEX might exacerbate motion artifacts. The purpose of this study was to intra-individually compare the image quality of liver FSE-T2WI obtained with NEX 1 along with DLR (NEX1-DLR) versus that with NEX 2 along with conventional reconstruction (NEX2-CR).

METHODS AND MATERIALS

Forty-seven patients were included in this study who were followed-up in our hospital and underwent liver MRI examinations before and after an introduction of DLR into our 3T-MR system. Respiratory-triggered FSE-T2WI was obtained with NEX2-CR and NEX1-DLR before and after the introduction of DLR, respectively. One radiologist measured the signal-to-noise-ratio (SNR) and the relative contrast. Two radiologists assessed the two sets of T2WI in a random order regarding noise, ghost artifacts, homogeneity, sharpness, liver conspicuity, lesion conspicuity, and overall image quality. After reviewing each image separately, they compared the two series side-to-side and selected better series considering the total visual quality. The results were compared using the paired t-test or Wilcoxon signed-rank test.

RESULTS

The mean acquisition time was 136 and 197 sec with NEX1-DLR and NEX2-CR, respectively. NEX1-DLR provided significantly higher SNR of the liver than NEX2-CR (mean, 10.13 and 8.60, respectively, $p < .001$). There was no significant difference in liver-to-focal liver lesion contrast between them. Qualitative analyses showed that the score of noise was significantly better with NEX1-DLR than with NEX2-CR in both reviewers ($p < .001$). There were no significant differences in the other evaluations except that one reviewer rated significantly better scores for NEX2-CR than for NEX1-DLR regarding homogeneity. In the side-to-side comparisons, NEX1-DLR was preferred in 21 and 20 patients while NEX2-CR was preferred in 20 and 18 patients by the two reviewers.

CONCLUSION

s Liver FSE-T2WI with NEX1-DLR and NEX2-CR showed almost the same image quality.

CLINICAL RELEVANCE/APPLICATION

DLR can effectively reduce the scan time of liver FSE-T2WI by reducing NEX without diminishing the image quality.

S3A-SPGI-9

The Automatic diagnosis model for acute appendicitis in CT images based on deep learning

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - GI DPS

Participants
Kexin Wang, (*Presenter*) Nothing to Disclose

PURPOSE

To train a model based on 3D Residual Network for the triage of acute appendicitis with emergency CT images.

METHODS AND MATERIALS

991 sets of emergency plain CT scans from July 1st, 2019 to December 31st, 2020 were used. The clinical diagnosis was archived from the electronic medical recording system. 492 patients were diagnosed with acute appendicitis, and the other 499 patients were diagnosed without acute appendicitis. The images were allocated into three datasets. There was no overlap among the three datasets. In dataset 1, 100 of the images were annotated in the appendix area. A 3D UNet model (model 1) was trained to segment the area of the appendix. In dataset 2, 800 of the images were used to train a 3D ResNet (model 2) to classify acute appendicitis, within the predicted area of model 1. In dataset 3, 91 of the images were used to test the detection rate of acute appendicitis, sequentially by model 1 and model 2.

RESULTS

For model 1, the average Dice coefficient of the predicted appendix area was 0.87. For model 2, the accuracy, sensitivity, specificity, and F1-score of the classification of acute appendicitis were 0.82, 0.86, 0.88, and 0.81, respectively. In dataset 3, all the appendix areas were predicted by model 1 and the classification accuracy was 0.79 by model 2.

CONCLUSION

s It is possible to use deep learning models to establish a triage system for acute appendicitis in emergency radiology department.

CLINICAL RELEVANCE/APPLICATION

Automatic and rapid detection of patients with acute appendicitis after CT examinations in ER, facilitating patient management and improving safety.

Genitourinary Sunday Poster Discussions - A

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - GU DPS

Sub-Events

S3A-SPGU-1 Thin-slice T2-weighted TSE prostate MRI including deep learning image reconstruction: improvement of image quality without increase of acquisition time

Participants
Sebastian Gassenmaier, MD, Tuebingen, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the impact of a thin-slice deep learning reconstructed T2-weighted (w) TSE imaging sequence (T2DL) of the prostate without increase of acquisition time as compared to conventional T2w TSE imaging (T2S).

METHODS AND MATERIALS

Thirty patients were included in this prospective study at one university center after obtaining written informed consent. T2S (3 mm slice thickness) was acquired first in three orthogonal planes. Afterwards, the thin-slice T2DL consisting of a 2 mm slice thickness was acquired in axial plane. Regular acquisition time of T2S was 4:12 min compared to 4:11 min of T2DL due to reduction of signal averages in T2DL. Afterwards, the remaining sequences (DWI, T1, DCE) of the multiparametric imaging protocol were obtained in standard manner. Imaging datasets were evaluated by two radiologists independently consisting of axial T2w TSE imaging (T2S and T2DL), DWI, and DCE imaging in a blinded random order reading. T2w TSE imaging was evaluated using a Likert-scale ranging from 1 - 4 with 4 being the best regarding the following parameters: noise, sharpness, lesion detectability, artifacts, overall image quality, and diagnostic confidence. Furthermore, T2 as well as PI-RADS scoring was obtained.

RESULTS

Mean patient age was 68 ± 8 years (range, 49-85 years). Noise levels were evaluated to be significantly improved in T2DL versus T2S by both readers with a median of 4 versus a median of 3.5 ($p<0.001$ for both readers). The extent of artifacts was also assessed to be superior in T2DL with a median 4 in comparison to a median of 3 in T2S ($p<0.001$ for both readers). Sharpness of images and lesion detectability were rated better in T2DL with a median of 4 versus a median of 3 in T2S ($p<0.001$ for both readers). Consequently, overall image quality was also evaluated to be superior in T2DL versus T2S with a median of 4 versus 3 ($p<0.001$ for both readers). Diagnostic confidence was significantly higher in T2DL as compared to T2S for reader 1 with a median of 4 versus 3 as well as for reader 2 with a median of 4 for both ($p<0.001$ and $p=0.004$, respectively).

CONCLUSION

s Thin-slice T2DL of the prostate provides a significant improvement of image quality without prolongation of acquisition time.

CLINICAL RELEVANCE/APPLICATION

Apart from acquisition time reduction, deep learning image reconstruction can be applied successfully for improvement of diagnostic image quality without extension of examination times. Application of these techniques might lead to higher diagnostic accuracy in prostate MRI.

S3A-SPGU-3 Fully Automated Longitudinal Assessment of Volumetric Renal Stone Burden on Computed Tomography Using Deep Learning

Participants
Pritam Mukherjee, PhD, Bethesda, MD (*Presenter*) Nothing to Disclose

PURPOSE

To develop and evaluate a fully automated deep learning based pipeline for assessing and tracking total renal stone burden in serial computed tomography (CT) scans.

METHODS AND MATERIALS

This retrospective study included 177 subjects (median age 56; male 66%) who underwent CT colonography between 2004 and 2016, had an initial noncontrast scan with slice thickness less than 2 mm, at least one follow-up, and were confirmed to have at least one renal calculus in the initial scan by a board-certified radiologist. A deep learning model was used to detect and segment stones, and measure their volumes on the initial and follow-up scans. The true (predicted) volumetric total stone burden (SB) was the sum of the volumes of all true (predicted) stones on a scan. The segmentation performance of the deep learning algorithm was evaluated using the Dice similarity coefficient (DSC). Given the initial and first follow-up (FU1) scans of the same patient, we computed the difference SBC = SBFU1 - SBinitial, and the relative change SBR = SBC/SBinitial for the true and the predicted stones. We evaluated the agreement between the ground truth and predictions for SB, SBC, and SBR using the Lin's concordance correlation coefficient (CCC).

RESULTS

The sensitivity for our deep learning model was 100%, the mean number of false positives (FPs) per scan was 0.3 (max: 8, IQR: [0,0]), and the median DSC for a random sample of 30 true stones was 100% (100% in 29 stones and 94% on 1 stone). The median number of true stones per scan was 1 (max: 12, IQR: [1,2]). In total, 272 true stones and 40 FPs were present in the initial scans, and 265 true stones and 53 FPs a were found in the follow-up scan. The mean SB increased from 57.3 mm3 in the initial scan to 69.7 mm3 in the follow-up scan. The CCC for SB, SBC and SBR were 77% (73% - 80%), 66% (59% - 72%) and 87% (83% - 90%), respectively. On removing 8 outliers which lie beyond the 1st and 99th percentile, the CCC improves to 96% (95% - 97%), 95% (94% - 97%) and 98% (98% - 99%) for SB, SBC, and SBR, respectively.

CONCLUSION

s The predictions of the deep learning based pipeline shows strong agreement with the ground truth when assessing the volumetric total stone burden on a scan and tracking its change on longitudinal CT scans.

CLINICAL RELEVANCE/APPLICATION

Automating the longitudinal assessment of renal stone burden on CTs can facilitate the opportunistic screening and follow-up of renal stones, reduce physician burden, and help improve patient care.

S3A-SPGU-4 High diagnostic accuracy of Transperineal Multiparametric Magnetic Resonance Imaging-Ultrasound Fusion Targeted Prostate Biopsy

Participants
Ryan Ward, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Although transrectal (TR) prostate biopsy remains the gold standard, there is growing interest in the use of transperineal (TP) biopsy. The main aim of this study was to assess the performance of MRI in distinguishing patients with and without cancer, among those who received transperineal (TP) biopsy.

METHODS AND MATERIALS

Using an IRB-approved, HIPPA compliant prostate MRI registry, we identified all men who underwent transperineal biopsy from February 2019 to March 2021. Patients were excluded who had no MRI recorded prior to biopsy or the MRI was obtained more than 6 months prior to the biopsy. Patients with prior treatment were also excluded. We extracted the relevant clinical data and Prostate Imaging Reporting Data System (PI-RADS) scores from the associated prostate MRI reports.

RESULTS

The initial sample consisted of 296 TP biopsies. A total of 194 TP biopsies (from 192 patients) were included in the final sample. A summary of the MRI and TP biopsy results is provided in Table 1. Estimates of intrinsic accuracy and predictive values when MRI results are used to distinguish cases that are positive and negative at TP biopsy are provided in table 2. A positive MRI (PI-RADS>=3) combined with TP biopsy rendered positive predictive values of 89-97%, increasing with higher PI-RADS scores.

CONCLUSION

s In patients with positive MRI, TP MRI-US fusion guided biopsy has high diagnostic performance in the diagnosis of prostate cancer.

CLINICAL RELEVANCE/APPLICATION

TP biopsy offers advantages over conventional TR biopsy. Our data supports the growing evidence that TP biopsy is at least as good as TR biopsy and may have advantages in certain patient populations.

S3A-SPHN

Head and Neck Sunday Poster Discussions - A

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - HN DPS

Sub-Events

S3A-SPHN-1 Utility of the Echo Planar Imaging with Compressed SENSE (EPICS) for the Evaluation in Head and Neck

Participants
Yuya Hirano, Sapporo, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To compare the image quality between echo-planar imaging (EPI) with compressed SENSE (EPICS)-based diffusion weighted imaging (DWI) and conventional parallel imaging (PI)-based DWI of the head and neck.

METHODS AND MATERIALS

This prospective study was approved by our institutional review board, and written informed consent was obtained from all participants. Ten healthy volunteers (10 men, 30.5 ± 2.9 years) participated in this study. EPICS-DWI was acquired based on the axial spin-echo EPI sequence with the EPICS acceleration factor of 2, 3, and 4 respectively, with two b-values of 0 and 1000 sec/mm2. Conventional PI-DWI was also acquired using the same acceleration factors (2, 3, and 4) and b-values (0 and 1000 sec/mm2) as the EPCS-DWI. The quantitative assessments were performed by measuring the value of SNR and apparent diffusion coefficient (ADC) by placing the circular region of interest (ROI) on the parotid gland tissue. For qualitative evaluation, three-point grading system was used for the visual assessment in 1) the overall image quality (1; poor, 2; moderate, 3; good) and 2) degree of the image distortion (1; moderate-severe distortion, 2; slight distortion, 3 almost no distortion); these qualitative assessments were performed by board-certified neuroradiologist.

RESULTS

In quantitative assessment, the value of SNR in EPICS-DWI was significantly higher than that in PI-DWI for acceleration factors of 3 and 4 ($p<0.05$, respectively). The value of ADC was revealed slightly lower in EPICS-DWI compared to PI-DWI. In qualitative assessment, overall image quality in EPICS-DWI was significantly higher than PI-DWI for acceleration factor of 3 ($p<0.01$). The degree of image distortion was significantly larger in EPICS-DWI with acceleration factor of 2 than that of 3 and 4 ($p<0.01$, respectively).

CONCLUSION

s With the appropriate setting of the acceleration factor, EPICS-DWI demonstrated the higher quantitative SNR and better qualitative overall image quality than PI-DWI without the increase of image distortion in acquiring the head and neck DWI.

CLINICAL RELEVANCE/APPLICATION

EPICS can provide improved image quality with high SNR even in DWI of the head and neck, where poor image quality due to the magnetic field inhomogeneity is frequently problematic.

S3A-SPHN-2 The Value of Dual-Energy CT in the Diagnosis and Localization of Middle Ear and External Acoustic Meatus Cholesteatoma.

Participants
MINGYUE HUO, (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the diagnostic accuracy of the dual-energy CT(DECT) for cholesteatoma qualitatively and quantitatively, and assess the accuracy of DECT for cholesteatoma tissues localization.

METHODS AND MATERIALS

This prospective study included 40 consecutive patients (44 ears) who received preoperative DECT and surgery with a clinical suspicion of cholesteatoma from July 2021 to January 2022. Two radiologists (both with more than 5 years of experience) evaluated the presence or absence of cholesteatoma randomly and independently on DECT then measured four parameters including CT value, Water [hydroxyapatite (Hap)] concentration, Hap (Water) concentration, and the effective Z (Eff-Z) value for statistical analysis. The receiver operating characteristic curves (ROCs) were used for finding out the parameter with the best diagnostic performance for cholesteatoma. The localization accuracy of DECT for cholesteatoma was evaluated ulteriorly by dividing the external acoustic meatus and middle ear into 7 anatomic sites (external acoustic meatus, tympanic antrum, mastoid cavity, epitympanum, mesotympanum, hypotympanum, posterior tympanum).

RESULTS

Taking the surgical results as the reference standard, the sensitivity, specificity, PPV, and NPV of visual evaluation on DECT for

Taking the surgical results as the reference standard, the sensitivity, specificity, PPV, and NPV of visual evaluation on DECT for cholesteatoma were 95.8%, 80.0%, 85.2%, and 94.1% respectively, and the Kappa value was 0.764. Water (Hap) concentration was the best parameter for diagnosis of cholesteatoma with the area under the curve (AUC) of 0.898, the corresponding sensitivity, specificity, PPV and NPV were 91.67%, 80%, 84.6%, and 88.9% respectively when the Water (Hap) concentration was more than 1040.82 mg/cm3. The overall accuracy of DECT in evaluating cholesteatoma localization was 91.7%.

CONCLUSION

s DECT can be capable of diagnosing cholesteatoma qualitatively and quantitatively, and evaluating the localization accurately, to help clinicians to choose a reasonable surgical plan.

CLINICAL RELEVANCE/APPLICATION

We hypothesized that the difference in histological composition between cholesteatoma and non-cholesteatoma would lead to characteristics of the DECT that can be visualized and quantified. The present study confirmed that DECT technique can be used to identify cholesteatoma qualitatively and quantitatively, and assess the localization of cholesteatoma precisely.

S3A-SPHN-3 Application of Multi-Shot Echo Planar Imaging Diffusion Weighted Imaging of the Skull Base

Participants
HEDAN LUO, DALIAN, China (*Presenter*) Nothing to Disclose

PURPOSE

Exploring the performance of Image Reconstruction Using Image-space Sampling (IRIS)-based muti-shot echo planar imaging diffusion weighted imaging (MS-EPI DWI) for the skull base region.

METHODS AND MATERIALS

31 healthy volunteers were recruited, with an average age of 38.23±18.99 years old.All patients were scanned using a 3.0 T MR scanner (Ingenia CX,Philips Healthcare,the Netherlands)with a thirty-two-channe bilateral phase-array brain coil.All subjects underwent conventional single-shot Echo Planar Imaging Diffusion Weighted Imaging (SS-EPI DWI) and IRIS-based multiple-shot diffusion-weighted imaging (8, 6, 4, and 2 shots, respectively),scan parameters were shown in Table 1.The ADC values, Signal to Noise Ratio (SNR) and Contrast to Noise Ratio (CNR) of bilateral cerebellum, brainstem and pons were measured or calculated.A five-point scoring method was used by two observers to subjectively evaluate the image quality(Table2).The Kappa test was adopted to evaluate the consistency of the scores by the two observers.The differences of ADC,SNR,CNR and subjective scores among MS-EPI DWI with different number of shots and SS-EPI DWI were analyzed using Friedman test.If the differences were statistically significant, perform multiple comparisons.

RESULTS

The scores by the two observers were in good agreement (kappa=0.806,0.874,0.843,0.805,0.850).Comparing MS-EPI DWI with different the number of shots , there was no significant difference in ADC of bilateral cerebellum and CNR of right brainstem and pons .Pairwise comparison of the Bonferroni test results showed that when the number of shots was 4, the ADC difference of the right brainstem and pons was statistically significant compared with SS-EPI DWI.When the number of shots was 2, the left brainstem and pons ADC difference was statistically significant compared with SS-EPI DWI($p<0.05$).The SNR and CNR of both sides of the cerebellum,brainstem and pons on MS-EPI DWI were greater than those on SS-EPI DWI.When the number of shots was 6, the left cerebellum,brainstem and pons SNR, CNR, right cerebellum SNR, CNR, right brainstem and pons SNR and subjective scores were significantly different than SS-EPI DWI($p<0.05$).(Table3,4)

CONCLUSION

s Compared with SS-EPI DWI , MS-EPI DWI based on IRIS that showed higher SNR and lower geometric distortion compared with SS-EPI DWI.MS-EPI DWI shots 6 is recommended for clinical skull base between imaging time and image quality.

CLINICAL RELEVANCE/APPLICATION

IRIS-based MS-EPI DWI technology can significantly reduce the geometric distortion of the skull base and high signal artifacts, it can be applied to MS-EPI DWI when the skull base needs to be observed or suspected of lesions,and has broad clinical application prospects.

S3A-SPHN-1

Utility of the Echo Planar Imaging with Compressed SENSE (EPICS) for the Evaluation in Head and Neck

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - HN DPS

Participants
Yuya Hirano, Sapporo, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To compare the image quality between echo-planar imaging (EPI) with compressed SENSE (EPICS)-based diffusion weighted imaging (DWI) and conventional parallel imaging (PI)-based DWI of the head and neck.

METHODS AND MATERIALS

This prospective study was approved by our institutional review board, and written informed consent was obtained from all participants. Ten healthy volunteers (10 men, 30.5 ± 2.9 years) participated in this study. EPICS-DWI was acquired based on the axial spin-echo EPI sequence with the EPICS acceleration factor of 2, 3, and 4 respectively, with two b-values of 0 and 1000 sec/mm2. Conventional PI-DWI was also acquired using the same acceleration factors (2, 3, and 4) and b-values (0 and 1000 sec/mm2) as the EPCS-DWI. The quantitative assessments were performed by measuring the value of SNR and apparent diffusion coefficient (ADC) by placing the circular region of interest (ROI) on the parotid gland tissue. For qualitative evaluation, three-point grading system was used for the visual assessment in 1) the overall image quality (1; poor, 2; moderate, 3; good) and 2) degree of the image distortion (1; moderate-severe distortion, 2; slight distortion, 3 almost no distortion); these qualitative assessments were performed by board-certified neuroradiologist.

RESULTS

In quantitative assessment, the value of SNR in EPICS-DWI was significantly higher than that in PI-DWI for acceleration factors of 3 and 4 ($p<0.05$, respectively). The value of ADC was revealed slightly lower in EPICS-DWI compared to PI-DWI. In qualitative assessment, overall image quality in EPICS-DWI was significantly higher than PI-DWI for acceleration factor of 3 ($p<0.01$). The degree of image distortion was significantly larger in EPICS-DWI with acceleration factor of 2 than that of 3 and 4 ($p<0.01$, respectively).

CONCLUSION

s With the appropriate setting of the acceleration factor, EPICS-DWI demonstrated the higher quantitative SNR and better qualitative overall image quality than PI-DWI without the increase of image distortion in acquiring the head and neck DWI.

CLINICAL RELEVANCE/APPLICATION

EPICS can provide improved image quality with high SNR even in DWI of the head and neck, where poor image quality due to the magnetic field inhomogeneity is frequently problematic.

RESULTS

Taking the surgical results as the reference standard, the sensitivity, specificity, PPV, and NPV of visual evaluation on DECT for cholesteatoma were 95.8%, 80.0%, 85.2%, and 94.1% respectively, and the Kappa value was 0.764. Water (Hap) concentration was the best parameter for diagnosis of cholesteatoma with the area under the curve (AUC) of 0.898, the corresponding sensitivity, specificity, PPV and NPV were 91.67%, 80%, 84.6%, and 88.9% respectively when the Water (Hap) concentration was more than 1040.82 mg/cm3. The overall accuracy of DECT in evaluating cholesteatoma localization was 91.7%.

CONCLUSION

s DECT can be capable of diagnosing cholesteatoma qualitatively and quantitatively, and evaluating the localization accurately, to help clinicians to choose a reasonable surgical plan.

CLINICAL RELEVANCE/APPLICATION

We hypothesized that the difference in histological composition between cholesteatoma and non-cholesteatoma would lead to characteristics of the DECT that can be visualized and quantified. The present study confirmed that DECT technique can be used to identify cholesteatoma qualitatively and quantitatively, and assess the localization of cholesteatoma precisely.

S3A-SPHN-3

Application of Multi-Shot Echo Planar Imaging Diffusion Weighted Imaging of the Skull Base

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - HN DPS

Participants
HEDAN LUO, DALIAN, China (*Presenter*) Nothing to Disclose

PURPOSE

Exploring the performance of Image Reconstruction Using Image-space Sampling (IRIS)-based muti-shot echo planar imaging diffusion weighted imaging (MS-EPI DWI) for the skull base region.

METHODS AND MATERIALS

31 healthy volunteers were recruited, with an average age of 38.23±18.99 years old.All patients were scanned using a 3.0 T MR scanner (Ingenia CX,Philips Healthcare,the Netherlands)with a thirty-two-channe bilateral phase-array brain coil.All subjects underwent conventional single-shot Echo Planar Imaging Diffusion Weighted Imaging (SS-EPI DWI) and IRIS-based multiple-shot diffusion-weighted imaging (8, 6, 4, and 2 shots, respectively),scan parameters were shown in Table 1.The ADC values, Signal to Noise Ratio (SNR) and Contrast to Noise Ratio (CNR) of bilateral cerebellum, brainstem and pons were measured or calculated.A five-point scoring method was used by two observers to subjectively evaluate the image quality(Table2).The Kappa test was adopted to evaluate the consistency of the scores by the two observers.The differences of ADC,SNR,CNR and subjective scores among MS-EPI DWI with different number of shots and SS-EPI DWI were analyzed using Friedman test.If the differences were statistically significant, perform multiple comparisons.

RESULTS

The scores by the two observers were in good agreement (kappa=0.806,0.874,0.843,0.805,0.850).Comparing MS-EPI DWI with different the number of shots , there was no significant difference in ADC of bilateral cerebellum and CNR of right brainstem and pons .Pairwise comparison of the Bonferroni test results showed that when the number of shots was 4, the ADC difference of the right brainstem and pons was statistically significant compared with SS-EPI DWI.When the number of shots was 2, the left brainstem and pons ADC difference was statistically significant compared with SS-EPI DWI($p<0.05$).The SNR and CNR of both sides of the cerebellum,brainstem and pons on MS-EPI DWI were greater than those on SS-EPI DWI.When the number of shots was 6, the left cerebellum,brainstem and pons SNR, CNR, right cerebellum SNR, CNR, right brainstem and pons SNR and subjective scores were significantly different than SS-EPI DWI($p<0.05$).(Table3,4)

CONCLUSION

s Compared with SS-EPI DWI , MS-EPI DWI based on IRIS that showed higher SNR and lower geometric distortion compared with SS-EPI DWI.MS-EPI DWI shots 6 is recommended for clinical skull base between imaging time and image quality.

CLINICAL RELEVANCE/APPLICATION

IRIS-based MS-EPI DWI technology can significantly reduce the geometric distortion of the skull base and high signal artifacts, it can be applied to MS-EPI DWI when the skull base needs to be observed or suspected of lesions,and has broad clinical application prospects.

S3A-SPIN-1 Significantly Accelerated Longitudinal Assessment of Imaging Findings on CT and MRI with Deep Learning Identification of Relevant Prior Exams and Finding Locations

Participants
Thomas Weikert, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Comparison to relevant prior studies is a requisite component in the assessment of radiology imaging findings. It is the aim of this study to evaluate the impact of a deep learning tool identifying relevant prior images, time lens (TL), on the longitudinal assessment of lesions on CT and MRI.

METHODS AND MATERIALS

The algorithm pipeline used in this retrospective study is based on natural language processing (NLP) and a descriptor-based image matching algorithm. The dataset used for testing comprised 3872 series of 246 radiology examinations from 75 patients (189 CTs, 95 MRIs, time period: 06/2010-06/2021). Five finding types were included: Aortic Aneurysm, Intracranial Aneurysm, Kidney Lesion, Meningioma, Pulmonary Nodule. After a standardized training session, nine radiologists from three university hospitals (2x U.S.A, 1x Switzerland) performed two reading sessions in which the finding of interest was measured on two or more exams: first without use of the tool, and a second session at a 21-day interval with the use of the tool. All user actions were logged for each round, including time needed to measure the finding at all timepoints, number of mouse clicks, and mouse distance travelled. Mouse movement patterns were analyzed with heatmaps. To assess the effect of habituation to the cases, a third round of readings was performed without the tool. A standardized 5-item questionnaire was used to assess user experience.

RESULTS

Across scenarios, time needed to assess a finding at all time-points was reduced by 39.0 % (107 vs. 65 seconds; $p<0.001$). Largest accelerations were demonstrated for assessment of pulmonary nodules (47.0%; $p<0.001$), and for less experienced readers (44.3%; $p=0.02$). Less mouse-clicks (-39.0%, $p<0.001$) and mouse-meters (-25.8%, $p<0.001$) were needed for finding evaluation with TL. The heatmaps showed consistently simplified mouse-movement-patterns with TL. The habituation effect was not decisive. Overall, user satisfaction was high (4.2/5).

CONCLUSION

s TL significantly reduces time needed to assess findings of interest on cross-sectional imaging at multiple timepoints.

CLINICAL RELEVANCE/APPLICATION

Because comparison to relevant prior studies is routinely performed in radiology departments, the time-saving potential by computer assistance is tremendous, and more so for cross-sectional imaging.

S3A-SPIN-2 Effect of Deep Learning Image Reconstruction Algorithm on Image Quality and Detectability of Hypovascular Hepatic Metastases at DDifferent Radiation Dose Levels

Participants
Nana Liu, Zhengzhou, China (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the effects of deep learning image reconstruction algorithm by comparing with adaptive statistical iterative construction-V on detecting and diagnosin of hypovascular hepatic metastases and image quality under different radiation doses.

METHODS AND MATERIALS

Fifty-six patients with suspected liver disease who underwent abdominal enhanced CT scans were collected prospectively. According to the second venous phase currents, the selected patients were randomly assigned into three groups A, B and C. Patients in each group received conventional radiation dose with tube current-time products of 400mAs CT scans in the first vein phase, low-dose CT scans in the second vein phase, which were set as tube current-time products of were 280mAs for group A, 200mAs for group B and 120mAs for group C. The images of first vein phase and second vein phase were reconstructed with ASIR-V60% and DLIR-H. Quantitative parameters [image noise, contrast to noise ratio (CNR), liver and portal vein signal to noise ratio (SNR)] and qualitative parameters [overall image quality, lesion conspicuity, diagnostic confidence] of ASIR-V60% and DLIR-H images were compared, and the effective radiation dose of each group was recorded. Quantitative parameters and effective radiation doses were compared by paired t test, and qualitative parameters were compared by Wilcoxon test.

RESULTS

The radiation dose of each group decreased with the decreasing of tube current, the effective radiation doses (ED) were significantly different between the first vein phase and the second vein phase (P<0.001). Compared with the conventional dose first vein phase, the effective radiation dose of group A, B and C decreased by about 30%, 50% and 70%, respectively. The quantitative and qualitative scores of the conventional dose first vein phase were the best. Moreover, with the decrease of radiation dose, the noise gradually increased, and the CNRlesions, SNRliver and SNRportal vein gradually decreased. Notably, under the same radiation dose condition, the quantitative scores of DLIR-H images were statistically better than those of ASiR-V60% (all P<0.001).Furthermore, the qualitative parameters of each group decreased with the decrease of radiation dose. Under the same radiation dose, the overall image quality, lesion conspicuity and diagnostic confidence of DLIR-H were higher than those of ASiR-V60% (all P<0.001).

CONCLUSION

s Compared with ASiR-V60%, DLIR-H could reduce image noise, improve overall image quality and lesion conspicuity of liver metastasis, as well as increase diagnostic confidence under different radiation doses.

CLINICAL RELEVANCE/APPLICATION

Compared with ASiR-V60%, DLIR can reduce image noise, improve image quality and lesion conspicuity of liver metastasis.

S3A-SPIN-3 Can We Combine the Best of Two Worlds? Artifact Reduction from Dental Implants in Photon-Counting Detector CT Datasets Based on high-keV Monoenergetic Reconstructions and Iterative Metal Artifact Reduction (IMAR) Reconstructions

Participants
Franka Risch, MSc, Augsburg, Germany (*Presenter*) Nothing to Disclose

PURPOSE

This study assessed the effect of virtual monoenergetic imaging (VMI) settings, the use of iterative metal artifact reduction (iMAR), and kernel choice on metal artifacts caused by dental fillings/ implants on photon-counting detector CT (PCD-CT) datasets.

METHODS AND MATERIALS

Patients with dental fillings or implants undergoing staging CT including the neck region on a PCD-CT were screened for study inclusion. A standard and sharp quantitative kernel were reconstructed with and without iterative metal artifact reduction (Qr40, Qr40 iMAR, Qr60, Qr60 iMAR) in nine different virtual monoenergetic keV-levels (range: 40-190 keV). On four selected slices, two with and two without metal artifacts caused by dental fillings/implants, six regions of interest (ROIs) were positioned in air and various defined soft tissues. For each ROI, the mean and standard deviation of CT values were recorded in all series at identical positions. The mean absolute error of CT values and an artifact index were calculated. Statistical analyses focused on differences in artifact index between VMI levels (low vs. high keV), between kernels (standard vs. sharp) and between reconstructions with vs. without iMAR.

RESULTS

Fifty consecutive patients (age 71.7 ± 10.8 years; 15 female) were included. For each patient, 4 image series for 9 different VMIs were reconstructed, resulting in 36 series per patient. The artifact index severely increased for lower VMI levels (< 50 keV) but did not exhibit significant changes in the 60 - 190 keV range. Overall, the effect of keV settings on noise parameters was relatively small. Sharp Kernels increased artifact index moderately (~ 35%). By using iMAR, the most pronounced reduction of both calculated indices was observed for the standard and sharp kernel as well as in all measured regions of interest (Qr40/Qr60 vs. Qr40 iMAR/ Qr60 iMAR, reduction in ?HU: 57 % - 79 %, reduction in AI: 55 % - 88 %).

CONCLUSION

s Metal artifacts caused by dental fillings/ implants are profoundly reduced using iMAR for standard and sharp kernels. Unlike reported for artifacts around orthopedic surgical material, VMI levels had very little effect on artifacts by dental implants.

CLINICAL RELEVANCE/APPLICATION

Metal artifacts can significantly affect image quality and reduce diagnostic value. iMAR offers effective and reliable reduction of metal artifacts from dental implants.

S3A-SPIN-4 AI Enabled Automatic CNR Measurement: Development and Evaluation using Multi-energy Images in Abdomen Dual-Energy Contrast-Enhanced CT

Participants
Sihwan Kim, BS, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To develop a system automatically measuring contrast-to-noise ratio (CNR) for evaluating image quality of different dual-energy CT (DECT) scan protocols.

METHODS AND MATERIALS

The system consists of three stages - deep learning (DL) based liver segmentation, extraction of homogenous ROIs and structure ROIs, and calculation of CNR. For the DL-based segmentation model, U-net architecture with multi-planar reconstruction (MPR) approach was used. The model was trained with contrast and non-contrast CT images of three-hundred patients. For the evaluation of the segmentation model, 131 contrast-enhanced CT (CECT) from Decathlon open-challenge dataset was used. The performance of liver segmentation model was evaluated with dice-coefficient. To extract homogeneous and structure edge regions on CT images, structure coherence map was analyzed using gradient and hessian images. For the evaluation of system performance, twenty-four abdominal DECT scans were retrospectively investigated. The evaluation was performed on four different reconstructed image types; 40-keV VMI image (40-keV VMI), 50-keV VMI image (50-keV VMI), 80-kVp image and linearly blended images simulating 100-kVp image (100-kVp). All the reconstructed images were automatically evaluated with three evaluation metrics; noise, signal-to-noise (SNR) and contrast-to-noise ratio (CNR). In addition, one radiologist visually assessed the successive of CNR measurement with five-point scale.

RESULTS

The dice value of liver segmentation model was 0. 0.90±0.08 (Mean±S.D.) in open challenge dataset. The system presented SNR values as 8.73±2.12 in 40-keV VMI, 9.08±2.05 in 50-keV VMI, 9.29±1.67 in 80-kVp, and 10.79±2.04 in linearly blended 100-kVp. CNR values were 3.98±1.53 in 40-keV VMI, 3.32±1.16 in 50-keV VMI, 2.80±1.15 in 80-kVp, and 2.15±1.00 in linearly blended 100-kVp. Measured noises of each energy-level images had 20.09±2.83 HU, 14.50±1.81 HU, 11.92±1.32 HU, and 8.51±0.72 HU in 40-keV VMI, 50-keV VMI, 80-kVp, and linearly blended 100-kVp, respectively. The five-scale visual assessment result by the radiologist was 4.08±0.72 in 40-keV VMI, 4.00±0.72 in 50-keV VMI, 4.13±0.74 in 80-kVp, and 3.96±0.62 in linearly blended 100-kVp.

CONCLUSION

s We developed a deep learning-assisted CNR measurement system to evaluate the image quality of different DECT scan protocols. We believe that developed system can contribute to the monitoring of CT machine maintenance and optimization of CT scan protocols in clinical practice.

CLINICAL RELEVANCE/APPLICATION

Image Quality Assessment in Dual-energy CT

S3A-SPIN-6 A Unified Framework for Accurate and Robust Lesion RECIST Diameter Prediction and Segmentation with Transformers

Participants
Youbao Tang, PhD, Bethesda, MD (*Presenter*) Nothing to Disclose

PURPOSE

Accurately measuring lesion/tumor size with RECIST (Response Evaluation Criteria In Solid Tumors) diameters and segmentation is important for assessing the lesion growth rates and making therapeutic plan. Manually annotating them is tedious, time-consuming, and prone to observer-inconsistency. To overcome these issues, we propose a transformer-based unified framework (MeaFormer) for lesion RECIST diameter prediction and segmentation on CT scans automatically and accurately.

METHODS AND MATERIALS

MeaFormer formulates LRDPS as three correlative and complementary sub-tasks: lesion segmentation, heatmap prediction, and keypoint regression. It employs transformers to model the long-range dependencies of the high-resolution deep features extracted by a small convolutional neural network. Two consistency losses are introduced to explicitly build relationships among these sub-tasks for multi-task learning and joint optimization. Only requiring a single click operation within the lesion region from clinicians, MeaFormer can output accurate RECIST diameter predictions and 2D mask of the lesion on the key slice where the lesion has the largest spatial extent. Besides, a 3D mask can be obtained by segmenting the lesion slice-by-slice where the center point of the segmented mask on the previous slice is considered as the click point on the current slice. It was evaluated on the DeepLesion dataset containing 32,735 lesions from 10,594 studies of 4,427 patients. 200/1,000 lesion images from 500 patients are manually segmented with 3D/2D masks for testing. The rest patient data are used for training (80%) and validation (20%). Also, 480 lesion pairs from the test set are used for a downstream task evaluation (i.e., longitudinal RECIST assessment based on the predicted diameters).

RESULTS

Compared to the best previous work on each sub-task, MeaFormer achieved the best performance. For RECIST diameter prediction, the long/short diameter error between the automatic results and manual reference standard is 1.6±1.3 mm/1.4±1.5 mm. For lesion segmentation, a 2D/3D Dice score of 0.927±0.043/0.856±0.065 is obtained. On the 480 test lesion pairs, it achieved an accuracy of 91.7% for the tumor response classification (4 classes based on RECIST version 1.1).

CONCLUSION

s We proposed a transformer-based deep learning framework to annotate tumor sizes automatically and accurately with RECIST diameters and segmentations via a simple click operation. It achieved comparable accuracies to manual annotations, but improved efficiency with greatly reduced time and effort.

CLINICAL RELEVANCE/APPLICATION

It can serve as a useful tool for clinicians to accurately measure tumor sizes with minimal effort and may provide high positive values on clinical workflows.

A Unified Framework for Accurate and Robust Lesion RECIST Diameter Prediction and Segmentation with Transformers

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - IN DPS

Participants
Youbao Tang, PhD, Bethesda, MD (*Presenter*) Nothing to Disclose

PURPOSE

Accurately measuring lesion/tumor size with RECIST (Response Evaluation Criteria In Solid Tumors) diameters and segmentation is important for assessing the lesion growth rates and making therapeutic plan. Manually annotating them is tedious, time-consuming, and prone to observer-inconsistency. To overcome these issues, we propose a transformer-based unified framework (MeaFormer) for lesion RECIST diameter prediction and segmentation on CT scans automatically and accurately.

METHODS AND MATERIALS

MeaFormer formulates LRDPS as three correlative and complementary sub-tasks: lesion segmentation, heatmap prediction, and keypoint regression. It employs transformers to model the long-range dependencies of the high-resolution deep features extracted by a small convolutional neural network. Two consistency losses are introduced to explicitly build relationships among these sub-tasks for multi-task learning and joint optimization. Only requiring a single click operation within the lesion region from clinicians, MeaFormer can output accurate RECIST diameter predictions and 2D mask of the lesion on the key slice where the lesion has the largest spatial extent. Besides, a 3D mask can be obtained by segmenting the lesion slice-by-slice where the center point of the segmented mask on the previous slice is considered as the click point on the current slice. It was evaluated on the DeepLesion dataset containing 32,735 lesions from 10,594 studies of 4,427 patients. 200/1,000 lesion images from 500 patients are manually segmented with 3D/2D masks for testing. The rest patient data are used for training (80%) and validation (20%). Also, 480 lesion pairs from the test set are used for a downstream task evaluation (i.e., longitudinal RECIST assessment based on the predicted diameters).

RESULTS

Compared to the best previous work on each sub-task, MeaFormer achieved the best performance. For RECIST diameter prediction, the long/short diameter error between the automatic results and manual reference standard is 1.6±1.3 mm/1.4±1.5 mm. For lesion segmentation, a 2D/3D Dice score of 0.927±0.043/0.856±0.065 is obtained. On the 480 test lesion pairs, it achieved an accuracy of 91.7% for the tumor response classification (4 classes based on RECIST version 1.1).

CONCLUSION

s We proposed a transformer-based deep learning framework to annotate tumor sizes automatically and accurately with RECIST diameters and segmentations via a simple click operation. It achieved comparable accuracies to manual annotations, but improved efficiency with greatly reduced time and effort.

CLINICAL RELEVANCE/APPLICATION

It can serve as a useful tool for clinicians to accurately measure tumor sizes with minimal effort and may provide high positive values on clinical workflows.

Sub-Events

S3A-SPIR-1 Systematic Assessment of Formulation Parameters Affecting Stability of Sclerosing Foams: Implications for Image Guided Sclerotherapy

Participants
Felipe Berg, (*Presenter*) Nothing to Disclose

PURPOSE

Sodium tetradecyl sulfate (STS) is a commonly utilized sclerosant used to treat various pathologies including vascular malformations and venous disease. It is often utilized as a foam, created by mixing STS with air and various contrast agents using the Tessari Method. Reported ratios of STS, contrast and air used to create sclerosing foam vary widely, and the impact of various ratios on foam stability are not well described. The purpose of this study is to evaluate the effect of various STS, air to Lipiodol® volume ratios on sclerosing foam stability.

METHODS AND MATERIALS

Different sclerosing foam combinations were generated with different ratios of Sodium tetradecyl sulfate, air and contrast. STS 30 mg/mL was used as a surfactant; and foam was created using various air:STS:Lipiodol ratios including 1:1.5:0; 1:2:0; 1:3:0; 1:4:0, 1:1.5:1, 1:2:1, 1:3:1, and 1:4:1 . Each mixture was agitated 30 times at room temperature using Tessari Method for each trial by the same researcher. Foam decay rates were recorded with a camera system for 45min or until all the foam had returned to its liquid phase. For trials with a contrast agent, 1 mL of Lipiodol® ethiodized oil (Guerbet LLC®) was added to the mixture. The drainage time and drainage rate were recorded for each trial.

RESULTS

In the trials with only STS, smaller air:STS with an average foam half-life of 1.8 min for the 4:1 ratio and 3.2 min for the 1.5 ratios, the foam has drained completely in 5 min for all trials. By adding Lipiodol to the mixture the foam stability increased significantly with an average foam half-life of 7.5 min and foam was present for more than 45min. No difference was observed within trials with Lipiodol related to the varying of the air:STS ratio.

CONCLUSION

s Increasing the air-to-liquid ratio reduces foam stability. Addition of Lipiodol significantly increases the foam stability. The air-to-liquid ratio could be used as a simple, and reproducible strategy to produce foams with stability suitable to the clinical scenario. Furthermore, the use of oil-based contrast agents (e.g. Lipiodol) can be used to produce foams with extended stability and radio-opacity, which may be appropriate for specific clinical indications.

CLINICAL RELEVANCE/APPLICATION

Sclerotherapy plays an important role in management of various pathologic processes including vascular malformation, venous insufficiency, and variceal gastrointestinal bleeding. A stable foam may increase efficacy due to a longer duration of contact with the targeted structure, and yet it may also act as a more effective and therefore dangerous vascular embolic in the setting of non-target embolization. Characterization of basic foam properties, including stability, created during a procedure is key for an effective and safe procedure.

S3A-SPIR-2 Differences in Outcomes Between Patients with Lower Gastrointestinal Bleeding Undergoing Primary Endovascular vs Primary Endoscopic Interventions

Participants
Alexander Villalobos, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To compare outcomes in patients with lower gastrointestinal bleeding (LGIB) treated with primary endovascular vs endoscopic interventions.

METHODS AND MATERIALS

All LGIB encounters and associated procedures in the 2005-2015 National Inpatient Sample databases were identified using ICD-9 codes. Encounters initially treated with surgery or conservative management were excluded. Those initially treated with angiography and/or embolization (IR-PEI) vs diagnostic and/or therapeutic endoscopy (GI-PEI) were evaluated. Afterwards, encounters initially treated with only diagnostic angiography and/or endoscopy were excluded and those initially treated with transarterial embolization (IR-ITE) vs therapeutic endoscopy (GI-ITE) evaluated. Odds ratios (OR) for mortality and prolonged (>7 days) length of stay (LOS) were evaluated using multivariate logistic regression after propensity score matching of clinically relevant baseline covariates.

RESULTS

Of 617,735 LGIB encounters, 8,514 underwent an IR intervention, 5,987 IR-PEI, 2,172 IR-ITE, 193,476 GI-PEI, and 58,957 GI-ITE. Overall mean age, gender, and race/ethnicity was 69 years, 54% female, and 73% Caucasian. Any IR intervention usage was associated with increased risk of mortality (OR=1.4 [95%CI 1.3-1.5], p<0.001) and prolonged LOS (OR=2.5 [95%CI 2.4-2.6], p<0.001). With GI-PEI as reference, IR-PEI was associated with increased mortality (OR=3.2 [95%CI 2.9-3.4], p<0.001) and prolonged LOS (OR=3.6 [95%CI 3.1-4.2], p<0.001). With GI-ITE as reference, IR-ITE was associated with increased mortality (OR=8.5 [95%CI 6.4-11.2], p<0.001) and prolonged LOS (OR=3.57 [95%CI 3.05-4.18], p<0.001).

CONCLUSION

s Compared to endoscopic interventions, endovascular interventions for LGIB were associated with an increased mortality and prolonged LOS.

CLINICAL RELEVANCE/APPLICATION

Primary endovascular interventions for the management of lower gastrointestinal bleeding are associated with an increased risk of mortality and prolonged hospital length of stay as compared to standard-of-care primary endoscopic interventions.

S3A-SPIR-3 Prediction of Oncologic Outcomes Following CT-guided Thermal Ablation of Colorectal Liver Metastasis

Participants
Iwan Paolucci, PhD, (*Presenter*) Stockholder, Intuitive Surgical, Inc ;Stockholder, SOPHiA GENETICS

PURPOSE

To build and evaluate predictive models for local tumor progression (LTP) and intrahepatic progression outside the ablation zone (IHP) following CT-guided thermal (TA) ablation of colorectal liver metastasis (CLM).

METHODS AND MATERIALS

A single-center retrospective evaluation of a liver ablation registry was surveyed to identify patients with CLM submitted to CT-guided TA between 10/2015 to 03/2020. Patients with $lt;1-year imaging follow-up, combined treatment with other local therapies, insufficient image quality for tumor depiction, and repeat ablations (IHP model only) were excluded. Oncologic outcomes (LTP/IHP) were determined prior to prediction model development by two radiologists. Definition for the Assessment of Time-to-Event End Points in Cancer Trials was applied for LTP- and IHP-free survival (LTPFS/IHPFS) assessment.The data was split into a training and test set (80%/20% split) on a patient level and ensuring similar LTPFS and IHPFS. LTPFS and IHPFS were truncated at 36 and 18 months respectively. A Bayesian parametric Weibull survival model was used with the following prognosticators: CLM diameter, nr of ablated CLM, TP53 mutation, CEA, NLR, extrahepatic metastasis, hepatic steatosis (only for IHP), RAS mutation (only for LTP), and software-based minimum ablation margin (only for LTP). Tumors/patients were stratified into High and Low risk of progression using the median predicted survival on the training set. Model performance was reported with positive predictive value (PPV), negative predictive value (NPV), and Kaplan-Meier curves of LTPFS and IHPFS of High and Low risk groups.

RESULTS

For the LTP model, training/testing comprised of 217/54 CLM, respectively. In testing, 9 CLM (16.6%) had LTP within 3 years and all of them were classified as High risk. The LTP model had a PPV 31% and an NPV of 100%. The risk of LTP within 36 months was 34.2% (CI95% = [11.8, 50.8]) vs. 0% in the High vs. Low risk group respectively (p=0.003). For the IHP model, training/testing comprised of 101/25 ablation naïve patients, respectively. In testing, 16/25 (64%) of patients had IHP within 18 months and 15 of those were classified as High risk. The IHP model had a PPV of 83.3% and an NPV of 85.7%. The risk of IHP within 18 months was 14.3% (CI95% = [0, 36.7]) vs. 83.3% (CI95% = [53.2, 94.1]) in the High vs. Low risk group respectively (p=0.007).

CONCLUSION

s Both models showed good performance in identifying patients and CLM that are unlikely to progress following TA. However, the LTP model shows a low PPV suggesting that there are more patient-/ablation-related factors that protect from LTP.

CLINICAL RELEVANCE/APPLICATION

Prediction models could be used to tailor treatment strategies for patients with CLM based on a per-tumor and -patient’s prognosis.

S3A-SPIR-5 Influence of Pelvic Magnetic Resonance Angiography for Prostatic Artery Embolization Planning and Technical Success

Participants
Matthias Boschheidgen, Dusseldorf, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Knowledge about anatomical details seems to facilitate the procedure of prostatic artery embolization (PAE) in patients with benign prostatic hyperplasia (BPH). We analysed pre-interventional MR angiography (MRA) of prostatic vessels to identify anatomical parameters which may influence procedural factors and technical success.

METHODS AND MATERIALS

MRA and digital subtraction angiography (DSA) of patients with PAE between 04/2018 and 03/2021 were analysed retrospectively regarding prostatic artery (PA) visibility, PA type, vessel elongation, and defined angles. These parameters were correlated with the DSA (intervention time, fluoroscopy time, dose area product (DAP), cumulative air kerma (CAK), contrast media (CM) dose) and technical success of embolization. T-test, ANOVA, Pearson correlation, and Kruskal-Wallis test were applied to check for statistical significance.

RESULTS

Seventy-eight patients (mean age 71 years) were included. MRA identified PA in 126 of 147 cases (accuracy 86%). PA had similar origin on both sides only in 57% of the patients. PA type showed no significant effect on DSA parameters. Contrarily, vessel elongation affected time for catheterization of right PA (p=0.02), fluoroscopy time (p=0.05), and CM dose (p=0.02) significantly.

Moderate correlation was observed for iliac bifurcation angles with DAP (r=0.30 left; r=0.34 right; p=0.01) and CAK (r=0.32 left; r=0.36 right; p=0.01) on both sides.

CONCLUSION

s Pre-interventional MRA could reliably identify PA origin, offering a good anatomic orientation before performing PAE. PA type did not have an influence on procedural complexity of PAE and technical success while vessel elongation prolonged the intervention preceding to longer intervention times and higher doses of contrast media. MRA could not predict technical success for selective PA catheterization.

CLINICAL RELEVANCE/APPLICATION

Pre-interventional MRA can provide useful information on anatomic details of patients undergoing PAE. This can facilitate the intervention and has the potential to save time and ressources as well as radiation dose.

S3A-SPIR-6 Clinical and Imaging Outcomes of Percutaneous Sclerotherapy for the Management of Lymphatic Malformations

Participants
Tushar Garg, MD, Baltimore, MD (*Presenter*) Conference Travel, Siemens Healthineers

PURPOSE

To evaluate the safety and outcomes of percutaneous sclerotherapy (PS) for lymphatic malformations (LMs) involving any part of the body.

METHODS AND MATERIALS

We reviewed all patients who underwent PS for the management of LMs between 4/2003 to 3/2022. Clinical and imaging findings were assessed to evaluate clinical response, lesion size changes, and complication rates. Fisher's Exact Tests were used for statistical analysis. Clinical symptoms response was classified as resolved, improved and stable and/or worsened. The LM size change was assessed by calculating the difference between pre-and post-procedure MRI of the largest lesion diameter in one plane, comparable to the response evaluation criteria in solid tumors (RECIST): complete response (CR, 100% reduction), partial response (PR, 30% reduction), stable disease (SD, =30% reduction or =20% enlargement), and progressive disease (PD, =20% VM size increase). Adverse events were classified by SIR classification criteria.

RESULTS

158 patients (49.4% F, 14.9 ± 18.4 years) underwent 241 PS (average 1.7 ± 1.1) sessions with a technical success rate of 97.1% (234/241). Most of the LMs presented after birth (43.7%; 69/158) with swelling (55%; 87/158) and pain (21.5%; 34/158) being the most common symptoms. 53.8% (85/158) of the LMs were in the head and neck and rest were almost equally distributed throughout the body. 38.6% (61/158) of the patients received previous outside PS, surgery or medical management. Doxycycline (80.5%; 191/241) was the most common sclerosant used, followed by bleomycin foam and liquid (12%; 29/241), ethanol (10.7%; 26/241), sotradecol foam (1.7%; 4/241) and n-BCA (0.4%; 4/241). A cosmetic deformity was seen in 77.2% (122/158) and functional deficit was seen in 24.8% (45/158) of the patients. For these patients with adequate follow-up, PS significantly improved cosmetic symptoms with 12.9% (13/101) resolved, 70.3% (71/101) improved, and 16.8% (17/101) stable or worsened ($p < 0.0001$) and functional deficits with 20.7% (6/29) resolved, 69% (20/29) improved, and 10.3% (3/29) stable or worsened ($p < 0.0001$). PS also significantly decreased LM size on imaging ($p = 0.0001$). Of the 140 (58.5%) procedures with both pre-and post-MRI imaging, 2 patients saw CR (1.4%), 51 patients (36.2%) experienced PR, 67 patients (47.5%) experienced SD and 19 patients (13.5%) saw PD. Early (30-day) post-procedural complications occurred after 30 of 241 procedures (12.4%), the majority of which were hyperpigmentation (23.3%; 7/30) and mild in severity (56.7%; 17/30).

CONCLUSION

s PS significantly decreases lesion size and improves clinical symptoms in LMs.

CLINICAL RELEVANCE/APPLICATION

PS is a safe and effective treatment option for the management of patients with LMs.

S3A-SPIR-7 Prospective Study of Different Embolic Agents for Pulmonary Arteriovenous Malformation (PAVM) Embolization: Technical Results, Time Saved, and Financial Costs

Participants
Anna Gong, Baltimore, MD (*Presenter*) Nothing to Disclose

PURPOSE

While embolization of PAVMs with Micro Vascular Plug Systems (MVP™ systems) has been shown to have a 0-2% PAVM persistence rate, few attempts have been made to understand the technical features, time and costs of embolization with MVP™ systems versus other embolics.

METHODS AND MATERIALS

We evaluated 34 patients with PAVMs who underwent embolization with at least one MVP™ systems, Amplatzer vascular plug (AVP) or coil between 4/2019 and 2/2022. All data was collected in real time by dedicated scribes. Technical success, occlusion time, room-time, and costs were analyzed. Occlusion time was evaluated immediately after device deployment and in two-minute intervals until occlusion occurred or until another embolic was delivered. We extracted cost information from the electronic medical record. Mann-Whitney U tests (Bonferroni correction factor: adjusted significance value $p<0.01667$) were used for statistical analyses.

RESULTS

In 34 patients, 64 PAVMs and 81 feeding arteries were treated: 58 with at least one MVP™ systems, 20 with coils alone, and 3 with AVP. The per-feeding artery technical success rates were 100% for all cases. Median occlusion time was 1.0 min (Range <1 to 30 min) for feeding arteries treated with at least one MVP™ systems, 9.0 min (Range 3.0 to 25.0 min) for coils, and 5.0 min (Range 4.0 to 6.0 min) for AVP). Embolization with MVP™ systems achieves a significantly shorter occlusion time than embolization with coils

(median 8.0 min saved per feeding artery) (P<0.0001).When compared to embolization with coils, embolization with MVP™ systems reduce room costs by a median of $429.77 per feeding artery (p<0.0001). Device costs for embolization with MVP™ systems versus coils were not significantly different per feeding artery (MVP™ systems: $2790.45; Coils: $3531: Median difference $740.55) (p=0.1718).

CONCLUSION

s When compared to coils, MVP™ systems have an equivalently high technical success rate and significant time and cost savings in addition to a known 0-2% PAVM persistence rate.

CLINICAL RELEVANCE/APPLICATION

MVP™ systems should be considered as a first-line agent for embolization of PAVMs for eligible patients.

S3A-SPIR-8 Application and Potential Benefits of Color-coded Digital Variance Angiography in Prostatic Artery Embolization

Participants
Leona Alizadeh, MD, Frankfurt, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Color-coded digital variance angiography (ccDVA) is a recently developed image processing technology capable of visualization of hemodynamic conditions in 2D X-ray angiography setting. Our aim was to explore the potential advantages of ccDVA in prostatic artery embolization (PAE).

METHODS AND MATERIALS

This retrospective study evaluated 108 angiographic acquisitions from 30 patients (mean ± SD age 68.0 ± 8.9, range 41-87) undergoing PAE between May and October 2020. DSA and ccDVA images were generated from the same unsubtracted acquisition. Visual evaluation of ccDVA and DSA images was performed by four experienced interventional. The diagnostic value of DSA and ccDVA images was evaluated using clinically relevant criteria (visibility of small [< 2.5 mm] and large arteries [> 2.5 mm], feeding arteries and tissue blush) in a paired comparison. Data were analysed by the binomial test, the interrater agreement was determined by the Fleiss Kappa analysis.

RESULTS

The preference of ccDVA images was significantly higher in all criteria. The preference of ccDVA images was the highest in the tissue blush category (quality agreement [QA] 89%, interrater agreement [IR] 79%, followed by the small arteries (QA: 79%, IR: 70%), feeding arteries (QA: 79%, IR: 65%) and large arteries (QA: 63%, IR: 58%). The Fleiss Kappa range was 0.02-0.18, significant in all criteria except large vessels.

CONCLUSION

s Our data show that ccDVA significantly improves the diagnostic evaluation of tissue blush, small arteries and feeding arteries in PAE. As these structures are critically important in the procedure, the ccDVA technology might help the decision-making process in PAE interventions, although these benefits have to be validated in further prospective clinical studies.

CLINICAL RELEVANCE/APPLICATION

Color-coded DVA (ccDVA) significantly improves the visualization of small arteries, feeding arteries and tissue blush, thereby provides more information for PAE procedures than DSA in 79-89 % of comparisons.

S3A-SPIR-9 The Role of Machine Learning Algorithms in Predicting the Treatment Outcome of High-Intensity Focused Ultrasound Ablation of Uterine Fibroids with an Immediate Nonperfused Volume Ratio of at least 90%

Participants
Bilgin Keserci, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the role of machine learning (ML) classifiers to find the most informative multiparametric (mp) magnetic resonance imaging (MRI) features in predicting the treatment outcome of high intensity focused ultrasound (HIFU) ablation with an immediate nonperfused volume (NPV) ratio of at least 90%.

METHODS AND MATERIALS

This retrospective study was approved by the institutional review board, and informed consent was obtained in all participants. Seventy-three women who underwent HIFU treatment were divided into groups A (n=47), and B (n=26), comprising patients with an NPV ratio of at least 90% and less than 90%, respectively. An ensemble feature ranking model was introduced based on the score values ??assigned to the 37 features by five different ML classifiers including Logistic Regression (LR), Support Vector Classifier (SVC), Random Forest (RF), Adaptive Boosting (Adaboost), Gradient Boosting (GBM), to find the most informative mpMRI features. The relationship between the mpMRI features and the immediate NPV ratio of 90% was evaluated using Pearson's correlation coefficients. The diagnostic ability of ML classifiers was performed by means of standard performance metrics, including the area under the receiver operating characteristic curve (AUROC), accuracy, sensitivity, and specificity in eight folds cross-validation.

RESULTS

For all the 12 most informative features, the AUROC ranged from 0.5 to 0.97, accuracy ranged from 0.34 to 0.97, specificity ranged from 0.56 to 1.0, and sensitivity ranged from 0.87 to 1.0. The GBM classifier showed the best predictive performance with an AUROC of 0.95 and accuracy of 0.92, followed by the RF, Adaboost, LR, and SVC classifiers, which yielded an AUROC of 0.92, 0.92, 0.83 and 0.78, and accuracy of 0.96, 0.88, 0.84 and 0.84, respectively. The best classifier performance with the best-performing features from each mpMRI group, Ktrans ratio of the fibroid to the myometrium, the ratio of AUC of the fibroid to the myometrium, subcutaneous fat thickness, the ratio of ADC value of fibroid to the myometrium, and T2-signal intensity (SI) of fibroid, was

achieved using GBM.

CONCLUSION

s The preliminary findings in this study suggest that the most informative 12 and best performing features from each mpMRI group should considered in predicting the treatment outcome of HIFU ablation to achieve an immediate NPV ratio of 90%.

CLINICAL RELEVANCE/APPLICATION

The best classifier performance with the best-performing features from each mpMRI group should be considered by the treating physician in the screening phase to predict the treatment outcome of HIFU ablation to achieve an immediate NPV ratio of 90%.

Systematic Assessment of Formulation Parameters Affecting Stability of Sclerosing Foams: Implications for Image Guided Sclerotherapy

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - IR DPS

Participants
Felipe Berg, (*Presenter*) Nothing to Disclose

PURPOSE

Sodium tetradecyl sulfate (STS) is a commonly utilized sclerosant used to treat various pathologies including vascular malformations and venous disease. It is often utilized as a foam, created by mixing STS with air and various contrast agents using the Tessari Method. Reported ratios of STS, contrast and air used to create sclerosing foam vary widely, and the impact of various ratios on foam stability are not well described. The purpose of this study is to evaluate the effect of various STS, air to Lipiodol® volume ratios on sclerosing foam stability.

METHODS AND MATERIALS

Different sclerosing foam combinations were generated with different ratios of Sodium tetradecyl sulfate, air and contrast. STS 30 mg/mL was used as a surfactant; and foam was created using various air:STS:Lipiodol ratios including 1:1.5:0; 1:2:0; 1:3:0; 1:4:0, 1:1.5:1, 1:2:1, 1:3:1, and 1:4:1 . Each mixture was agitated 30 times at room temperature using Tessari Method for each trial by the same researcher. Foam decay rates were recorded with a camera system for 45min or until all the foam had returned to its liquid phase. For trials with a contrast agent, 1 mL of Lipiodol® ethiodized oil (Guerbet LLC®) was added to the mixture. The drainage time and drainage rate were recorded for each trial.

RESULTS

In the trials with only STS, smaller air:STS with an average foam half-life of 1.8 min for the 4:1 ratio and 3.2 min for the 1.5 ratios, the foam has drained completely in 5 min for all trials. By adding Lipiodol to the mixture the foam stability increased significantly with an average foam half-life of 7.5 min and foam was present for more than 45min. No difference was observed within trials with Lipiodol related to the varying of the air:STS ratio.

CONCLUSION

s Increasing the air-to-liquid ratio reduces foam stability. Addition of Lipiodol significantly increases the foam stability. The air-to-liquid ratio could be used as a simple, and reproducible strategy to produce foams with stability suitable to the clinical scenario. Furthermore, the use of oil-based contrast agents (e.g. Lipiodol) can be used to produce foams with extended stability and radio-opacity, which may be appropriate for specific clinical indications.

CLINICAL RELEVANCE/APPLICATION

Sclerotherapy plays an important role in management of various pathologic processes including vascular malformation, venous insufficiency, and variceal gastrointestinal bleeding. A stable foam may increase efficacy due to a longer duration of contact with the targeted structure, and yet it may also act as a more effective and therefore dangerous vascular embolic in the setting of non-target embolization. Characterization of basic foam properties, including stability, created during a procedure is key for an effective and safe procedure.

Differences in Outcomes Between Patients with Lower Gastrointestinal Bleeding Undergoing Primary Endovascular vs Primary Endoscopic Interventions

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - IR DPS

Participants
Alexander Villalobos, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To compare outcomes in patients with lower gastrointestinal bleeding (LGIB) treated with primary endovascular vs endoscopic interventions.

METHODS AND MATERIALS

All LGIB encounters and associated procedures in the 2005-2015 National Inpatient Sample databases were identified using ICD-9 codes. Encounters initially treated with surgery or conservative management were excluded. Those initially treated with angiography and/or embolization (IR-PEI) vs diagnostic and/or therapeutic endoscopy (GI-PEI) were evaluated. Afterwards, encounters initially treated with only diagnostic angiography and/or endoscopy were excluded and those initially treated with transarterial embolization (IR-ITE) vs therapeutic endoscopy (GI-ITE) evaluated. Odds ratios (OR) for mortality and prolonged (>7 days) length of stay (LOS) were evaluated using multivariate logistic regression after propensity score matching of clinically relevant baseline covariates.

RESULTS

Of 617,735 LGIB encounters, 8,514 underwent an IR intervention, 5,987 IR-PEI, 2,172 IR-ITE, 193,476 GI-PEI, and 58,957 GI-ITE. Overall mean age, gender, and race/ethnicity was 69 years, 54% female, and 73% Caucasian. Any IR intervention usage was associated with increased risk of mortality (OR=1.4 [95%CI 1.3-1.5], p<0.001) and prolonged LOS (OR=2.5 [95%CI 2.4-2.6], p<0.001). With GI-PEI as reference, IR-PEI was associated with increased mortality (OR=3.2 [95%CI 2.9-3.4], p<0.001) and prolonged LOS (OR=3.6 [95%CI 3.1-4.2], p<0.001). With GI-ITE as reference, IR-ITE was associated with increased mortality (OR=8.5 [95%CI 6.4-11.2], p<0.001) and prolonged LOS (OR=3.57 [95%CI 3.05-4.18], p<0.001).

CONCLUSION

s Compared to endoscopic interventions, endovascular interventions for LGIB were associated with an increased mortality and prolonged LOS.

CLINICAL RELEVANCE/APPLICATION

Primary endovascular interventions for the management of lower gastrointestinal bleeding are associated with an increased risk of mortality and prolonged hospital length of stay as compared to standard-of-care primary endoscopic interventions.

Prediction of Oncologic Outcomes Following CT-guided Thermal Ablation of Colorectal Liver Metastasis

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - IR DPS

Participants
Iwan Paolucci, PhD, (*Presenter*) Stockholder, Intuitive Surgical, Inc ;Stockholder, SOPHiA GENETICS

PURPOSE

To build and evaluate predictive models for local tumor progression (LTP) and intrahepatic progression outside the ablation zone (IHP) following CT-guided thermal (TA) ablation of colorectal liver metastasis (CLM).

METHODS AND MATERIALS

A single-center retrospective evaluation of a liver ablation registry was surveyed to identify patients with CLM submitted to CT-guided TA between 10/2015 to 03/2020. Patients with $lt;1-year imaging follow-up, combined treatment with other local therapies, insufficient image quality for tumor depiction, and repeat ablations (IHP model only) were excluded. Oncologic outcomes (LTP/IHP) were determined prior to prediction model development by two radiologists. Definition for the Assessment of Time-to-Event End Points in Cancer Trials was applied for LTP- and IHP-free survival (LTPFS/IHPFS) assessment.The data was split into a training and test set (80%/20% split) on a patient level and ensuring similar LTPFS and IHPFS. LTPFS and IHPFS were truncated at 36 and 18 months respectively. A Bayesian parametric Weibull survival model was used with the following prognosticators: CLM diameter, nr of ablated CLM, TP53 mutation, CEA, NLR, extrahepatic metastasis, hepatic steatosis (only for IHP), RAS mutation (only for LTP), and software-based minimum ablation margin (only for LTP). Tumors/patients were stratified into High and Low risk of progression using the median predicted survival on the training set. Model performance was reported with positive predictive value (PPV), negative predictive value (NPV), and Kaplan-Meier curves of LTPFS and IHPFS of High and Low risk groups.

RESULTS

For the LTP model, training/testing comprised of 217/54 CLM, respectively. In testing, 9 CLM (16.6%) had LTP within 3 years and all of them were classified as High risk. The LTP model had a PPV 31% and an NPV of 100%. The risk of LTP within 36 months was 34.2% (CI95% = [11.8, 50.8]) vs. 0% in the High vs. Low risk group respectively (p=0.003). For the IHP model, training/testing comprised of 101/25 ablation naïve patients, respectively. In testing, 16/25 (64%) of patients had IHP within 18 months and 15 of those were classified as High risk. The IHP model had a PPV of 83.3% and an NPV of 85.7%. The risk of IHP within 18 months was 14.3% (CI95% = [0, 36.7]) vs. 83.3% (CI95% = [53.2, 94.1]) in the High vs. Low risk group respectively (p=0.007).

CONCLUSION

s Both models showed good performance in identifying patients and CLM that are unlikely to progress following TA. However, the LTP model shows a low PPV suggesting that there are more patient-/ablation-related factors that protect from LTP.

CLINICAL RELEVANCE/APPLICATION

Prediction models could be used to tailor treatment strategies for patients with CLM based on a per-tumor and -patient’s prognosis.

S3A-SPIR-5

Influence of Pelvic Magnetic Resonance Angiography for Prostatic Artery Embolization Planning and Technical Success

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - IR DPS

Participants
Matthias Boschheidgen, Dusseldorf, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Knowledge about anatomical details seems to facilitate the procedure of prostatic artery embolization (PAE) in patients with benign prostatic hyperplasia (BPH). We analysed pre-interventional MR angiography (MRA) of prostatic vessels to identify anatomical parameters which may influence procedural factors and technical success.

METHODS AND MATERIALS

MRA and digital subtraction angiography (DSA) of patients with PAE between 04/2018 and 03/2021 were analysed retrospectively regarding prostatic artery (PA) visibility, PA type, vessel elongation, and defined angles. These parameters were correlated with the DSA (intervention time, fluoroscopy time, dose area product (DAP), cumulative air kerma (CAK), contrast media (CM) dose) and technical success of embolization. T-test, ANOVA, Pearson correlation, and Kruskal-Wallis test were applied to check for statistical significance.

RESULTS

Seventy-eight patients (mean age 71 years) were included. MRA identified PA in 126 of 147 cases (accuracy 86%). PA had similar origin on both sides only in 57% of the patients. PA type showed no significant effect on DSA parameters. Contrarily, vessel elongation affected time for catheterization of right PA (p=0.02), fluoroscopy time (p=0.05), and CM dose (p=0.02) significantly. Moderate correlation was observed for iliac bifurcation angles with DAP (r=0.30 left; r=0.34 right; p=0.01) and CAK (r=0.32 left; r=0.36 right; p=0.01) on both sides.

CONCLUSION

s Pre-interventional MRA could reliably identify PA origin, offering a good anatomic orientation before performing PAE. PA type did not have an influence on procedural complexity of PAE and technical success while vessel elongation prolonged the intervention preceding to longer intervention times and higher doses of contrast media. MRA could not predict technical success for selective PA catheterization.

CLINICAL RELEVANCE/APPLICATION

Pre-interventional MRA can provide useful information on anatomic details of patients undergoing PAE. This can facilitate the intervention and has the potential to save time and ressources as well as radiation dose.

Clinical and Imaging Outcomes of Percutaneous Sclerotherapy for the Management of Lymphatic Malformations

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - IR DPS

Participants
Tushar Garg, MD, Baltimore, MD (*Presenter*) Conference Travel, Siemens Healthineers

PURPOSE

To evaluate the safety and outcomes of percutaneous sclerotherapy (PS) for lymphatic malformations (LMs) involving any part of the body.

METHODS AND MATERIALS

We reviewed all patients who underwent PS for the management of LMs between 4/2003 to 3/2022. Clinical and imaging findings were assessed to evaluate clinical response, lesion size changes, and complication rates. Fisher's Exact Tests were used for statistical analysis. Clinical symptoms response was classified as resolved, improved and stable and/or worsened. The LM size change was assessed by calculating the difference between pre-and post-procedure MRI of the largest lesion diameter in one plane, comparable to the response evaluation criteria in solid tumors (RECIST): complete response (CR, 100% reduction), partial response (PR, 30% reduction), stable disease (SD, =30% reduction or =20% enlargement), and progressive disease (PD, =20% VM size increase). Adverse events were classified by SIR classification criteria.

RESULTS

158 patients (49.4% F, 14.9 ± 18.4 years) underwent 241 PS (average 1.7 ± 1.1) sessions with a technical success rate of 97.1% (234/241). Most of the LMs presented after birth (43.7%; 69/158) with swelling (55%; 87/158) and pain (21.5%; 34/158) being the most common symptoms. 53.8% (85/158) of the LMs were in the head and neck and rest were almost equally distributed throughout the body. 38.6% (61/158) of the patients received previous outside PS, surgery or medical management. Doxycycline (80.5%; 191/241) was the most common sclerosant used, followed by bleomycin foam and liquid (12%; 29/241), ethanol (10.7%; 26/241), sotradecol foam (1.7%; 4/241) and n-BCA (0.4%; 4/241). A cosmetic deformity was seen in 77.2% (122/158) and functional deficit was seen in 24.8% (45/158) of the patients. For these patients with adequate follow-up, PS significantly improved cosmetic symptoms with 12.9% (13/101) resolved, 70.3% (71/101) improved, and 16.8% (17/101) stable or worsened ($p < 0.0001$) and functional deficits with 20.7% (6/29) resolved, 69% (20/29) improved, and 10.3% (3/29) stable or worsened ($p < 0.0001$). PS also significantly decreased LM size on imaging ($p = 0.0001$). Of the 140 (58.5%) procedures with both pre-and post-MRI imaging, 2 patients saw CR (1.4%), 51 patients (36.2%) experienced PR, 67 patients (47.5%) experienced SD and 19 patients (13.5%) saw PD. Early (30-day) post-procedural complications occurred after 30 of 241 procedures (12.4%), the majority of which were hyperpigmentation (23.3%; 7/30) and mild in severity (56.7%; 17/30).

CONCLUSION

s PS significantly decreases lesion size and improves clinical symptoms in LMs.

CLINICAL RELEVANCE/APPLICATION

PS is a safe and effective treatment option for the management of patients with LMs.

Prospective Study of Different Embolic Agents for Pulmonary Arteriovenous Malformation (PAVM) Embolization: Technical Results, Time Saved, and Financial Costs

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - IR DPS

Participants
Anna Gong, Baltimore, MD (*Presenter*) Nothing to Disclose

PURPOSE

While embolization of PAVMs with Micro Vascular Plug Systems (MVP™ systems) has been shown to have a 0-2% PAVM persistence rate, few attempts have been made to understand the technical features, time and costs of embolization with MVP™ systems versus other embolics.

METHODS AND MATERIALS

We evaluated 34 patients with PAVMs who underwent embolization with at least one MVP™ systems, Amplatzer vascular plug (AVP) or coil between 4/2019 and 2/2022. All data was collected in real time by dedicated scribes. Technical success, occlusion time, room-time, and costs were analyzed. Occlusion time was evaluated immediately after device deployment and in two-minute intervals until occlusion occurred or until another embolic was delivered. We extracted cost information from the electronic medical record. Mann-Whitney U tests (Bonferroni correction factor: adjusted significance value $p<0.01667$) were used for statistical analyses.

RESULTS

In 34 patients, 64 PAVMs and 81 feeding arteries were treated: 58 with at least one MVP™ systems, 20 with coils alone, and 3 with AVP. The per-feeding artery technical success rates were 100% for all cases. Median occlusion time was 1.0 min (Range <1 to 30 min) for feeding arteries treated with at least one MVP™ systems, 9.0 min (Range 3.0 to 25.0 min) for coils, and 5.0 min (Range 4.0 to 6.0 min) for AVP). Embolization with MVP™ systems achieves a significantly shorter occlusion time than embolization with coils (median 8.0 min saved per feeding artery) ($P<0.0001$).When compared to embolization with coils, embolization with MVP™ systems reduce room costs by a median of $429.77 per feeding artery ($p<0.0001$). Device costs for embolization with MVP™ systems versus coils were not significantly different per feeding artery (MVP™ systems: $2790.45; Coils: $3531: Median difference $740.55) ($p=0.1718$).

CONCLUSION

s When compared to coils, MVP™ systems have an equivalently high technical success rate and significant time and cost savings in addition to a known 0-2% PAVM persistence rate.

CLINICAL RELEVANCE/APPLICATION

MVP™ systems should be considered as a first-line agent for embolization of PAVMs for eligible patients.

Application and Potential Benefits of Color-coded Digital Variance Angiography in Prostatic Artery Embolization

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - IR DPS

Participants
Leona Alizadeh, MD, Frankfurt, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Color-coded digital variance angiography (ccDVA) is a recently developed image processing technology capable of visualization of hemodynamic conditions in 2D X-ray angiography setting. Our aim was to explore the potential advantages of ccDVA in prostatic artery embolization (PAE).

METHODS AND MATERIALS

This retrospective study evaluated 108 angiographic acquisitions from 30 patients (mean ± SD age 68.0 ± 8.9, range 41-87) undergoing PAE between May and October 2020. DSA and ccDVA images were generated from the same unsubtracted acquisition. Visual evaluation of ccDVA and DSA images was performed by four experienced interventional. The diagnostic value of DSA and ccDVA images was evaluated using clinically relevant criteria (visibility of small [< 2.5 mm] and large arteries [> 2.5 mm], feeding arteries and tissue blush) in a paired comparison. Data were analysed by the binomial test, the interrater agreement was determined by the Fleiss Kappa analysis.

RESULTS

The preference of ccDVA images was significantly higher in all criteria. The preference of ccDVA images was the highest in the tissue blush category (quality agreement [QA] 89%, interrater agreement [IR] 79%, followed by the small arteries (QA: 79%, IR: 70%), feeding arteries (QA: 79%, IR: 65%) and large arteries (QA: 63%, IR: 58%). The Fleiss Kappa range was 0.02-0.18, significant in all criteria except large vessels.

CONCLUSION

s Our data show that ccDVA significantly improves the diagnostic evaluation of tissue blush, small arteries and feeding arteries in PAE. As these structures are critically important in the procedure, the ccDVA technology might help the decision-making process in PAE interventions, although these benefits have to be validated in further prospective clinical studies.

CLINICAL RELEVANCE/APPLICATION

Color-coded DVA (ccDVA) significantly improves the visualization of small arteries, feeding arteries and tissue blush, thereby provides more information for PAE procedures than DSA in 79-89 % of comparisons.

The Role of Machine Learning Algorithms in Predicting the Treatment Outcome of High-Intensity Focused Ultrasound Ablation of Uterine Fibroids with an Immediate Nonperfused Volume Ratio of at least 90%

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - IR DPS

Participants
Bilgin Keserci, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the role of machine learning (ML) classifiers to find the most informative multiparametric (mp) magnetic resonance imaging (MRI) features in predicting the treatment outcome of high intensity focused ultrasound (HIFU) ablation with an immediate nonperfused volume (NPV) ratio of at least 90%.

METHODS AND MATERIALS

This retrospective study was approved by the institutional review board, and informed consent was obtained in all participants. Seventy-three women who underwent HIFU treatment were divided into groups A (n=47), and B (n=26), comprising patients with an NPV ratio of at least 90% and less than 90%, respectively. An ensemble feature ranking model was introduced based on the score values ??assigned to the 37 features by five different ML classifiers including Logistic Regression (LR), Support Vector Classifier (SVC), Random Forest (RF), Adaptive Boosting (Adaboost), Gradient Boosting (GBM), to find the most informative mpMRI features. The relationship between the mpMRI features and the immediate NPV ratio of 90% was evaluated using Pearson's correlation coefficients. The diagnostic ability of ML classifiers was performed by means of standard performance metrics, including the area under the receiver operating characteristic curve (AUROC), accuracy, sensitivity, and specificity in eight folds cross-validation.

RESULTS

For all the 12 most informative features, the AUROC ranged from 0.5 to 0.97, accuracy ranged from 0.34 to 0.97, specificity ranged from 0.56 to 1.0, and sensitivity ranged from 0.87 to 1.0. The GBM classifier showed the best predictive performance with an AUROC of 0.95 and accuracy of 0.92, followed by the RF, Adaboost, LR, and SVC classifiers, which yielded an AUROC of 0.92, 0.92, 0.83 and 0.78, and accuracy of 0.96, 0.88, 0.84 and 0.84, respectively. The best classifier performance with the best-performing features from each mpMRI group, Ktrans ratio of the fibroid to the myometrium, the ratio of AUC of the fibroid to the myometrium, subcutaneous fat thickness, the ratio of ADC value of fibroid to the myometrium, and T2-signal intensity (SI) of fibroid, was achieved using GBM.

CONCLUSION

s The preliminary findings in this study suggest that the most informative 12 and best performing features from each mpMRI group should considered in predicting the treatment outcome of HIFU ablation to achieve an immediate NPV ratio of 90%.

CLINICAL RELEVANCE/APPLICATION

The best classifier performance with the best-performing features from each mpMRI group should be considered by the treating physician in the screening phase to predict the treatment outcome of HIFU ablation to achieve an immediate NPV ratio of 90%.

Musculoskeletal Sunday Poster Discussions - A

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - MK DPS

Sub-Events

S3A-SPMK-1 Does the dGEMRIC Index Recover 3 Years After Fai Surgery Following an Initial Decrease at 1 Year Follow-up? A Controlled Prospective Study

Participants
Florian Schmaranzer, MD, Bern, Switzerland (*Presenter*) Nothing to Disclose

PURPOSE

Delayed gadolinium-enhanced MRI of cartilage (dGEMRIC) allows objective and noninvasive assessment of cartilage quality. An interim analysis 1 year after correction of femoroacetabular impingement previously showed that the dGEMRIC index decreased despite good clinical outcome. Our aim was to evaluate dGEMRIC indices longitudinally in patients with FAI correction and in a control group undergoing non-operative therapy for FAI.

METHODS AND MATERIALS

Prospective, comparative longitudinal study. 39 patients (40 hips) who received either surgical FAI correction (n=20) or non-operative therapy (n=20) were included. Baseline demographics and presence of osseous deformities did not differ between groups. All patients received indirect MR arthrography at all three time points (baseline, 1 and 3 year follow-up [FU]). The 3D cartilage models were created using a custom-developed deep learning-based software and were manually corrected if necessary. The dGEMRIC indices were determined separately for acetabular and femoral cartilage. A mixed-effects model was used for statistical analysis in repeated measures.

RESULTS

The surgical group showed an initial (preoperative to 1-year FU) decrease of dGEMRIC indices: acetabular cartilage 512±174 ms to 392±123 ms; femoral cartilage 530±173 ms to 411± 117 ms (both $p < 0.001$).From 1-year to 3-year FU, dGEMRIC indices increased: acetabular cartilage 392±123 ms to 456±163 ms; femoral cartilage 411±117 ms to 477±169 ms (both $p < 0.001$).The nonoperative group showed no significant changes in dGEMRIC indices of acetabular and femoral cartilage between the 3 timepoints (all $p > 0.6$).

CONCLUSION

s Three years after FAI correction, an improvement in dGEMRIC indices was found compared to short-term 1-year FU. This may be due to normalized joint biomechanics or regressive postoperative activation of the inflammatory cascade at mid-term following intra-articular surgery.

CLINICAL RELEVANCE/APPLICATION

This study shows the potential of deep learning based analysis of quantitative cartilage mapping techniques to detect adaptive changes in cartilage composition following therapeutic interventions.

S3A-SPMK-3 Enthesis Assessment Using Ultrashort Echo Time Magnetic Resonance Imaging (UTE-MRI) T1 And Magnetization Transfer (MT) Modeling in Psoriatic Arthritis

Participants
Dina Moazamian, San Diego, CA (*Presenter*) Nothing to Disclose

PURPOSE

This study uses ultrashort echo time (UTE) magnetic resonance imaging (MRI) techniques to quantify the collagen proton content and T1 values of Achilles tendon entheses, and evaluates differences between patients with psoriatic arthritis disease (PSA) and healthy controls.

METHODS AND MATERIALS

Seventeen PSA patients (59±15 years old, 41% female) and twenty-one healthy control participants (33 ±11 years old, 47% female) were scanned with newly developed 3D UTE Cones sequences, including T1 and MT modeling on a 3T clinical scanner (MR750, GE) employing a 3-inch surface coil. The enthesis region between the Achilles tendon and the calcaneus bone was imaged in the sagittal plane. To conduct UTE-MT modeling, T1 was measured with an actual variable flip angle (AFI-VFA) sequence (AFI: TE=0.032ms, TRs=20,100ms, FA=45°; VFA: TE=0.032ms, TR=18ms, FAs=5, 12, and 24°). A 3D-UTE-Cones-MT sequence (pulse power=350°, 750°; frequency offset=2, 5, 10, 20, and 50kHz; FA=7°; 11 spokes per MT preparation) was performed for the two-pool MT modeling. MT modeling estimates collagen proton content (i.e., macromolecular proton fraction, MMF). The total scan time was 25 mins. Two different regions of interest (ROIs) for each participant were drawn, one on the enthesis (close to the calcaneus bone) and the other one on the tensile Achilles tendon (Fig.1A). UTE-MRI markers were calculated for the two groups and were compared using the Mann-Whitney-U test. P values <0.05 were considered significant.

RESULTS

T1 and MMF pixel maps of a representative patient and a healthy control are presented in Fig.1 B-C and Fig.1 D-E, respectively. Average and standard deviation of T1 and MMF and their statistical significance are presented in Fig.1F. Significant differences in T1 and MMF values between entheses and tendon regions were found between the PSA and control groups. MMF difference between the control and PSA groups (23.8%) was higher than the T1 difference (12.1%).

CONCLUSION

s UTE-T1 and MMF from UTE-MT modeling can be used as quantitative methods for assessing entheses. As MMF values were significantly lower and T1 levels significantly higher in the entheses of PSA patients, this suggests a lower macromolecular content (collagen and proteoglycan) in the entheses of PSA patients compared with the control group.

CLINICAL RELEVANCE/APPLICATION

UTE-MT and T1 sequences are capable of evaluating entheses and tendons and may be able to detect abnormalities in PSA patients in order to improve the diagnosis and monitoring of PSA patients.

S3A-SPMK-4 The Abnormal Calcified Layer of Articular Cartilage of Knee (CLC) In 3D Ultrashort Echo Time MRI Correlating With Cartilage Degeneration in Proton Density Spin-Echo Sequence With Fat Suppression (PDFS)

Participants
Sunmin Lee, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the association between the abnormal calcified layer of articular cartilage of the knee (CLC) in 3D ultrashort echo time MRI (UTE) and cartilage degeneration in proton density spin-echo sequence with fat suppression (PDFS).

METHODS AND MATERIALS

96 knees were performed sagittal 3D UTE (TR = 16.1ms TE = 0.028ms and 6.6ms) and sagittal proton density spin-echo sequence with fat suppression (PDFS). Two musculoskeletal radiologists evaluated cartilage using Modified Noyer's chondromalacia grading system and subchondral bone change (SBC) in seven zones of the knee (mid, and posterior portion of the medial femoral condyle, medial tibial plateau, anterior, mid, and posterior portion of the lateral femoral condyle, lateral tibial plateau). CLC was analyzed in the same zone and divided into normal and abnormal (irregularity, thickening, thinning, and defect). The grade of chondromalacia and the presence of SBC were compared with the morphology of CLC using Kendall's tau b correlation and linear by linear correlation.

RESULTS

The zones of abnormal CLC were found 3 of 526 grade 0 (7%), 16 of 44 grade 1 (36%), 8 of 37 grade 2a (22%), 13 of 22 grade 2b (59%) and 33 of 41 grade 3 (80%) and 2 of 2 osteochondral defect (100%). The higher grade of chondromalacia, the higher frequency of abnormal CLC with statistical significance ($P < 0.001$). In the same grade, the area with SBC was more frequently accompanied by abnormal CLC than the area without SBC ($P < 0.05$).

CONCLUSION

s The CLC abnormality can be successfully visualized in 3D UTE and may be associated with cartilage degeneration.

CLINICAL RELEVANCE/APPLICATION

The calcified layer of cartilage has been expected to play an important role in cartilage damage. However, the Conventional PDFS could not see the calcified cartilage layer. Our study proves that 3D UTE can visualize abnormalities in the calcified cartilage layer and correlates with the degree of Noyer's chondromalacia in PDFS, which is expected to help understand the pathophysiology and early detection of cartilage damage and may affect treatment and cartilage surgery in the future.

Enthesis Assessment Using Ultrashort Echo Time Magnetic Resonance Imaging (UTE-MRI) T1 And Magnetization Transfer (MT) Modeling in Psoriatic Arthritis

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - MK DPS

Participants
Dina Moazamian, San Diego, CA (*Presenter*) Nothing to Disclose

PURPOSE

This study uses ultrashort echo time (UTE) magnetic resonance imaging (MRI) techniques to quantify the collagen proton content and T1 values of Achilles tendon entheses, and evaluates differences between patients with psoriatic arthritis disease (PSA) and healthy controls.

METHODS AND MATERIALS

Seventeen PSA patients (59±15 years old, 41% female) and twenty-one healthy control participants (33 ±11 years old, 47% female) were scanned with newly developed 3D UTE Cones sequences, including T1 and MT modeling on a 3T clinical scanner (MR750, GE) employing a 3-inch surface coil. The enthesis region between the Achilles tendon and the calcaneus bone was imaged in the sagittal plane. To conduct UTE-MT modeling, T1 was measured with an actual variable flip angle (AFI-VFA) sequence (AFI: TE=0.032ms, TRs=20,100ms, FA=45°; VFA: TE=0.032ms, TR=18ms, FAs=5, 12, and 24°). A 3D-UTE-Cones-MT sequence (pulse power=350°, 750°; frequency offset=2, 5, 10, 20, and 50kHz; FA=7°; 11 spokes per MT preparation) was performed for the two-pool MT modeling. MT modeling estimates collagen proton content (i.e., macromolecular proton fraction, MMF). The total scan time was 25 mins. Two different regions of interest (ROIs) for each participant were drawn, one on the enthesis (close to the calcaneus bone) and the other one on the tensile Achilles tendon (Fig.1A). UTE-MRI markers were calculated for the two groups and were compared using the Mann-Whitney-U test. P values <0.05 were considered significant.

RESULTS

T1 and MMF pixel maps of a representative patient and a healthy control are presented in Fig.1 B-C and Fig.1 D-E, respectively. Average and standard deviation of T1 and MMF and their statistical significance are presented in Fig.1F. Significant differences in T1 and MMF values between entheses and tendon regions were found between the PSA and control groups. MMF difference between the control and PSA groups (23.8%) was higher than the T1 difference (12.1%).

CONCLUSION

s UTE-T1 and MMF from UTE-MT modeling can be used as quantitative methods for assessing entheses. As MMF values were significantly lower and T1 levels significantly higher in the entheses of PSA patients, this suggests a lower macromolecular content (collagen and proteoglycan) in the entheses of PSA patients compared with the control group.

CLINICAL RELEVANCE/APPLICATION

UTE-MT and T1 sequences are capable of evaluating entheses and tendons and may be able to detect abnormalities in PSA patients in order to improve the diagnosis and monitoring of PSA patients.

The Abnormal Calcified Layer of Articular Cartilage of Knee (CLC) In 3D Ultrashort Echo Time MRI Correlating With Cartilage Degeneration in Proton Density Spin-Echo Sequence With Fat Suppression (PDFS)

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - MK DPS

Participants
Sunmin Lee, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the association between the abnormal calcified layer of articular cartilage of the knee (CLC) in 3D ultrashort echo time MRI (UTE) and cartilage degeneration in proton density spin-echo sequence with fat suppression (PDFS).

METHODS AND MATERIALS

96 knees were performed sagittal 3D UTE (TR = 16.1ms TE = 0.028ms and 6.6ms) and sagittal proton density spin-echo sequence with fat suppression (PDFS). Two musculoskeletal radiologists evaluated cartilage using Modified Noyer's chondromalacia grading system and subchondral bone change (SBC) in seven zones of the knee (mid, and posterior portion of the medial femoral condyle, medial tibial plateau, anterior, mid, and posterior portion of the lateral femoral condyle, lateral tibial plateau). CLC was analyzed in the same zone and divided into normal and abnormal (irregularity, thickening, thinning, and defect). The grade of chondromalacia and the presence of SBC were compared with the morphology of CLC using Kendall's tau b correlation and linear by linear correlation.

RESULTS

The zones of abnormal CLC were found 3 of 526 grade 0 (7%), 16 of 44 grade 1 (36%), 8 of 37 grade 2a (22%), 13 of 22 grade 2b (59%) and 33 of 41 grade 3 (80%) and 2 of 2 osteochondral defect (100%). The higher grade of chondromalacia, the higher frequency of abnormal CLC with statistical significance ($P < 0.001$). In the same grade, the area with SBC was more frequently accompanied by abnormal CLC than the area without SBC ($P < 0.05$).

CONCLUSION

s The CLC abnormality can be successfully visualized in 3D UTE and may be associated with cartilage degeneration.

CLINICAL RELEVANCE/APPLICATION

The calcified layer of cartilage has been expected to play an important role in cartilage damage. However, the Conventional PDFS could not see the calcified cartilage layer. Our study proves that 3D UTE can visualize abnormalities in the calcified cartilage layer and correlates with the degree of Noyer's chondromalacia in PDFS, which is expected to help understand the pathophysiology and early detection of cartilage damage and may affect treatment and cartilage surgery in the future.

S3A-SPMS

Multisystem Sunday Poster Discussions - A

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - MS DPS

Sub-Events

S3A-SPMS-1 Thickening of The Parotid Facial Process As a Sign of Hypertrophy and/or Inflammation in Patients with Sjogren's or Sicca syndrome

Participants
Andrea Portella Alegre, MD, Barcelona, Spain (*Presenter*) Nothing to Disclose

PURPOSE

Primary Sjögren's syndrome (pSS) is an autoimmune exocrinopathy which often manifests with asthenia, musculoskeletal and sicca syndrome (xerostomia and xerophthalmia). The salivary gland ultrasound (SGUS) is a simple and non-invasive procedure that is readily available and supplies important information on the major salivary glands. The score that assesses the heterogeneity of the glandular parenchyma has shown similar weight compared to minor items of the last set of criteria (2016 ACR/EULAR criteria) established to classify pSS patients. Our objective is to define new sonographic (US) features that can be included in a sonographic scoring system for the diagnosis of pSS.

METHODS AND MATERIALS

SGUS were conducted on 53 pSS and 26 sicca patients and 15 healthy controls (HC). The criteria for pSS was based on the 2016 ACR-EULAR classification, and the non-Sjögren's sicca patients presented symptoms but the score was less than 4. The US features that were examined were the maximum thickness of the facial process of the PG (FPPG) and Stensen's duct (SD) width. The analysis of continuous variables was made with Student's test and receiver operating characteristic (ROC) curve was employed to evaluate the performance of the width of the FPPG and the best cut-off value was determined.

RESULTS

There were no statistically significant differences between the thickness of the FPPG between pSS and sicca patients, although were significantly higher compared with the control group of both pSS and sicca patients independently. Consequently, the pSS and sicca patients were clustered into a single group and compared with HC, obtaining statistically significant differences with a mean value of 4.49 ± 1.61 mm for pSS+sicca and 2.93 ± 0.84 mm HC, $p<0.001$. ROC curves was performed to obtain a cut-off point between pSS+sicca patients and HC that would allow discriminating which thickness can be considered pathological, obtaining an AUC value of 0.8/0.037 and confidence interval (CI) of (0.73-0.87) with sensitivity of 0.67 (67%) CI (0.59-0.75) and specificity of 0.79 (79%) CI (0.60-0.92). The cut-off width of FPPG was 4mm. SD thickness was also significantly higher in the group of pSS+sicca patients versus HC with a value of 1.05 ± 0.52mm and 0.72 ± 0.22 mm, respectively.

CONCLUSION

s The width of FPPG may be an US feature to take into account to assess hypertrophies or signs of inflammation in patients with pSS or sicca versus HC, with a pathological cut-off point of =4mm, as well as the assessment of the thickness of SD.

CLINICAL RELEVANCE/APPLICATION

SGUS may be a candidate diagnostic test to be included in the ACR/EULAR criteria for the diagnosis of pSS. These new ultrasound features can help to make a score that can be incorporated as an item within the diagnostic criteria.

S3A-SPNMMI-1 Screening of Optimal Concentration of Magnetic Labeled Placental Mesenchymal Stem Cells

Participants
Hua He, MMedSc, MMedSc, Yinchuan, China (*Presenter*) Nothing to Disclose

PURPOSE

To determine the optimal magnetic labeling concentration range of human placental mesenchymal stem cells (hPMSCs) labeled with Ultrasmall Superparamagnetic Iron Oxides (USPIO), is critical to the realization of the external dynamic imaging and clinical application of the MR in vivo.

METHODS AND MATERIALS

hPMSCs were isolated and cultured , Polylysine(PLL) were transfected into USPIO to form PLL-USPIO complex, then label hPMSCs and investigate the labeling efficiency . Detect biological characteristics of labeled hPMSCs: cell survival rate calculated by trypan blue exclusion test, cell proliferation detected by Cell count (CCK-8) kit, and flow cytometry was used to judge the apoptosis of the cells. the difference of cell proliferation ability was analyzed by one way ANOVA or Kruskal Wallis testing, and the cell survival rate and apoptosis rate were compared by chi-square test.

RESULTS

Prussian blue staining in the experimental group showed that a large number of iron particles existed in the cytoplasm, and no iron particles stained blue were found in or outside the cells of the experimental group,the labeling rate was more than 95% , When the concentration of magnetic labeling was 15, 20 and 25 μg·mL-1, the survival rate of hPMSCs was 87.06±2.11, 87.06±2.11, 80.95±0.28, which were all lower than those of the control group ($P < 0.05$). on the 7th day of culture, the OD value of the labeling concentration of 25 μg·mL-1 group was 1.068±0.134, which was lower than that of the control group ($P=0.047$); There was no significant difference in late apoptosis rate between labeled cells and unlabeled cells (all $P>0.05$, the early apoptosis rate increased with the increase of marker concentration, the early apoptosis rate was higher than that of the control group when the concentration of labeling was =15 μg·mL-1

CONCLUSION

s When the concentration range of PLL-USPIO is 5ug/ml-15ug/ml-1, hPMSCs can be effectively labeled and has no significant effect on its activity, proliferation and apoptosis rate.

CLINICAL RELEVANCE/APPLICATION

This study provides basic research data for the realization of hPMSCs in vivo MRI dynamic imaging and clinical application.

S3A-SPNMMI-2 Simultaneous 18F-FDG PET/MRI for the Prediction of Early Response to Neoadjuvant Chemotherapy in Breast Cancer

Participants
Valeria Romeo, MD, PhD, Naples, Italy (*Presenter*) Nothing to Disclose

PURPOSE

To assess whether pre- and intra-treatment simultaneous 18F-FDG PET/MRI could be useful in the prediction of the response to neoadjuvant chemotherapy (NAC) in breast cancer (BC) patients.

METHODS AND MATERIALS

Between January 2017 and January 2020, 37 consecutive patients (mean age 45 ± 15 yrs) with 41 histologically proven BC lesions, candidate to anthracycline- and taxane-based NAC were prospectively enrolled. Simultaneous breast 18F-FDG PET/MRI examination was performed twice in each patient, one week before NAC and after the second anthracycline administration. PET/MRI images were analyzed to extract quantitative diffusion (ADCmin, ADCmean), perfusion (Ktrans, Kep, Ve, IAUC) and metabolic (SUV2D, SUV3D, MTV) parameters. The variation of each parameter (delta, ?) after the second anthracycline cycle was then calculated. Univariate analysis through Mann-Whitney U test was performed to assess differences in terms of pre-treatment and ? parameters between patients who showed complete and partial response (CR, PR) at histological examination after NAC. Multivariate logistic

regression analysis was then used to identify imaging parameters predictive of CR.

RESULTS

At Mann Mann-Whitney U test, significant differences were found between patients with PR and CR after NAC in terms of ?-Ve (p=0.016), SUV3D (p=0.022) and SUV2D (p=0.043). In detail, the early post-treatment variation of Ve was significantly higher in patients who showed CR after NAC. Furthermore, patients with CR showed higher pre-treatment SUV3D and SUV2D compared to patient with PR after NAC. At multivariate logistic regression, both ?-Ve and SUV3D resulted independent predictors of complete response to NAC, with p values of 0.013 and 0.021, respectively.

CONCLUSION

s Simultaneous breast PET/MRI could be useful to early predict the response to NAC in patients with BC. Our preliminary observations show that functional parameters (i.e. perfusion and metabolic)may identify patients who will respond completely, particularly using both pre-treatment and the variation of quantitative parameters early after the second cycle of NAC.

CLINICAL RELEVANCE/APPLICATION

Simultaneous breast PET/MRI may be useful for early identification of BC patients who would benefit from continuing NAC or for whom surgical excision could be optionally considered.

S3A-SPNPM-1 Financial Toxicity Analysis of Virtual Versus In-Person Radiation Oncology Residency Interviews

Participants
Yorleny Vicioso Mora, MD, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

Recent work has indicated that medical students may take loans of up to $7,000 to offset costs related to the residency match interview process. Because of the COVID-19 pandemic, US residency programs starting with the 2021 match cycle have adopted virtual interviews as replacements for in-person interviews. The financial toxicity of virtual versus in-person interviews for Radiation Oncology is addressed in the following cost analysis.

METHODS AND MATERIALS

Previous literature (including national 2019-2022 Radiation Oncology residency match statistics) was assessed to identify the average number of interviews per applicant (n = 14). Using these data, the cost of Electronic Residency Application Services (ERAS) applications, transportation (flight costs, Uber rides), and hotel stay was analyzed to estimate the total cost of in-person or virtual interviews. The cost of interviewing at 14 programs and at 20 programs (maximum rank list size without increased ERAS financial toxicity) was calculated regionally and broadly throughout the US.

RESULTS

The estimated total cost of interviewing at 14 programs in-person is $8,151 compared to $944 virtually, yielding a per-interview cost of $582.21 in-person versus $67.43 virtually. For applicants desiring to interview at 20 programs, the cost of in-person interviews increases to $10,986 while remaining at $944 virtually. This translates to a per-interview cost of $549.30 in-person versus $47.20 virtually to maximize rank list size.

CONCLUSION

s The financial toxicity for applicants applying to the average number of radiation oncology interviews is nearly 9 times more for in-person versus virtual interviews; this increases to nearly 12 times more toxicity for applicants interviewing at 20 programs.

CLINICAL RELEVANCE/APPLICATION

The virtual interview process substantially decreases financial toxicity, allowing applicants to interview at approximately 10 programs virtually per one program in-person. This sizeable increase in opportunity has the potential to increase the diversity, equity, and inclusion of medicine by decreasing the longstanding financial limitations facing residency applicants of lower socioeconomic status.

S3A-SPNPM-2 Predictors of Workforce Paid Time-off and Productivity Lost After COVID MRNA Vaccination Within a Department of Radiology at a Large Academic Hospital

Participants
Moses Flash, Boston, MA (*Presenter*) Nothing to Disclose

PURPOSE

Hospitals have implemented COVID vaccination requirements for employees. The BNT162b2 (Pfizer) and mRNA-1273 (Moderna) mRNA vaccines have demonstrated high effectiveness but cause transient reactogenicity that can require time off work to recover. We aimed to identify predictors of requiring post-vaccination sick leave and to determine the cost of productivity loss with mandatory vaccination of hospital employees.

METHODS AND MATERIALS

An IRB-approved, HIPAA-compliant survey was sent to all 2,655 employees of the radiology department of a large academic hospital to assess vaccine side effects and whether sick leave was required. Logistic regression identified factors associated with requiring sick leave. A budget impact analysis compared productivity loss with mandatory vs non-mandatory vaccination over the course of one year. Sick leave duration, vaccine efficacy, and vaccine uptake were varied in a sensitivity analysis.

RESULTS

Among the 477 (18%) employees who completed surveys, the majority experienced symptoms after each dose (dose 1, 81.3%;

dose 2, 89.5%). 188 (39.4%) employees required a total of 339.5 days of sick leave (0.74 days/employee among all respondents; Table 1). On multivariate logistic regression, factors associated with taking sick leave were receiving the Moderna vaccine (odds ratio [OR], 1.89; P=.01), the number of symptoms after dose 1 (1-2: OR, 2.57; P=.006; 5+: 2.46, P=.05) and dose 2 (3-4: OR, 7.99; P=.001; 5+: OR, 23.34; P<.001), underreporting symptoms to the employer (OR, 0.10; P<.001) and injection site symptoms after dose 1 (OR, 0.50; P=.01). At the base rates of vaccine-related sick leave, vaccine uptake, and vaccine efficacy, annual productivity losses were $115,647 with mandatory vaccination and $128,594 without mandatory vaccination, yielding a cost benefit of $12,947 with mandatory vaccination among the 352 employees with available salary data. Sensitivity analyses demonstrated a cost benefit with mandatory vaccination across a wide range of vaccine efficacies, uptakes, and sick-leave durations.

CONCLUSION

s Despite the high rate of reactogenicity after vaccination requiring 339.5 days of sick leave, mandatory vaccination of healthcare employees was associated with an annual cost benefit across a wide range of sick leave durations, vaccine efficacies, and uptakes.

CLINICAL RELEVANCE/APPLICATION

With COVID now endemic, seasonal vaccination may be necessary for hospital workers. However, vaccine reactogenicity places strain on staffing productivity, affecting patient care. We evaluated productivity loss with mandatory vs non-mandatory vaccination for hospital workers.

To investigate microstructural, morphological, and functional connectivity correlates of ADHD on brain MRI of adolescents.

METHODS AND MATERIALS

We retrieved the imaging and clinical information of 1,830 subjects with ADHD and 6,067 without ADHD from the ABCD (https://abcdstudy.org/) database of 11,876 adolescents - participants' average (SD) age was 118.94 (7.46) months. We excluded those with incomplete clinical information, history of traumatic brain injury, and failure to pass image quality control. In multivariate logistic regression adjusted for age and sex, we examined the association of ADHD with different neuroimaging metrics. The neuroimaging metrics included fractional anisotropy (FA), neurite density (ND), mean-(MD), radial-(RD) and axial diffusivity (AD) of white matter (WM) tracts, cortical region thickness and surface areas from T1-MPRAGE series, and functional network connectivity correlations from resting-state fMRI. We applied False Discovery Rate (FDR) to correct for multiple comparisons. We also optimized, trained, tested, and validated different combinations of machine learning classifiers and feature selection algorithms for prediction of ADHD.

RESULTS

Individuals with ADHD had a significantly (adjusted $p<0.05$) lower FA and ND but higher MD and RD -predominantly in left hemispheric WM tracts compared to those without ADHD. Presence of ADHD was associated with reduced cortical regions, especially in the right middle temporal gyrus (adjusted $p<0.001$). The auditory-, cingulo-parietal, ventral-/dorsal-attention and default-network differed between those with and without ADHD. In repeated 10-fold cross-validation, a combination of elastic net logistic regression with hierarchical clustering feature selection yielded the highest and most stable performance, attaining an AUC of 0.6085, 95% CI [0,5757, 0,6414], in predicting ADHD in an independent validation set.

CONCLUSION

s Abnormal functional connectivity, involving networks related to memory processing, tonic alertness, and the auditory process, thinning of brain cortex, and WM tract neural fiber loss and microarchitectural disintegrity are markers of adolescents' ADHD. Multi-modal neuroimaging metrics can be used as input for machine learning models to support identification of at-risk children.

CLINICAL RELEVANCE/APPLICATION

Using a large population cohort, we elucidated the underlying neurobiology of adolescents' ADHD and suggest a possible role for neuroimage-based machine-learning models to assist with diagnosis.

S3A-SPNR-10 The Influence of Alcohol On In Utero Brain Development: A Structural Fetal MRI Study

Participants
Patric Kienast, Wien, Austria (*Presenter*) Nothing to Disclose

PURPOSE

Alcohol consumption during pregnancy affects brain development leading to a variety of behavioral and cognitive disorders. However, early structural alterations of fetal brain development have not yet been systematically studied. This prospective single center fetal MRI study aims is to assess the effects of alcohol exposure on brain development.

METHODS AND MATERIALS

After inclusion of 20 fetal MRI studies of fetuses with prenatal alcohol exposure (PAE, 22+1 - 36+4 weeks of gestation (GW)) due to the standardized systematic questionnaires (TACE and PRAMS). These cases were 1:1 age-matched to a healthy control case.Brain maturation was assessed by using the fetal total maturation score (fTMS) (Vossough et al. 2013) based on superresolution-postprocessed T2- weighted/SSFP sequences in 3 planes (1.5T). In addition, the depth of temporal and occipital sulci and the expression of fetal brain asymmetry in the temporal lobe were quantified.

RESULTS

In PAE fetuses, the fTMS score was significantly lower ($p=0.007$) and the right superior temporal sulcus (STS) was shallower ($p<0.001$). Delayed fetal brain development could be specifically related to an age inappropriate/delayed stage of myelination and

less distinct gyrification in the frontal and occipital lobes (p=0.04).

CONCLUSION

s This fetal MRI study revealed an early impact of PAE on structural fetal brain maturation and development. In addition to alterations of the periventricular zone and the corpus callosum detectable by atlas based analysis (Stuempflen et al. RSNA 2021), this study emphasizes early and diffuse alterations to fetal structural brain development and delayed brain maturation in fetuses affected by maternal alcohol consumption.

CLINICAL RELEVANCE/APPLICATION

Identification of the teratologic toxic effects on human brain development opens new diagnostic opportunities for fetal neuroradiology, allowing early postnatal support programs in these cases and stimulating the discussion of alcohol prevention during pregnancy to promote public health.

S3A-SPNR-12 Evaluation of Glymphatic System Activity Using Diffusion Tensor Image Analysis Along the Perivascular Space (DTI-ALPS) in Cognitively Normal Older Adults: Correlation with Amyloid PET

Participants
Chae Jung Park, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Diffusion Tensor Image-Analysis aLong the Perivascular Space (DTI-ALPS) is a recently introduced method for the assessment of glymphatic system without need for contrast injection. In this study, we aimed to evaluate the glymphatic system in cognitively normal elderly adults using DTI-ALPS, by correlating it with amyloid PET.

METHODS AND MATERIALS

In this prospective study, total 123 cognitively normal elderly adults with or without subjective cognitive decline (SCD) were recruited through advertisement in communities. They performed baseline cognitive test, MRI and PET. On DTI-MRI, the diffusivities along x-, y-, and z-axes were measured, and the ALPS-index was calculated. To measure the amyloid deposition from PET, standardized uptake value ratios (SUVR) were calculated from variable cortical regions. The differences in the ALPS-index between normal and SCD group were compared using the Mann-Whitney test. Pearson's correlation was used to analyze the correlation between ALPS-index and SUVRs. Multiple linear regression was performed to assess the association between ALPS-index and other relevant variables - age, duration of education, Mini-Mental State Examination score, presence of Apolipoprotein e4 allele and SUVRs.

RESULTS

Among total 123 subjects, 63 were asymptomatic (mean age, 73.0 years ± 4.2 [standard deviation], 43 men) and 60 had SCD (mean age, 73.7 years ± 3.5, 41 men). The ALPS-index was not significantly different between the normal and SCD group (1.34 ± 0.13 vs. 1.34 ± 0.12, P = 0.897). Among SUVRs from variable cortices, SUVR from paracentral cortex was the only variable which was negatively correlated with ALPS-index (r = -0.218, P = 0.016, figure). Multiple linear regression revealed that older age (coefficient, -0.007) and increased SUVR from paracentral cortex (coefficient, -0.101) were the two independent variables which had significant association with lower ALPS-index (P = 0.015 and 0.049, respectively).

CONCLUSION

s The ALPS-index was not significantly different between the normal and SCD group. Correlating DTI-ALPS with amyloid PET revealed that increased amyloid deposition in the paracentral cortex was significantly associated with lower ALPS-index, which gives the notion that the clearance in paracentral cortex might play an important role in the glymphatic system.

CLINICAL RELEVANCE/APPLICATION

In this study, we correlated DTI-ALPS with amyloid PET in cognitively normal elderly adults for better understanding of glymphatic system. We found that older age and increased amyloid deposition in the paracentral cortex identified from PET were significantly associated with lower ALPS-index. It implies that the clearance in paracentral cortex might have a significant impact on glymphatic system.

S3A-SPNR-13 Analysis of Neurite Orientation Dispersion and Density Imaging (NODDI) Parameters for Assessing the Hippocampal Neurodegenerative Progression in Early Alzheimer's Disease, Compared to Cerebrospinal Fluid (CSF) Level of Phosphorylated tau (P-tau)

Participants
Hiroto Takahashi, MD, Suita, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Cerebrospinal fluid (CSF) phosphorylated tau (p-tau) is sensitive to neurodegeneration in Alzheimer's disease (AD), but its measurement is invasive. Neurite orientation dispersion and density imaging (NODDI) is a diffusion magnetic resonance imaging (MRI) technique which assumes a three-compartment (intracellular, extracellular, and CSF) biophysical tissue model for each voxel, and can provide specific data on neuronal changes. We aimed to explore the imaging biomarker that supports the CSF biomarker for evaluating disease progression in early AD.

METHODS AND MATERIALS

Sixty-nine patients with mild cognitive impairment underwent both CSF measurement of Aß42 and p-tau and multi-shell diffusion MRI at 3T. Based on the CSF Aß42 and p-tau values, 35 patients with AD pathology (group AD) were discriminated from 34 patients with non-AD pathology (group non-AD). The NODDI and diffusion tensor imaging (DTI) parametric maps were generated from the obtained diffusion MRI data. Two neuroradiologists created the region of interest (ROI) of each side of hippocampus, separately. The hippocampal values were calculated using the ROIs. Inter-ROI value correlations between two neuroradiologists were calculated for the intraclass correlation coefficients (ICCs). Correlations between each hippocampal value and the CSF p-tau value were assessed using Pearson's correlation analysis.

RESULTS

Almost all the ICCs were substantial or almost perfect, besides the ICCs of the NODDI-derived isotropic volume fraction, throughout the group. There were significant correlations between the NODDI-derived orientation dispersion index (ODI) of the right hippocampal ROIs and the CSF p-tau value in the group AD ($P < 0.05$), whereas no significant correlation was shown in any other hippocampal value. The NODDI-derived intracellular volume fraction, the DTI-derived fractional anisotropy and axial diffusivity correlated weakly with the CSF p-tau value in the group AD.

CONCLUSION

s Present hippocampal ROI analysis indicated that diffusion MRI parameters, especially the right hippocampal ODI, might support the CSF p-tau measurement and be useful biomarker for evaluating disease progression in early AD.

CLINICAL RELEVANCE/APPLICATION

The hippocampal NODDI parameter might be a useful imaging biomarker for assessing neurodegenerative progression with the CSF p-tau elevation in early AD.

S3A-SPNR-14 Cognitive Impairment and Amygdala Sub-regions Atrophy in Patients with End-stage Renal Disease

Participants
Yuan Li, Dalian, China (*Presenter*) Nothing to Disclose

PURPOSE

Cognitive dysfunction is prevalent in end-stage renal disease (ESRD) patients, and the amygdala plays an important role in cognition. This study aimed to compare the volume of the amygdala subregions between ESRD patients and healthy controls (HCs), and to analyze the correlations of subregion volumes with cognitive function.

METHODS AND MATERIALS

Forty-nine ESRD patients and 41 age, gender, education matched HCs were recruited. All subjects were scanned using a 3T MRI to acquire 3D T1 anatomical images. Automatic volumetric measurement of the amygdala subregions was done using FreeSurfer 7.0. The amygdala was segmented, bilaterally, into the lateral nucleus, basal nucleus, accessory basal nucleus, anterior amygdaloid area, central nucleus, medial nucleus, cortical nucleus, corticoamygdaloid transition area, and paralaminar nucleus (Figure 1). Thirty-four ESRD patients and 16 HCs underwent neuropsychological examinations. The amygdala subregion volumes and cognitive test results were compared between the two groups using an independent sample t-test. Partial correlation analysis was used to assess correlations between the amygdala subregion volumes and cognitive test scores in the ESRD group, with sex, age and education level as covariates.

RESULTS

The volumes of the amygdala subregions were decreased in the ESRD group (Figure 2-3), especially the bilateral accessory basal nucleus (left: P=0.028, right: P=0.019) and bilateral corticoamygdaloid transition area (left: P=0.033, right: P=0.009)(Table 1). Compared with HCs, ESRD patients had lower MoCA (P<0.001) and DSST (P=0.030) scores but higher TMT-B (P=0.017), HAMA (P=0.030) and HAMD (P=0.001) scores (Table 2). The partial correlation analysis showed that the volume of the right lateral nucleus was negatively correlated with TMT-A scores (P=0.010, r=-0.390), as well as those of the left paralaminar nucleus, the right basal nucleus and the right paralaminar nucleus were positively correlated with immediately recall scores (P=0.047, r=0.305; P=0.046, r=0.306; P=0.036, r=0.321).

CONCLUSION

s ESRD patients are accompanied by cognitive impairment, anxiety and depression. Patients with ESRD develop atrophy of the amygdala subregions, which is related to impaired visuospatial function and short-term memory performance.

CLINICAL RELEVANCE/APPLICATION

Previous studies were based on the overall amygdala structure, but since the amygdala consists of several subregions, it cannot accurately reflect the subtle changes by measuring the whole volume of the amygdala. Therefore, it is essential to further explore the effects of specific substructures by automatic volumetric segmentation of the amygdala subregions, which is a stable and reproducible quantitative measurement.

S3A-SPNR-15 Correlation Hippocampal Subfields Alterations and Metabolic-neurologic Changes in Patients with Type 2 Diabetes Mellitus

Participants
Jiajun Cao, (*Presenter*) Nothing to Disclose

PURPOSE

To explore the changes of the volume and asymmetry of hippocampal subfields in patients with type 2 diabetes mellitus and the correlation between the significantly atrophied regions of the hippocampal subfields and clinical data, laboratory indicators, cerebral small vessel diseases scores and cognitive scores was analyzed.

METHODS AND MATERIALS

Thirty-one patients with T2DM and 24 volunteers as the control group were prospectively recruited into this present study. T1WI, T2WI, T2Flair and 3DT1WI sequences were performed using Philips Ingenia CX3.0TMRI scanner. The clinical data and laboratory indicators of all subjects were recorded, including gender, age, height, weight, waist circumference, hip circumference, systolic blood pressure, diastolic blood pressure, education level, insulin, fasting glucose, glycated hemoglobin, total cholesterol , triglyceride , low density lipoprotein , high density lipoprotein , homocysteic acid . Meanwhile, body mass indexand waist hip ratio were calculated. CSVD MRI features of all subjects were scored quantitatively including: periventricular hyperintense and deep white matter hyperintense grades, basal ganglia enlarged perivascular space and centrum-semiovale enlarged perivascular space grades, the grade of lacune and the grade of cerebral microbleed , and the CSVD total burden scores were calculated .Detailed neuropsychological scale assessment was performed on all subjects, including the mini-mental state examination, Montreal cognitive assessment , California verbal learning test, symbol digit modalities test.FreeSurfer(version6.0.0,http://surfer.nmr.mgh.harvard.edu/) software was used for imaging post-processing. The volume of all

subjects' hippocampal subfields and hippocampal asymmetry index were calculated.

RESULTS

Compared with the control group, the volumes of left presubiculum, left fimbria and left hippocampal amygdala transition area were significantly decreased in the T2DM group (p=0.041,p=0.048,p=0.030), HAI decreased in cornu ammonis 1,but increased in HATA area (p=0.029,p=0.023).Partial correlation analysis was carried out between the volume of left presubiculum, left fimbria, left HATA volume and clinical data, laboratory indicators, cognitive score and CSVD quantitative score, age, gender and years of education were taken as covariates .

CONCLUSION

s The atrophy of hippocampal subfields is asymmetric, and the volume of hippocampal subfields is closely related to metabolic syndrome, increased burden of CSVD and decline of cognitive function.

CLINICAL RELEVANCE/APPLICATION

The atrophy of hippocampal subfields is asymmetric, and the volume is closely related to metabolic syndrome, increased burden of CSVD and decline of cognitive function.

S3A-SPNR-17 Connectome-based Models Predict Cognitive Functions in Systemic Lupus Erythematosus

Participants
Jiaying Mo, (*Presenter*) Nothing to Disclose

PURPOSE

Systemic lupus erythematosus (SLE) is a mainly female inflammatory autoimmune disorder that can affect the central nervous system and cognitive functions in up to 80% of patients. This study aims to investigate whether the topological network of functional connectivity can predict the performance of neuropsychological tests in different domains, using connectome-based predictive modeling (CPM).

METHODS AND MATERIALS

We evaluated 61 SLE patients who underwent a resting-state functional MRI scanning in a Philips Achieva 3T MRI system and a comprehensive neuropsychological assessment for the four cognitive domains of verbal, visuospatial, visual memory, and attention. According to the Brainnetome atlas, ROI-based functional connectivity analysis was employed to extract the whole-brain functional networks. CPM with leave-one-out cross-validation was conducted to identify different networks that predicted the performance of neuropsychological tests. The predictive ability of identified networks would be tested in an independent sample of patients who were scanned in a different 3T MRI system (uMR 780, United Imaging Healthcare, Shanghai, China).

RESULTS

Four CPM models enabled prediction of neuropsychological scores for unseen subjects in cross-validation, with Pearson's correlation coefficients r of 0.40-0.48 (all p values < 0.001). In these four cognitive function predictions, brain connectivities that show top contributing power commonly concentrated on the hippocampus, parahippocampal gyrus, superior frontal gyrus, medial frontal gyrus, inferior parietal lobule, and insula, which were the key nodes of the default-mode network and salience network. Moreover, the CPM models based on these important brain regions could predict overall cognitive ability (MoCA score; $r = 0.45$, $p < 0.001$).

CONCLUSION

s Our results provide preliminary evidence that different functional networks with overlapping of important brain regions including frontal lobe, parietal lobe, insular lobe and several subcortical regions may contribute to cognitive ability of various domains and allow to predict the corresponding cognitive functions in SLE.

CLINICAL RELEVANCE/APPLICATION

CPM identified brain networks that underlie different cognitive functions in individuals and these "neural fingerprints" could potentially assist the diagnosis of cognitive dysfunction in SLE.

S3A-SPNR-18 Associations of Cortical Iron Accumulation with Cognition and Cerebral Atrophy in Alzheimer's Disease

Participants
Aocai Yang, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

Cerebral iron accumulation is consistently observed in Alzheimer's disease and co-localizes with the pathological proteins—amyloid-ß and tau. We aimed to investigate the whole-brain distributional pattern of cortical iron deposition and its relationships with cognition and cortical thickness in Alzheimer's disease via Quantitative Susceptibility Mapping (QSM).

METHODS AND MATERIALS

We prospectively recruited 30 participants with Alzheimer's disease (AD) and 26 age- and sex-matched healthy controls (HC) in this cross-sectional study. All the participants underwent QSM and structural T1 examinations on 3.0T MRI scanner. Mini-Mental State Examination (MMSE) and Montreal Cognitive Assessment (MoCA) were used to assess the global cognitive level. The whole-brain cross-sectional QSM analysis and the whole-brain QSM regression analyses against MMSE and MoCA scores were performed. Additionally, we conducted a surface-based morphometry analysis. Subsequently, in the significant atrophy regions, we compared the magnetic susceptibility between two groups and assessed the association of magnetic susceptibility with cortical thickness.

RESULTS

The whole-brain QSM cross-sectional analysis demonstrated that widespread susceptibility increased in AD across the cortical ribbon, asymmetrically covering left hemisphere cerebral cortex, caudate nucleus, putamen and partial cerebellar cortex. The whole-brain QSM regression analyses showed increased susceptibility that covaried with lower MMSE and MoCA scores in AD, and was predominantly located in the right parietal cortex and lateral occipital cortex. The reduced cortical thickness was located in the

left superior temporal, right frontal pole, fusiform and pars opercularis in AD and the corresponding susceptibility increased in right frontal pole (AD:0.034±0.007ppm, HC:0.030±0.005ppm; P=0.016) and pars opercularis (AD:0.020±0.003ppm, HC:0.017±0.002ppm; P=0.002). Susceptibility was negatively correlated with cortical thickness in right pars opercularis in both entire cohort(r=-0.521, P<0.001) and AD (r=-0.510, P= 0.005).

CONCLUSION

s Widespread cortical iron, measured by QSM, accumulated in Alzheimer's disease and was associated with poor cognitive performance. Increased iron content was associated with brain atrophy in AD. QSM may be a useful imaging biomarker to monitor the neurodegenerative progression of AD.

CLINICAL RELEVANCE/APPLICATION

Increased iron content was associated with cortical atrophy and cognitive level in Alzheimer's disease. These may be useful to monitor the disease progression and cognitive severity of Alzheimer's disease at the whole brain level in vivo, and provide new insights into the application of QSM as a disease biomarker.

S3A-SPNR-19 Classification of Major Depression Disorder Based on Integrated Temporal and Spatial Variability Features of Dynamic Brain Networks

Participants
Qun Gai, (*Presenter*) Nothing to Disclose

PURPOSE

The dynamics of brain networks has been a focus in the study of depression in recent years. However, most previous studies focused on single temporal dimension only, ignoring spatial dimension information. The present study aimed to integrate temporal and spatial variability features of dynamic brain networks to distinguish patients with major depressive disorder (MDD) from healthy controls (HC).

METHODS AND MATERIALS

245 MDD subjects and 230 well-matched HC were recruited in this study (the discovery cohort: 119 MDD and 106 HC, the validation cohort: 126 MDD and 124 HC). Temporal and spatial variability features were extracted from dynamic brain networks as features. A two-level feature selection strategy and random forest (RF) were employed for classification. Two other classifiers were also applied to validate our model. Furthermore, a linear regression model for assessing MDD symptom severity was established based on above selected temporal and spatial features.

RESULTS

Our model based on the integration of temporal and spatial variability features achieved the best performance with an accuracy of 93.33% (an accuracy of 83.40% for an independent sample). Moreover, features with high discriminative power to distinguish MDD from HC showed strong association with the visual network (VIS) and cognitive control network (CCN). Importantly, altered temporal and spatial variability could predict depression and anxiety severity of MDD.

CONCLUSION

s Our results demonstrate that integrating temporal and spatial variability features can discriminate MDD from HC with a high classification performance and suggest that spatiotemporal dynamics may explain underlying neurobiological mechanism of MDD symptoms.

CLINICAL RELEVANCE/APPLICATION

Our findings provide direct evidence that spatiotemporal dynamics could be used as effective biomarkers for clinical diagnosis of MDD and may play an important role in detecting depression and anxiety symptom severity of MDD.

S3A-SPNR-2 Evaluation and Clinical Validation of a Deep Learning Algorithm for Predicting Delayed Myelination in Infant Brains from MRI

Participants
Gunvant Chaudhari, BS, San Francisco, CA (*Presenter*) Nothing to Disclose

PURPOSE

Assisting diagnosis of infant delayed myelination by creating a convolutional neural network (CNN) capable of predicting delayed myelination based on routine clinical T1T2-weighted brain MRIs.

METHODS AND MATERIALS

MRIs were obtained from our institutional clinical database. Patients aged 0-25 months with reportedly normal myelination from 1995-2019 (n=5028) and delayed myelination from 1995-2021 (n=426) were included. For normal myelination MRIs, exclusion criteria included uneven age distribution (N=2659), myelination at the lower limits of normal (N=46), missing gestationally corrected age (GCA, N=1352), poor automated skullstripping or registration (N=103), and lack of T1 or T2 imaging (N=252). For delayed myelination MRIs, MRIs missing GCA (N=162), with poor automated skullstripping or registration (N=19), and without T1 or T2 imaging (N=121) were excluded. The CNN had input of paired, registered T1 T2 MRIs and GCA and was trained to predict delayed myelination status. Results from 10-fold cross-validation are reported. For a clinical benchmark, 3 neuroradiologists with 3-24 years of experience in pediatric neuroradiology blindly interpreted 30 randomly sampled MRIs, 15 normal and 15 delayed myelination, and assigned numerical values corresponding to confidence of delayed myelination (Figure 1). Ground-truth myelination status was defined as the average of 3 radiologists' and report label values.

RESULTS

The dataset consisted of 616 infant brain MRIs with normal myelination and 124 with delayed myelination. The CNN had an area under the receiver operator characteristic curve (AUC) of 0.77 (95% CI: 0.70-0.84) in cross-validation. In the subset of cases selected for the ready study, the CNN had an AUC of 0.83 (95% CI: 0.66-0.96) compared to 3 neuroradiologists with AUCs of 0.65 (0.45-0.84, p=0.19), 0.66 (0.46-0.85, p=0.19), and 0.78 (0.65-0.90, p=0.60), respectively.

CONCLUSION

s A CNN can recognize infant delayed myelination using T1- and T2-weighted brain MRI and GCAs, with performance similar to clinical neuroradiologists.

CLINICAL RELEVANCE/APPLICATION

Determining delayed myelination on infant brain MRI is subjective, especially for radiologists without high volume practice in pediatric neuroradiology. An AI system can aid radiologists in this task.

S3A-SPNR-20 Hippocampal Atrophy in Neurofunctional Subfields in Chronic Insomnia

Participants
Yang Yang, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the pattern of volume changes in neurofunctional hippocampal subfields in patients with chronic insomnia (PIs).

METHODS AND MATERIALS

A total of 120 PIs (78 females, 42 males; mean age± std, 43.74 ± 13.02 years) and 120 good sleepers (60 females, 60 males; mean age, 42.69 ± 12.24 years) were recruited. The left hippocampus was segmented into anterior (L1), middle (L2), and posterior (L3) subregions. The right hippocampus was segmented into top anterior (R1), second top anterior (R2), middle (R3), posterior (R4), and last posterior (R5) subregions. Multivariate Logistic regression was used to evaluate hippocampal subfields and the associations with the risk of chronic insomnia. Mediation analyses evaluated mediated associations with post-insomnia negative emotion, insomnia severity, and hippocampal atrophy. A visual easy-to-deploy risk nomogram was used for individual prediction of insomnia risk. All statistical analyses were performed using Matlab; P <0.05 was considered a statistically significant difference.

RESULTS

Hippocampal atrophy was identified in the L1, R1, and R2. L1 and R2 atrophy each predisposed to an approximate 3-fold higher risk of chronic insomnia (L1, OR: 2.90, 95% CI: [1.24, 6.76], P= 0.014; R2, 2.72 [1.19, 6.20], P= 0.018). Anxiety fully mediates the causal insomnia path, leading to R1 volume atrophy on positive affect. We developed a practical and visual competing risk-nomogram tool for individual prediction of insomnia risk, which stratifies individuals into different levels of insomnia risk with the highest prediction accuracy of 97.4% and an average C-statistic of 0.83.

CONCLUSION

s Chronic insomnia is associated with hippocampal atrophy in specific neurofunctional subfields that are risk factors for chronic insomnia.

CLINICAL RELEVANCE/APPLICATION

These findings could broaden our understanding of the etiology of insomnia, help individuals identify their potential risk profile, and guide individuals to take precise actions ipromptly to prevent the future incidence of insomnia.

S3A-SPNR-3 Synthetic MRI-based Fast Gray Matter Acquisition T1 Inversion Recovery (FGATIR) Contrasts identify Neonatal Brainstem Pathways

Participants
Victor Schmidbauer, MD, Vienna, Austria (*Presenter*) Nothing to Disclose

PURPOSE

Synthetic imaging allows to retrospectively reconstruct different MR contrasts using a single acquisition of a multi-dynamic multi-echo (MDME) sequence. This study aimed to investigate the feasibility of synthetic MRI-based fast gray matter acquisition T1 inversion recovery (FGATIR) contrasts for the qualitative identification of early myelinating neonatal brainstem pathways in vivo.

METHODS AND MATERIALS

Thirty-one cases of neonatal MRI (median gestational age at birth: 27+0; range, 23+4-41+6) were collected, which included MDME sequences and conventional T1-weighted/T2-weighted sequence acquisitions as a standard-of-reference. MDME-based FGATIR contrasts (TR/TE/TI: 3000/5/410 ms) were generated using the MR data post-processing software SyMRI®. The identification of seven brainstem pathways/regions of interest was assessed on synthetic FGATIR contrasts and conventionally acquired T1-weighted/T2-weighted imaging data: decussation of superior cerebellar peduncle (DSCP); left/right medial lemniscus (ML); left/right central tegmental tract (CTT); and left/right longitudinal medial fascicle (LMF).

RESULTS

SyMRI® provided FGATIR contrasts of diagnostic quality in 31/31 cases (100%). Based on MDME-based FGATIR contrasts, the DSCP [31/31 (100%)]; left/right ML [31/31 (100%)]; left/right CTT [20/31 (65%)]; and left/right LMF [31/31 (100%)] were reliably identified. Based on conventional T1-weighted contrasts, the DSCP [14/31 (45%)]; left/right ML [25/31 (81%)/23/31 (74%)]; left/right CTT [3/31 (10%)/7/31 (23%)]; and left/right LMF [15/31 (48%)] were reliably identified. Based on conventional T2-weighted contrasts, the DSCP [30/31 (97%)]; left/right ML [30/31 (97%)/29/31 (94%)]; left/right CTT [26/31 (84%)/25/31 (81%)]; and left/right LMF [30/31 (97%)] were reliably identified.

CONCLUSION

s Synthetic generation of FGATIR contrasts enables reliable radiological identification of neonatal brainstem pathway anatomy in vivo. The investigated MR approach depicts early myelinating tracts more reliable than standard-of-reference contrasts.

CLINICAL RELEVANCE/APPLICATION

Conventional, T1- and T2-weighted-based MRI currently lacks sensitivity for the reliable assessment of delayed brain myelination in former preterm neonates - therefore, MR approaches that utilize white matter signal suppression contribute to a more sensitive evaluation of myelination patterns at early stages of cerebral development.

S3A-SPNR-4 Development of The Orbitofrontal Cortex Through Childhood and Adolescence

Participants
Zhe Guan, (*Presenter*) Nothing to Disclose

PURPOSE

The orbitofrontal cortex is an incompletely understood part of the prefrontal cortex linked to adaptive learning and executive processes and known to be key towards successful maturation through adolescence to adulthood. The purpose of this study is to evaluate age-dependence of orbitofrontal cortical volume in a large cohort of young, healthy individuals.

METHODS AND MATERIALS

High-resolution, structural T1-weighted imaging from 655 healthy individuals (8 to 21 years old) from the Human Connectome Project Development (HCP-D) Study were used. FreeSurfer v6.0.0 measures of orbitofrontal cortical volume provided as part of the HCP dataset were used as well as an investigational deep learning-based, automated segmentation tool, DenseUnet-based Automatic Rapid Tool (DARTS). Pearson correlation coefficients were calculated. Subset analysis of male and female cohorts was performed and size asymmetry was assessed using Student's t test.

RESULTS

Segmentation data are available from HCP (FreeSurfer) for 415 of the 655 subjects of this cohort. DARTS segmentation was performed in all subjects. 323 subjects (49.3%) were male.We found a significant negative correlation between total orbitofrontal volume and age ($r = -0.360$, $p < 0.00001$; $r = -0.314$, $p < 0.00001$ using FreeSurfer and DARTS, respectively). For subsegments of the orbitofrontal cortex, the correlations under FreeSurfer and DARTS respectively were $r = -0.364$, $p < 0.00001$; $r = -0.407$, $p < 0.00001$ (left lateral orbitofrontal), $r = -0.200$, $p < 0.00001$; $r = -0.033$, $p = 0.396$ (left medial orbitofrontal), $r = -0.335$, $p < 0.00001$; $r = -0.283$, $p < 0.00001$ (right lateral orbitofrontal), and $r = -0.329$, $p < 0.00001$; $r = -0.099$, $p = 0.011$ (right medial orbitofrontal).The standard deviation of the total orbitofrontal volumes was lower using DARTS (2.40 mL) compared with FreeSurfer (3.73 mL).Similar trends were observed across males and females. Size asymmetry was noted with the left lateral and medial orbitofrontal cortical volumes being larger than the right ($p < 0.0001$ using FreeSurfer and DARTS).

CONCLUSION

s Orbitofrontal cortical volume as measured on MRI decreases with age during childhood and adolescence, suggesting that development of this area is complex and may involve cortical pruning or other anatomic refinement on the way to maturation.

CLINICAL RELEVANCE/APPLICATION

The orbitofrontal cortex is implicated in the development of adaptive learning and executive responses including stimulus-reinforcer associations. These functions undergo maturation and refinement during childhood and adolescence and unveiling anatomic changes to this area contribute to our understanding of how this process unfolds, potentially aiding identification of developmental aberrations.

S3A-SPNR-5 Development of Fetal Ventricular Volume Reference Norms Using nnUNet

Participants
Minerva Zhou, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To use deep learning methods to segment and measure ventricular volume of fetal brain MRIs across a wide range of gestational ages.

METHODS AND MATERIALS

We applied nnU-Net to segment the ventricular system of 91 nonpathologic and 9 pathologic fetal brain MRIs across a variety of gestational ages (19-36 weeks). Twenty fetal brain MRIs from our institution were reconstructed to a high-resolution 3D volume using slice-to-volume reconstruction and then manually segmented and combined with the MICCAI Fetal Tissue Annotation Challenge data to generate a dataset of 100 fetal brain MRI volumes, which were randomly split into 80 training studies and 20 test studies in a 5-fold cross-validation. Performance was assessed using Dice coefficients and volume comparison to manual reference segmentation. A normative reference of ventricular volume across gestational ages was generated using the 91 nonpathologic training studies.

RESULTS

The nnU-Net predicted segmentation of fetal ventricles across gestational ages with median Dice score of 0.90 (IQR 0.88-0.93; Fig 1A). The automatically computed ventricular volume measurements were highly correlated with manual measurements (Pearson's $r=0.99$, $P<0.001$, Fig 1B). A normative range of ventricular volumes across gestational ages was developed using the automated segmentation volumes. All 9 patients with hydrocephalus were predicted to be greater than two standard deviations higher than the age-specific reference mean (Fig 1C).

CONCLUSION

s Deep learning techniques can be used to provide an objective measure of ventricular volume on fetal brain MRI and identify hydrocephalus based on a normative reference standard.

CLINICAL RELEVANCE/APPLICATION

This study explores using deep learning techniques to quickly and accurately quantify ventricular volume on fetal brain MRI and subsequently identify pathological volumes.

S3A-SPNR-6 Brain Gray Matter Connectome Disorganization in Social Anxiety Disorder

Participants
Xun Zhang, (*Presenter*) Nothing to Disclose

PURPOSE

Phenotyping approaches grounded in structural network science can offer advanced insights into neurobiological substrates of psychosis, but this remains to be clarified at the individual level in social anxiety disorder (SAD). Herein, we aimed to investigate the topological organizations of individual structural covariance networks using a novel approach in a homogenous sample of SAD patients, and assess their potential clinical relationship and diagnostic value.

METHODS AND MATERIALS

Forty-nine non-comorbid adult patients with SAD and fifty-three demographically-matched healthy controls (HC) were recruited to obtain clinical evaluation and 3.0-Tesla high-resolution T1-weighted images. We constructed single-subject structural covariance networks based on multivariate morphometry (i.e., cortical thickness, surface area, curvature, and gray matter volume) using a recent novel approach combining probability density estimation and Kullback-Leibler divergence, and estimated their global and nodal network properties via graph theory analysis. Network metrics were compared between SAD and HC groups, and the relationship to clinical characteristics was analyzed. Furthermore, exploratory support vector machine analyses were conducted to discriminate SAD from HC.

RESULTS

Globally, SAD patients showed significantly altered topological characteristics, including higher global efficiency, shorter characteristic path length, and stronger small-worldness. Locally, SAD patients exhibited abnormal nodal degree and efficiency mainly involving left superior frontal gyrus, right superior parietal lobe, right paracentral gyrus, right lingual, right pericalcarine cortex, and left amygdala. Furthermore, altered global and nodal topological metrics were associated with the symptom severity and disease duration in SAD cohort, suggesting a pathophysiological relevance. Graph-based metrics allowed single-subject classification of SAD versus HC with significant accuracy, indicating potential diagnostic efficacy.

CONCLUSION

s The topological organization of structural covariance networks was disrupted in SAD in a way that suggests compensatory greater integration of information processing with a more randomly organized brain network, which may extend neurobiological understandings of a system-level brain maturational disruption in SAD.

CLINICAL RELEVANCE/APPLICATION

These results provide structural network insights into the neurobiology of SAD, and may navigate the development of reliable and objective neuroanatomical biomarkers for clinical diagnosis, targeted intervention, and therapeutic efficacy evaluation in SAD.

S3A-SPNR-7 Pediatric Low-Grade Glioma Molecular Subtype Identification Based on 3D Probability Distributions of Tumor Location in MRI

Participants
Farzad Khalvati, PhD, MSc, Toronto, ON (*Presenter*) Board of Directors, MESH Scheduling Inc

PURPOSE

Genetic marker identification of pediatric Low-Grade Glioma (pLGG) is crucial for early prognostication and individualized treatment planning. We propose a method to exploit tumor location in MRI data to identify the most common pLGG subtypes (BRAF V600E mutation vs. BRAF fusion) without using any other information.

METHODS AND MATERIALS

In this REB-approved retrospective study, Fluid-Attenuated Inversion Recovery (FLAIR) sequences of the baseline MRI from 200 patients with pLGG acquired between Jan. 2000 and Dec. 2018 were included. Tumor segmentations were provided by a pediatric neuroradiology fellow and verified by a senior pediatric neuroradiologist. The ground truth molecular subtype labels (BRAF V600E mutation and BRAF fusion) were obtained through biopsy.To build the probability density functions (PDF) of BRAF V600E mutation and BRAF fusion, the 3D binary masks of segmentation in FLAIR images for each class in the training dataset were added together and then normalized. In the test cohort, the probabilities of belonging to each class were calculated by a voxel-wise multiplication of the binary segmentation mask of the test case and the 3D PDF of the corresponding class in the training dataset. We repeated the data split (80/20 for training and test) 100 times and calculated the Area Under ROC Curve (AUROC).

RESULTS

Using only location of the tumor in the FLAIR images, we achieved a mean AUROC of 0.783 with a 95% Confidence Interval (CI) of (0.769, 0.798) over 100 experiments for the classification of BRAF V600E mutation vs. BRAF fusion in pLGG.

CONCLUSION

s 3D PDFs of tumor subtypes can help create a location-based pipeline for molecular subtype identification of pLGG. While location is ignored in the majority of radiomics and neural-network-based classification models, our results show BRAF V600E mutation and BRAF fusion in pLGG tumors follow different location distributions, which can be utilized for subtype identification.

CLINICAL RELEVANCE/APPLICATION

The location-based subtype identification of pLGG can be used as a stand-alone classifier or as an adjunct to Artificial Intelligence based classification models to allow imaging-based molecular characterization.

S3A-SPNR-8 MRI Alterations in Patients with Psychogenic Non-epileptic Seizures: Prevalence, Distribution and Classification of The Findings

Participants
Aleix Jareno Badenas, MD, Sant Vicenc de Castellet, Spain (*Presenter*) Nothing to Disclose

PURPOSE

Psychogenic non-epileptic seizures (PNES) are paroxysmic episodes that mimic epileptic seizures without electroencephalographic representation. Conversive psychiatric origin is attributed to this kind of episode. However, beyond this psychiatric perspective, the possible neurobiological basis of PNES has not received much attention. Some studies have documented structural and functional alterations in these patients, but without consistent results to support a causative hypothesis. The objectives of this study are:-

To evaluate the MRI findings in patients with PNES- To classify the results- To evaluate a possible structural basis of these episodes

METHODS AND MATERIALS

We performed a retrospective analysis of the MRI studies conducted on patients of our epilepsy unit with a confirmed diagnosis of only PNES or PNES and epilepsy (PNES+epilepsy). A descriptive study of the findings in both groups was performed and compared with the incidental findings in the general population obtained from the literature. The radiologic findings were classified into: vascular, tumoral, posttraumatic/gliotic, small vessel, cortical, hippocampal sclerosis, unspecific or normal studies, as well as into epileptogenic and non-epileptogenic.

RESULTS

Our study population was formed of 60 patients with a confirmed diagnosis of PNES and 16 patients with PNES+epilepsy (75% women, 25% men, mean age at diagnostic of 41 years). 55% of patients with PNES and 81% with PNES+epilepsy had a pathological finding. These findings were considered epileptogenic in 13% of the PNES group and in 31% of the PNES+epilepsy group. The most frequent findings in patients with were unspecific, vascular and hippocampal sclerosis, whilst in the PNES+epilepsy group were unspecific, hippocampal sclerosis and small vessel.

CONCLUSION

s Patients with PNES have a higher prevalence of abnormalities in MRI than the general population (around 18% according to existing literature) and this prevalence is even higher when PNES are associated with epilepsy. There is a higher prevalence of PNES among women.

CLINICAL RELEVANCE/APPLICATION

Our study shows higher prevalence of MRI structural findings in patients with PNES than in the general population, suggesting a neurobiological/structural basis in a pathology considered psychiatric.

S3A-SPNR-9 The Individual Association Between Functional and Morphological Asymmetry During Fetal Brain Development observed in In-utero MRI

Participants
Georg Langs, Vienna, Austria (*Presenter*) Co-founder, contextflow GmbH Shareholder, contextflow GmbH

PURPOSE

While function is shaped and constrained by brain structure, there is also possible impacts of functional activity on morphology. At the early stages of life, this relationship is particularly dynamic due to maturational processes and rapid conformational changes of the fetal brain. Cross-sectional studies in the early infancy and newborns suggest that the impaired development of cerebral morphology may promote the recruitment of alternative axonal pathways to sustain function, affecting the integration and specification of functional circuits at both cortical and sub-cortical levels. However, little is known about their complex interplay at the developmentally critical period in utero. Here, we assess the individual association of structural and functional brain development in the fetus.

METHODS AND MATERIALS

Resting-state fMRI and consecutive T2-weighted scans were acquired for 72 singleton fetuses between 19 and 39 weeks of gestation. Data were processed by customized functional- and anatomical image processing pipelines including irregular fetal movement correction, age-specific segmentation, and atlas registration. Individualized functional connectivity (FC) matrices were obtained by correlating regional brain activity over time and individualized local surface folding was quantified by measuring gyrification index (GI). We calculated the morphological and functional laterality indices for each individual subject as the normalized difference of GI and of FC degree between the hemispheres, respectively. The P-values for all evaluations were corrected for multiple comparisons using Benjamini-Yekutieli procedure.

RESULTS

After computational quality benchmarking, 24 cases were excluded and the final study cohort consisted of 48 fetuses that had no confirmed brain abnormalities (mean gestational age ±SD: 28.97±4.84 weeks). We found significant leftward laterality in Temporal-Superior ($p=0.043$), Temporal-Medial ($p=0.047$), and Temporal-Inferior ($p=0.048$) regions after correcting for multiple comparisons. Statistical tests of the functional asymmetry did not reach statistical significance for the rest of cortical regions. Significant morphological asymmetry was found in medial wall ($p=0.0089$) and mesial frontal region ($p=0.003$). We observed significant individual association between functional- and morphological asymmetry in the limbic area ($p<0.001$ corrected)

CONCLUSION

s Our results support the hypothesis that a significant relationship between brain structure and function is present during prenatal brain development.

CLINICAL RELEVANCE/APPLICATION

It may lead to a better understanding of the neural mechanisms involved in adverse outcomes.

Morphologic, Microstructural, and Connectomic Correlates of Attention-Deficit/Hyperactivity Disoder in Adolescents

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - NR DPS

Participants
Huang Lin, New Haven, CT (*Presenter*) Nothing to Disclose

PURPOSE

To investigate microstructural, morphological, and functional connectivity correlates of ADHD on brain MRI of adolescents.

METHODS AND MATERIALS

We retrieved the imaging and clinical information of 1,830 subjects with ADHD and 6,067 without ADHD from the ABCD (https://abcdstudy.org/) database of 11,876 adolescents - participants' average (SD) age was 118.94 (7.46) months. We excluded those with incomplete clinical information, history of traumatic brain injury, and failure to pass image quality control. In multivariate logistic regression adjusted for age and sex, we examined the association of ADHD with different neuroimaging metrics. The neuroimaging metrics included fractional anisotropy (FA), neurite density (ND), mean-(MD), radial-(RD) and axial diffusivity (AD) of white matter (WM) tracts, cortical region thickness and surface areas from T1-MPRAGE series, and functional network connectivity correlations from resting-state fMRI. We applied False Discovery Rate (FDR) to correct for multiple comparisons. We also optimized, trained, tested, and validated different combinations of machine learning classifiers and feature selection algorithms for prediction of ADHD.

RESULTS

Individuals with ADHD had a significantly (adjusted $p<0.05$) lower FA and ND but higher MD and RD -predominantly in left hemispheric WM tracts compared to those without ADHD. Presence of ADHD was associated with reduced cortical regions, especially in the right middle temporal gyrus (adjusted $p<0.001$). The auditory-, cingulo-parietal, ventral-/dorsal-attention and default-network differed between those with and without ADHD. In repeated 10-fold cross-validation, a combination of elastic net logistic regression with hierarchical clustering feature selection yielded the highest and most stable performance, attaining an AUC of 0.6085, 95% CI [0,5757, 0,6414], in predicting ADHD in an independent validation set.

CONCLUSION

s Abnormal functional connectivity, involving networks related to memory processing, tonic alertness, and the auditory process, thinning of brain cortex, and WM tract neural fiber loss and microarchitectural disintegrity are markers of adolescents' ADHD. Multi-modal neuroimaging metrics can be used as input for machine learning models to support identification of at-risk children.

CLINICAL RELEVANCE/APPLICATION

Using a large population cohort, we elucidated the underlying neurobiology of adolescents' ADHD and suggest a possible role for neuroimage-based machine-learning models to assist with diagnosis.

S3A-SPNR-10

The Influence of Alcohol On In Utero Brain Development: A Structural Fetal MRI Study

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - NR DPS

Participants
Patric Kienast, Wien, Austria (*Presenter*) Nothing to Disclose

PURPOSE

Alcohol consumption during pregnancy affects brain development leading to a variety of behavioral and cognitive disorders. However, early structural alterations of fetal brain development have not yet been systematically studied. This prospective single center fetal MRI study aims is to assess the effects of alcohol exposure on brain development.

METHODS AND MATERIALS

After inclusion of 20 fetal MRI studies of fetuses with prenatal alcohol exposure (PAE, 22+1 - 36+4 weeks of gestation (GW)) due to the standardized systematic questionnaires (TACE and PRAMS). These cases were 1:1 age-matched to a healthy control case.Brain maturation was assessed by using the fetal total maturation score (fTMS) (Vossough et al. 2013) based on superresolution-postprocessed T2- weighted/SSFP sequences in 3 planes (1.5T). In addition, the depth of temporal and occipital sulci and the expression of fetal brain asymmetry in the temporal lobe were quantified.

RESULTS

In PAE fetuses, the fTMS score was significantly lower ($p=0.007$) and the right superior temporal sulcus (STS) was shallower ($p<0.001$). Delayed fetal brain development could be specifically related to an age inappropriate/delayed stage of myelination and less distinct gyrification in the frontal and occipital lobes ($p=0.04$).

CONCLUSION

s This fetal MRI study revealed an early impact of PAE on structural fetal brain maturation and development. In addition to alterations of the periventricular zone and the corpus callosum detectable by atlas based analysis (Stuempflen et al. RSNA 2021), this study emphasizes early and diffuse alterations to fetal structural brain development and delayed brain maturation in fetuses affected by maternal alcohol consumption.

CLINICAL RELEVANCE/APPLICATION

Identification of the teratologic toxic effects on human brain development opens new diagnostic opportunities for fetal neuroradiology, allowing early postnatal support programs in these cases and stimulating the discussion of alcohol prevention during pregnancy to promote public health.

Evaluation of Glymphatic System Activity Using Diffusion Tensor Image Analysis Along the Perivascular Space (DTI-ALPS) in Cognitively Normal Older Adults: Correlation with Amyloid PET

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - NR DPS

Participants
Chae Jung Park, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Diffusion Tensor Image-Analysis aLong the Perivascular Space (DTI-ALPS) is a recently introduced method for the assessment of glymphatic system without need for contrast injection. In this study, we aimed to evaluate the glymphatic system in cognitively normal elderly adults using DTI-ALPS, by correlating it with amyloid PET.

METHODS AND MATERIALS

In this prospective study, total 123 cognitively normal elderly adults with or without subjective cognitive decline (SCD) were recruited through advertisement in communities. They performed baseline cognitive test, MRI and PET. On DTI-MRI, the diffusivities along x-, y-, and z-axes were measured, and the ALPS-index was calculated. To measure the amyloid deposition from PET, standardized uptake value ratios (SUVR) were calculated from variable cortical regions. The differences in the ALPS-index between normal and SCD group were compared using the Mann-Whitney test. Pearson's correlation was used to analyze the correlation between ALPS-index and SUVRs. Multiple linear regression was performed to assess the association between ALPS-index and other relevant variables - age, duration of education, Mini-Mental State Examination score, presence of Apolipoprotein e4 allele and SUVRs.

RESULTS

Among total 123 subjects, 63 were asymptomatic (mean age, 73.0 years ± 4.2 [standard deviation], 43 men) and 60 had SCD (mean age, 73.7 years ± 3.5, 41 men). The ALPS-index was not significantly different between the normal and SCD group (1.34 ± 0.13 vs. 1.34 ± 0.12, P = 0.897). Among SUVRs from variable cortices, SUVR from paracentral cortex was the only variable which was negatively correlated with ALPS-index (r = -0.218, P = 0.016, figure). Multiple linear regression revealed that older age (coefficient, -0.007) and increased SUVR from paracentral cortex (coefficient, -0.101) were the two independent variables which had significant association with lower ALPS-index (P = 0.015 and 0.049, respectively).

CONCLUSION

s The ALPS-index was not significantly different between the normal and SCD group. Correlating DTI-ALPS with amyloid PET revealed that increased amyloid deposition in the paracentral cortex was significantly associated with lower ALPS-index, which gives the notion that the clearance in paracentral cortex might play an important role in the glymphatic system.

CLINICAL RELEVANCE/APPLICATION

In this study, we correlated DTI-ALPS with amyloid PET in cognitively normal elderly adults for better understanding of glymphatic system. We found that older age and increased amyloid deposition in the paracentral cortex identified from PET were significantly associated with lower ALPS-index. It implies that the clearance in paracentral cortex might have a significant impact on glymphatic system.

Analysis of Neurite Orientation Dispersion and Density Imaging (NODDI) Parameters for Assessing the Hippocampal Neurodegenerative Progression in Early Alzheimer's Disease, Compared to Cerebrospinal Fluid (CSF) Level of Phosphorylated tau (P-tau)

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - NR DPS

Participants
Hiroto Takahashi, MD, Suita, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Cerebrospinal fluid (CSF) phosphorylated tau (p-tau) is sensitive to neurodegeneration in Alzheimer's disease (AD), but its measurement is invasive. Neurite orientation dispersion and density imaging (NODDI) is a diffusion magnetic resonance imaging (MRI) technique which assumes a three-compartment (intracellular, extracellular, and CSF) biophysical tissue model for each voxel, and can provide specific data on neuronal changes. We aimed to explore the imaging biomarker that supports the CSF biomarker for evaluating disease progression in early AD.

METHODS AND MATERIALS

Sixty-nine patients with mild cognitive impairment underwent both CSF measurement of Aß42 and p-tau and multi-shell diffusion MRI at 3T. Based on the CSF Aß42 and p-tau values, 35 patients with AD pathology (group AD) were discriminated from 34 patients with non-AD pathology (group non-AD). The NODDI and diffusion tensor imaging (DTI) parametric maps were generated from the obtained diffusion MRI data. Two neuroradiologists created the region of interest (ROI) of each side of hippocampus, separately. The hippocampal values were calculated using the ROIs. Inter-ROI value correlations between two neuroradiologists were calculated for the intraclass correlation coefficients (ICCs). Correlations between each hippocampal value and the CSF p-tau value were assessed using Pearson's correlation analysis.

RESULTS

Almost all the ICCs were substantial or almost perfect, besides the ICCs of the NODDI-derived isotropic volume fraction, throughout the group. There were significant correlations between the NODDI-derived orientation dispersion index (ODI) of the right hippocampal ROIs and the CSF p-tau value in the group AD ($P < 0.05$), whereas no significant correlation was shown in any other hippocampal value. The NODDI-derived intracellular volume fraction, the DTI-derived fractional anisotropy and axial diffusivity correlated weakly with the CSF p-tau value in the group AD.

CONCLUSION

s Present hippocampal ROI analysis indicated that diffusion MRI parameters, especially the right hippocampal ODI, might support the CSF p-tau measurement and be useful biomarker for evaluating disease progression in early AD.

CLINICAL RELEVANCE/APPLICATION

The hippocampal NODDI parameter might be a useful imaging biomarker for assessing neurodegenerative progression with the CSF p-tau elevation in early AD.

S3A-SPNR-14

Cognitive Impairment and Amygdala Sub-regions Atrophy in Patients with End-stage Renal Disease

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - NR DPS

Participants
Yuan Li, Dalian, China (*Presenter*) Nothing to Disclose

PURPOSE

Cognitive dysfunction is prevalent in end-stage renal disease (ESRD) patients, and the amygdala plays an important role in cognition. This study aimed to compare the volume of the amygdala subregions between ESRD patients and healthy controls (HCs), and to analyze the correlations of subregion volumes with cognitive function.

METHODS AND MATERIALS

Forty-nine ESRD patients and 41 age, gender, education matched HCs were recruited. All subjects were scanned using a 3T MRI to acquire 3D T1 anatomical images. Automatic volumetric measurement of the amygdala subregions was done using FreeSurfer 7.0. The amygdala was segmented, bilaterally, into the lateral nucleus, basal nucleus, accessory basal nucleus, anterior amygdaloid area, central nucleus, medial nucleus, cortical nucleus, corticoamygdaloid transition area, and paralaminar nucleus (Figure 1). Thirty-four ESRD patients and 16 HCs underwent neuropsychological examinations. The amygdala subregion volumes and cognitive test results were compared between the two groups using an independent sample t-test. Partial correlation analysis was used to assess correlations between the amygdala subregion volumes and cognitive test scores in the ESRD group, with sex, age and education level as covariates.

RESULTS

The volumes of the amygdala subregions were decreased in the ESRD group (Figure 2-3), especially the bilateral accessory basal nucleus (left: P=0.028, right: P=0.019) and bilateral corticoamygdaloid transition area (left: P=0.033, right: P=0.009)(Table 1). Compared with HCs, ESRD patients had lower MoCA (P<0.001) and DSST (P=0.030) scores but higher TMT-B (P=0.017), HAMA (P=0.030) and HAMD (P=0.001) scores (Table 2). The partial correlation analysis showed that the volume of the right lateral nucleus was negatively correlated with TMT-A scores (P=0.010, r=-0.390), as well as those of the left paralaminar nucleus, the right basal nucleus and the right paralaminar nucleus were positively correlated with immediately recall scores (P=0.047, r=0.305; P=0.046, r=0.306; P=0.036, r=0.321).

CONCLUSION

s ESRD patients are accompanied by cognitive impairment, anxiety and depression. Patients with ESRD develop atrophy of the amygdala subregions, which is related to impaired visuospatial function and short-term memory performance.

CLINICAL RELEVANCE/APPLICATION

Previous studies were based on the overall amygdala structure, but since the amygdala consists of several subregions, it cannot accurately reflect the subtle changes by measuring the whole volume of the amygdala. Therefore, it is essential to further explore the effects of specific substructures by automatic volumetric segmentation of the amygdala subregions, which is a stable and reproducible quantitative measurement.

S3A-SPNR-15

Correlation Hippocampal Subfields Alterations and Metabolic-neurologic Changes in Patients with Type 2 Diabetes Mellitus

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - NR DPS

Participants
Jiajun Cao, (*Presenter*) Nothing to Disclose

PURPOSE

To explore the changes of the volume and asymmetry of hippocampal subfields in patients with type 2 diabetes mellitus and the correlation between the significantly atrophied regions of the hippocampal subfields and clinical data, laboratory indicators, cerebral small vessel diseases scores and cognitive scores was analyzed.

METHODS AND MATERIALS

Thirty-one patients with T2DM and 24 volunteers as the control group were prospectively recruited into this present study. T1WI, T2WI, T2Flair and 3DT1WI sequences were performed using Philips Ingenia CX3.0TMRI scanner. The clinical data and laboratory indicators of all subjects were recorded, including gender, age, height, weight, waist circumference, hip circumference, systolic blood pressure, diastolic blood pressure, education level, insulin, fasting glucose, glycated hemoglobin, total cholesterol , triglyceride , low density lipoprotein , high density lipoprotein , homocysteic acid . Meanwhile, body mass indexand waist hip ratio were calculated. CSVD MRI features of all subjects were scored quantitatively including: periventricular hyperintense and deep white matter hyperintense grades, basal ganglia enlarged perivascular space and centrum-semiovale enlarged perivascular space grades, the grade of lacune and the grade of cerebral microbleed , and the CSVD total burden scores were calculated .Detailed neuropsychological scale assessment was performed on all subjects, including the mini-mental state examination, Montreal cognitive assessment , California verbal learning test, symbol digit modalities test.FreeSurfer(version6.0.0,http://surfer.nmr.mgh.harvard.edu/) software was used for imaging post-processing. The volume of all subjects' hippocampal subfields and hippocampal asymmetry index were calculated.

RESULTS

Compared with the control group, the volumes of left presubiculum, left fimbria and left hippocampal amygdala transition area were significantly decreased in the T2DM group (p=0.041,p=0.048,p=0.030), HAI decreased in cornu ammonis 1,but increased in HATA area (p=0.029,p=0.023).Partial correlation analysis was carried out between the volume of left presubiculum, left fimbria, left HATA volume and clinical data, laboratory indicators, cognitive score and CSVD quantitative score, age, gender and years of education were taken as covariates .

CONCLUSION

s The atrophy of hippocampal subfields is asymmetric, and the volume of hippocampal subfields is closely related to metabolic syndrome, increased burden of CSVD and decline of cognitive function.

CLINICAL RELEVANCE/APPLICATION

The atrophy of hippocampal subfields is asymmetric, and the volume is closely related to metabolic syndrome, increased burden of CSVD and decline of cognitive function.

Connectome-based Models Predict Cognitive Functions in Systemic Lupus Erythematosus

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - NR DPS

Participants
Jiaying Mo, (*Presenter*) Nothing to Disclose

PURPOSE

Systemic lupus erythematosus (SLE) is a mainly female inflammatory autoimmune disorder that can affect the central nervous system and cognitive functions in up to 80% of patients. This study aims to investigate whether the topological network of functional connectivity can predict the performance of neuropsychological tests in different domains, using connectome-based predictive modeling (CPM).

METHODS AND MATERIALS

We evaluated 61 SLE patients who underwent a resting-state functional MRI scanning in a Philips Achieva 3T MRI system and a comprehensive neuropsychological assessment for the four cognitive domains of verbal, visuospatial, visual memory, and attention. According to the Brainnetome atlas, ROI-based functional connectivity analysis was employed to extract the whole-brain functional networks. CPM with leave-one-out cross-validation was conducted to identify different networks that predicted the performance of neuropsychological tests. The predictive ability of identified networks would be tested in an independent sample of patients who were scanned in a different 3T MRI system (uMR 780, United Imaging Healthcare, Shanghai, China).

RESULTS

Four CPM models enabled prediction of neuropsychological scores for unseen subjects in cross-validation, with Pearson's correlation coefficients r of 0.40-0.48 (all p values < 0.001). In these four cognitive function predictions, brain connectivities that show top contributing power commonly concentrated on the hippocampus, parahippocampal gyrus, superior frontal gyrus, medial frontal gyrus, inferior parietal lobule, and insula, which were the key nodes of the default-mode network and salience network. Moreover, the CPM models based on these important brain regions could predict overall cognitive ability (MoCA score; $r = 0.45$, $p < 0.001$).

CONCLUSION

s Our results provide preliminary evidence that different functional networks with overlapping of important brain regions including frontal lobe, parietal lobe, insular lobe and several subcortical regions may contribute to cognitive ability of various domains and allow to predict the corresponding cognitive functions in SLE.

CLINICAL RELEVANCE/APPLICATION

CPM identified brain networks that underlie different cognitive functions in individuals and these "neural fingerprints" could potentially assist the diagnosis of cognitive dysfunction in SLE.

S3A-SPNR-18

Associations of Cortical Iron Accumulation with Cognition and Cerebral Atrophy in Alzheimer's Disease

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - NR DPS

Participants
Aocai Yang, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

Cerebral iron accumulation is consistently observed in Alzheimer's disease and co-localizes with the pathological proteins—amyloid-ß and tau. We aimed to investigate the whole-brain distributional pattern of cortical iron deposition and its relationships with cognition and cortical thickness in Alzheimer's disease via Quantitative Susceptibility Mapping (QSM).

METHODS AND MATERIALS

We prospectively recruited 30 participants with Alzheimer's disease (AD) and 26 age- and sex-matched healthy controls (HC) in this cross-sectional study. All the participants underwent QSM and structural T1 examinations on 3.0T MRI scanner. Mini-Mental State Examination (MMSE) and Montreal Cognitive Assessment (MoCA) were used to assess the global cognitive level. The whole-brain cross-sectional QSM analysis and the whole-brain QSM regression analyses against MMSE and MoCA scores were performed. Additionally, we conducted a surface-based morphometry analysis. Subsequently, in the significant atrophy regions, we compared the magnetic susceptibility between two groups and assessed the association of magnetic susceptibility with cortical thickness.

RESULTS

The whole-brain QSM cross-sectional analysis demonstrated that widespread susceptibility increased in AD across the cortical ribbon, asymmetrically covering left hemisphere cerebral cortex, caudate nucleus, putamen and partial cerebellar cortex. The whole-brain QSM regression analyses showed increased susceptibility that covaried with lower MMSE and MoCA scores in AD, and was predominantly located in the right parietal cortex and lateral occipital cortex. The reduced cortical thickness was located in the left superior temporal, right frontal pole, fusiform and pars opercularis in AD and the corresponding susceptibility increased in right frontal pole (AD:0.034±0.007ppm, HC:0.030±0.005ppm; P=0.016) and pars opercularis (AD:0.020±0.003ppm, HC:0.017±0.002ppm; P=0.002). Susceptibility was negatively correlated with cortical thickness in right pars opercularis in both entire cohort(r=-0.521, P<0.001) and AD (r=-0.510, P= 0.005).

CONCLUSION

s Widespread cortical iron, measured by QSM, accumulated in Alzheimer's disease and was associated with poor cognitive performance. Increased iron content was associated with brain atrophy in AD. QSM may be a useful imaging biomarker to monitor the neurodegenerative progression of AD.

CLINICAL RELEVANCE/APPLICATION

Increased iron content was associated with cortical atrophy and cognitive level in Alzheimer's disease. These may be useful to monitor the disease progression and cognitive severity of Alzheimer's disease at the whole brain level in vivo, and provide new insights into the application of QSM as a disease biomarker.

S3A-SPNR-19

Classification of Major Depression Disorder Based on Integrated Temporal and Spatial Variability Features of Dynamic Brain Networks

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - NR DPS

Participants
Qun Gai, (*Presenter*) Nothing to Disclose

PURPOSE

The dynamics of brain networks has been a focus in the study of depression in recent years. However, most previous studies focused on single temporal dimension only, ignoring spatial dimension information. The present study aimed to integrate temporal and spatial variability features of dynamic brain networks to distinguish patients with major depressive disorder (MDD) from healthy controls (HC).

METHODS AND MATERIALS

245 MDD subjects and 230 well-matched HC were recruited in this study (the discovery cohort: 119 MDD and 106 HC, the validation cohort: 126 MDD and 124 HC). Temporal and spatial variability features were extracted from dynamic brain networks as features. A two-level feature selection strategy and random forest (RF) were employed for classification. Two other classifiers were also applied to validate our model. Furthermore, a linear regression model for assessing MDD symptom severity was established based on above selected temporal and spatial features.

RESULTS

Our model based on the integration of temporal and spatial variability features achieved the best performance with an accuracy of 93.33% (an accuracy of 83.40% for an independent sample). Moreover, features with high discriminative power to distinguish MDD from HC showed strong association with the visual network (VIS) and cognitive control network (CCN). Importantly, altered temporal and spatial variability could predict depression and anxiety severity of MDD.

CONCLUSION

s Our results demonstrate that integrating temporal and spatial variability features can discriminate MDD from HC with a high classification performance and suggest that spatiotemporal dynamics may explain underlying neurobiological mechanism of MDD symptoms.

CLINICAL RELEVANCE/APPLICATION

Our findings provide direct evidence that spatiotemporal dynamics could be used as effective biomarkers for clinical diagnosis of MDD and may play an important role in detecting depression and anxiety symptom severity of MDD.

S3A-SPNR-2

Evaluation and Clinical Validation of a Deep Learning Algorithm for Predicting Delayed Myelination in Infant Brains from MRI

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - NR DPS

Participants
Gunvant Chaudhari, BS, San Francisco, CA (*Presenter*) Nothing to Disclose

PURPOSE

Assisting diagnosis of infant delayed myelination by creating a convolutional neural network (CNN) capable of predicting delayed myelination based on routine clinical T1T2-weighted brain MRIs.

METHODS AND MATERIALS

MRIs were obtained from our institutional clinical database. Patients aged 0-25 months with reportedly normal myelination from 1995-2019 (n=5028) and delayed myelination from 1995-2021 (n=426) were included. For normal myelination MRIs, exclusion criteria included uneven age distribution (N=2659), myelination at the lower limits of normal (N=46), missing gestationally corrected age (GCA, N=1352), poor automated skullstripping or registration (N=103), and lack of T1 or T2 imaging (N=252). For delayed myelination MRIs, MRIs missing GCA (N=162), with poor automated skullstripping or registration (N=19), and without T1 or T2 imaging (N=121) were excluded. The CNN had input of paired, registered T1 T2 MRIs and GCA and was trained to predict delayed myelination status. Results from 10-fold cross-validation are reported. For a clinical benchmark, 3 neuroradiologists with 3-24 years of experience in pediatric neuroradiology blindly interpreted 30 randomly sampled MRIs, 15 normal and 15 delayed myelination, and assigned numerical values corresponding to confidence of delayed myelination (Figure 1). Ground-truth myelination status was defined as the average of 3 radiologists' and report label values.

RESULTS

The dataset consisted of 616 infant brain MRIs with normal myelination and 124 with delayed myelination. The CNN had an area under the receiver operator characteristic curve (AUC) of 0.77 (95% CI: 0.70-0.84) in cross-validation. In the subset of cases selected for the ready study, the CNN had an AUC of 0.83 (95% CI: 0.66-0.96) compared to 3 neuroradiologists with AUCs of 0.65 (0.45-0.84, p=0.19), 0.66 (0.46-0.85, p=0.19), and 0.78 (0.65-0.90, p=0.60), respectively.

CONCLUSION

s A CNN can recognize infant delayed myelination using T1- and T2-weighted brain MRI and GCAs, with performance similar to clinical neuroradiologists.

CLINICAL RELEVANCE/APPLICATION

Determining delayed myelination on infant brain MRI is subjective, especially for radiologists without high volume practice in pediatric neuroradiology. An AI system can aid radiologists in this task.

Hippocampal Atrophy in Neurofunctional Subfields in Chronic Insomnia

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - NR DPS

Participants
Yang Yang, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the pattern of volume changes in neurofunctional hippocampal subfields in patients with chronic insomnia (PIs).

METHODS AND MATERIALS

A total of 120 PIs (78 females, 42 males; mean age± std, 43.74 ± 13.02 years) and 120 good sleepers (60 females, 60 males; mean age, 42.69 ± 12.24 years) were recruited. The left hippocampus was segmented into anterior (L1), middle (L2), and posterior (L3) subregions. The right hippocampus was segmented into top anterior (R1), second top anterior (R2), middle (R3), posterior (R4), and last posterior (R5) subregions. Multivariate Logistic regression was used to evaluate hippocampal subfields and the associations with the risk of chronic insomnia. Mediation analyses evaluated mediated associations with post-insomnia negative emotion, insomnia severity, and hippocampal atrophy. A visual easy-to-deploy risk nomogram was used for individual prediction of insomnia risk. All statistical analyses were performed using Matlab; P <0.05 was considered a statistically significant difference.

RESULTS

Hippocampal atrophy was identified in the L1, R1, and R2. L1 and R2 atrophy each predisposed to an approximate 3-fold higher risk of chronic insomnia (L1, OR: 2.90, 95% CI: [1.24, 6.76], P= 0.014; R2, 2.72 [1.19, 6.20], P= 0.018). Anxiety fully mediates the causal insomnia path, leading to R1 volume atrophy on positive affect. We developed a practical and visual competing risk-nomogram tool for individual prediction of insomnia risk, which stratifies individuals into different levels of insomnia risk with the highest prediction accuracy of 97.4% and an average C-statistic of 0.83.

CONCLUSION

s Chronic insomnia is associated with hippocampal atrophy in specific neurofunctional subfields that are risk factors for chronic insomnia.

CLINICAL RELEVANCE/APPLICATION

These findings could broaden our understanding of the etiology of insomnia, help individuals identify their potential risk profile, and guide individuals to take precise actions ipromptly to prevent the future incidence of insomnia.

S3A-SPNR-3

Synthetic MRI-based Fast Gray Matter Acquisition T1 Inversion Recovery (FGATIR) Contrasts identify Neonatal Brainstem Pathways

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - NR DPS

Participants
Victor Schmidbauer, MD, Vienna, Austria (*Presenter*) Nothing to Disclose

PURPOSE

Synthetic imaging allows to retrospectively reconstruct different MR contrasts using a single acquisition of a multi-dynamic multi-echo (MDME) sequence. This study aimed to investigate the feasibility of synthetic MRI-based fast gray matter acquisition T1 inversion recovery (FGATIR) contrasts for the qualitative identification of early myelinating neonatal brainstem pathways in vivo.

METHODS AND MATERIALS

Thirty-one cases of neonatal MRI (median gestational age at birth: 27+0; range, 23+4-41+6) were collected, which included MDME sequences and conventional T1-weighted/T2-weighted sequence acquisitions as a standard-of-reference. MDME-based FGATIR contrasts (TR/TE/TI: 3000/5/410 ms) were generated using the MR data post-processing software SyMRI®. The identification of seven brainstem pathways/regions of interest was assessed on synthetic FGATIR contrasts and conventionally acquired T1-weighted/T2-weighted imaging data: decussation of superior cerebellar peduncle (DSCP); left/right medial lemniscus (ML); left/right central tegmental tract (CTT); and left/right longitudinal medial fascicle (LMF).

RESULTS

SyMRI® provided FGATIR contrasts of diagnostic quality in 31/31 cases (100%). Based on MDME-based FGATIR contrasts, the DSCP [31/31 (100%)]; left/right ML [31/31 (100%)]; left/right CTT [20/31 (65%)]; and left/right LMF [31/31 (100%)] were reliably identified. Based on conventional T1-weighted contrasts, the DSCP [14/31 (45%)]; left/right ML [25/31 (81%)/23/31 (74%)]; left/right CTT [3/31 (10%)/7/31 (23%)]; and left/right LMF [15/31 (48%)] were reliably identified. Based on conventional T2-weighted contrasts, the DSCP [30/31 (97%)]; left/right ML [30/31 (97%)/29/31 (94%)]; left/right CTT [26/31 (84%)/25/31 (81%)]; and left/right LMF [30/31 (97%)] were reliably identified.

CONCLUSION

s Synthetic generation of FGATIR contrasts enables reliable radiological identification of neonatal brainstem pathway anatomy in vivo. The investigated MR approach depicts early myelinating tracts more reliable than standard-of-reference contrasts.

CLINICAL RELEVANCE/APPLICATION

Conventional, T1- and T2-weighted-based MRI currently lacks sensitivity for the reliable assessment of delayed brain myelination in former preterm neonates - therefore, MR approaches that utilize white matter signal suppression contribute to a more sensitive evaluation of myelination patterns at early stages of cerebral development.

S3A-SPNR-4

Development of The Orbitofrontal Cortex Through Childhood and Adolescence

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - NR DPS

Participants
Zhe Guan, (*Presenter*) Nothing to Disclose

PURPOSE

The orbitofrontal cortex is an incompletely understood part of the prefrontal cortex linked to adaptive learning and executive processes and known to be key towards successful maturation through adolescence to adulthood. The purpose of this study is to evaluate age-dependence of orbitofrontal cortical volume in a large cohort of young, healthy individuals.

METHODS AND MATERIALS

High-resolution, structural T1-weighted imaging from 655 healthy individuals (8 to 21 years old) from the Human Connectome Project Development (HCP-D) Study were used. FreeSurfer v6.0.0 measures of orbitofrontal cortical volume provided as part of the HCP dataset were used as well as an investigational deep learning-based, automated segmentation tool, DenseUnet-based Automatic Rapid Tool (DARTS). Pearson correlation coefficients were calculated. Subset analysis of male and female cohorts was performed and size asymmetry was assessed using Student's t test.

RESULTS

Segmentation data are available from HCP (FreeSurfer) for 415 of the 655 subjects of this cohort. DARTS segmentation was performed in all subjects. 323 subjects (49.3%) were male.We found a significant negative correlation between total orbitofrontal volume and age ($r = -0.360$, $p < 0.00001$; $r = -0.314$, $p < 0.00001$ using FreeSurfer and DARTS, respectively). For subsegments of the orbitofrontal cortex, the correlations under FreeSurfer and DARTS respectively were $r = -0.364$, $p < 0.00001$; $r = -0.407$, $p < 0.00001$ (left lateral orbitofrontal), $r = -0.200$, $p < 0.00001$; $r = -0.033$, $p = 0.396$ (left medial orbitofrontal), $r = -0.335$, $p < 0.00001$; $r = -0.283$, $p < 0.00001$ (right lateral orbitofrontal), and $r = -0.329$, $p < 0.00001$; $r = -0.099$, $p = 0.011$ (right medial orbitofrontal).The standard deviation of the total orbitofrontal volumes was lower using DARTS (2.40 mL) compared with FreeSurfer (3.73 mL).Similar trends were observed across males and females. Size asymmetry was noted with the left lateral and medial orbitofrontal cortical volumes being larger than the right ($p < 0.0001$ using FreeSurfer and DARTS).

CONCLUSION

s Orbitofrontal cortical volume as measured on MRI decreases with age during childhood and adolescence, suggesting that development of this area is complex and may involve cortical pruning or other anatomic refinement on the way to maturation.

CLINICAL RELEVANCE/APPLICATION

The orbitofrontal cortex is implicated in the development of adaptive learning and executive responses including stimulus-reinforcer associations. These functions undergo maturation and refinement during childhood and adolescence and unveiling anatomic changes to this area contribute to our understanding of how this process unfolds, potentially aiding identification of developmental aberrations.

S3A-SPNR-5

Development of Fetal Ventricular Volume Reference Norms Using nnUNet

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - NR DPS

Participants
Minerva Zhou, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To use deep learning methods to segment and measure ventricular volume of fetal brain MRIs across a wide range of gestational ages.

METHODS AND MATERIALS

We applied nnU-Net to segment the ventricular system of 91 nonpathologic and 9 pathologic fetal brain MRIs across a variety of gestational ages (19-36 weeks). Twenty fetal brain MRIs from our institution were reconstructed to a high-resolution 3D volume using slice-to-volume reconstruction and then manually segmented and combined with the MICCAI Fetal Tissue Annotation Challenge data to generate a dataset of 100 fetal brain MRI volumes, which were randomly split into 80 training studies and 20 test studies in a 5-fold cross-validation. Performance was assessed using Dice coefficients and volume comparison to manual reference segmentation. A normative reference of ventricular volume across gestational ages was generated using the 91 nonpathologic training studies.

RESULTS

The nnU-Net predicted segmentation of fetal ventricles across gestational ages with median Dice score of 0.90 (IQR 0.88-0.93; Fig 1A). The automatically computed ventricular volume measurements were highly correlated with manual measurements (Pearson's $r=0.99$, $P<0.001$, Fig 1B). A normative range of ventricular volumes across gestational ages was developed using the automated segmentation volumes. All 9 patients with hydrocephalus were predicted to be greater than two standard deviations higher than the age-specific reference mean (Fig 1C).

CONCLUSION

s Deep learning techniques can be used to provide an objective measure of ventricular volume on fetal brain MRI and identify hydrocephalus based on a normative reference standard.

CLINICAL RELEVANCE/APPLICATION

This study explores using deep learning techniques to quickly and accurately quantify ventricular volume on fetal brain MRI and subsequently identify pathological volumes.

Brain Gray Matter Connectome Disorganization in Social Anxiety Disorder

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - NR DPS

Participants
Xun Zhang, (*Presenter*) Nothing to Disclose

PURPOSE

Phenotyping approaches grounded in structural network science can offer advanced insights into neurobiological substrates of psychosis, but this remains to be clarified at the individual level in social anxiety disorder (SAD). Herein, we aimed to investigate the topological organizations of individual structural covariance networks using a novel approach in a homogenous sample of SAD patients, and assess their potential clinical relationship and diagnostic value.

METHODS AND MATERIALS

Forty-nine non-comorbid adult patients with SAD and fifty-three demographically-matched healthy controls (HC) were recruited to obtain clinical evaluation and 3.0-Tesla high-resolution T1-weighted images. We constructed single-subject structural covariance networks based on multivariate morphometry (i.e., cortical thickness, surface area, curvature, and gray matter volume) using a recent novel approach combining probability density estimation and Kullback-Leibler divergence, and estimated their global and nodal network properties via graph theory analysis. Network metrics were compared between SAD and HC groups, and the relationship to clinical characteristics was analyzed. Furthermore, exploratory support vector machine analyses were conducted to discriminate SAD from HC.

RESULTS

Globally, SAD patients showed significantly altered topological characteristics, including higher global efficiency, shorter characteristic path length, and stronger small-worldness. Locally, SAD patients exhibited abnormal nodal degree and efficiency mainly involving left superior frontal gyrus, right superior parietal lobe, right paracentral gyrus, right lingual, right pericalcarine cortex, and left amygdala. Furthermore, altered global and nodal topological metrics were associated with the symptom severity and disease duration in SAD cohort, suggesting a pathophysiological relevance. Graph-based metrics allowed single-subject classification of SAD versus HC with significant accuracy, indicating potential diagnostic efficacy.

CONCLUSION

s The topological organization of structural covariance networks was disrupted in SAD in a way that suggests compensatory greater integration of information processing with a more randomly organized brain network, which may extend neurobiological understandings of a system-level brain maturational disruption in SAD.

CLINICAL RELEVANCE/APPLICATION

These results provide structural network insights into the neurobiology of SAD, and may navigate the development of reliable and objective neuroanatomical biomarkers for clinical diagnosis, targeted intervention, and therapeutic efficacy evaluation in SAD.

S3A-SPNR-7

Pediatric Low-Grade Glioma Molecular Subtype Identification Based on 3D Probability Distributions of Tumor Location in MRI

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - NR DPS

Participants
Farzad Khalvati, PhD, MSc, Toronto, ON (*Presenter*) Board of Directors, MESH Scheduling Inc

PURPOSE

Genetic marker identification of pediatric Low-Grade Glioma (pLGG) is crucial for early prognostication and individualized treatment planning. We propose a method to exploit tumor location in MRI data to identify the most common pLGG subtypes (BRAF V600E mutation vs. BRAF fusion) without using any other information.

METHODS AND MATERIALS

In this REB-approved retrospective study, Fluid-Attenuated Inversion Recovery (FLAIR) sequences of the baseline MRI from 200 patients with pLGG acquired between Jan. 2000 and Dec. 2018 were included. Tumor segmentations were provided by a pediatric neuroradiology fellow and verified by a senior pediatric neuroradiologist. The ground truth molecular subtype labels (BRAF V600E mutation and BRAF fusion) were obtained through biopsy.To build the probability density functions (PDF) of BRAF V600E mutation and BRAF fusion, the 3D binary masks of segmentation in FLAIR images for each class in the training dataset were added together and then normalized. In the test cohort, the probabilities of belonging to each class were calculated by a voxel-wise multiplication of the binary segmentation mask of the test case and the 3D PDF of the corresponding class in the training dataset. We repeated the data split (80/20 for training and test) 100 times and calculated the Area Under ROC Curve (AUROC).

RESULTS

Using only location of the tumor in the FLAIR images, we achieved a mean AUROC of 0.783 with a 95% Confidence Interval (CI) of (0.769, 0.798) over 100 experiments for the classification of BRAF V600E mutation vs. BRAF fusion in pLGG.

CONCLUSION

s 3D PDFs of tumor subtypes can help create a location-based pipeline for molecular subtype identification of pLGG. While location is ignored in the majority of radiomics and neural-network-based classification models, our results show BRAF V600E mutation and BRAF fusion in pLGG tumors follow different location distributions, which can be utilized for subtype identification.

CLINICAL RELEVANCE/APPLICATION

The location-based subtype identification of pLGG can be used as a stand-alone classifier or as an adjunct to Artificial Intelligence based classification models to allow imaging-based molecular characterization.

MRI Alterations in Patients with Psychogenic Non-epileptic Seizures: Prevalence, Distribution and Classification of The Findings

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - NR DPS

Participants
Aleix Jareno Badenas, MD, Sant Vicenc de Castellet, Spain (*Presenter*) Nothing to Disclose

PURPOSE

Psychogenic non-epileptic seizures (PNES) are paroxysmic episodes that mimic epileptic seizures without electroencephalographic representation. Conversive psychiatric origin is attributed to this kind of episode. However, beyond this psychiatric perspective, the possible neurobiological basis of PNES has not received much attention. Some studies have documented structural and functional alterations in these patients, but without consistent results to support a causative hypothesis. The objectives of this study are:- To evaluate the MRI findings in patients with PNES- To classify the results- To evaluate a possible structural basis of these episodes

METHODS AND MATERIALS

We performed a retrospective analysis of the MRI studies conducted on patients of our epilepsy unit with a confirmed diagnosis of only PNES or PNES and epilepsy (PNES+epilepsy). A descriptive study of the findings in both groups was performed and compared with the incidental findings in the general population obtained from the literature. The radiologic findings were classified into: vascular, tumoral, posttraumatic/gliotic, small vessel, cortical, hippocampal sclerosis, unspecific or normal studies, as well as into epileptogenic and non-epileptogenic.

RESULTS

Our study population was formed of 60 patients with a confirmed diagnosis of PNES and 16 patients with PNES+epilepsy (75% women, 25% men, mean age at diagnostic of 41 years). 55% of patients with PNES and 81% with PNES+epilepsy had a pathological finding. These findings were considered epileptogenic in 13% of the PNES group and in 31% of the PNES+epilepsy group. The most frequent findings in patients with were unspecific, vascular and hippocampal sclerosis, whilst in the PNES+epilepsy group were unspecific, hippocampal sclerosis and small vessel.

CONCLUSION

s Patients with PNES have a higher prevalence of abnormalities in MRI than the general population (around 18% according to existing literature) and this prevalence is even higher when PNES are associated with epilepsy. There is a higher prevalence of PNES among women.

CLINICAL RELEVANCE/APPLICATION

Our study shows higher prevalence of MRI structural findings in patients with PNES than in the general population, suggesting a neurobiological/structural basis in a pathology considered psychiatric.

S3A-SPNR-9

The Individual Association Between Functional and Morphological Asymmetry During Fetal Brain Development observed in In-utero MRI

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - NR DPS

Participants
Georg Langs, Vienna, Austria (*Presenter*) Co-founder, contextflow GmbH Shareholder, contextflow GmbH

PURPOSE

While function is shaped and constrained by brain structure, there is also possible impacts of functional activity on morphology. At the early stages of life, this relationship is particularly dynamic due to maturational processes and rapid conformational changes of the fetal brain. Cross-sectional studies in the early infancy and newborns suggest that the impaired development of cerebral morphology may promote the recruitment of alternative axonal pathways to sustain function, affecting the integration and specification of functional circuits at both cortical and sub-cortical levels. However, little is known about their complex interplay at the developmentally critical period in utero. Here, we assess the individual association of structural and functional brain development in the fetus.

METHODS AND MATERIALS

Resting-state fMRI and consecutive T2-weighted scans were acquired for 72 singleton fetuses between 19 and 39 weeks of gestation. Data were processed by customized functional- and anatomical image processing pipelines including irregular fetal movement correction, age-specific segmentation, and atlas registration. Individualized functional connectivity (FC) matrices were obtained by correlating regional brain activity over time and individualized local surface folding was quantified by measuring gyrification index (GI). We calculated the morphological and functional laterality indices for each individual subject as the normalized difference of GI and of FC degree between the hemispheres, respectively. The P-values for all evaluations were corrected for multiple comparisons using Benjamini-Yekutieli procedure.

RESULTS

After computational quality benchmarking, 24 cases were excluded and the final study cohort consisted of 48 fetuses that had no confirmed brain abnormalities (mean gestational age ±SD: 28.97±4.84 weeks). We found significant leftward laterality in Temporal-Superior ($p=0.043$), Temporal-Medial ($p=0.047$), and Temporal-Inferior ($p=0.048$) regions after correcting for multiple comparisons. Statistical tests of the functional asymmetry did not reach statistical significance for the rest of cortical regions. Significant morphological asymmetry was found in medial wall ($p=0.0089$) and mesial frontal region ($p=0.003$). We observed significant individual association between functional- and morphological asymmetry in the limbic area ($p<0.001$ corrected)

CONCLUSION

s Our results support the hypothesis that a significant relationship between brain structure and function is present during prenatal brain development.

CLINICAL RELEVANCE/APPLICATION

It may lead to a better understanding of the neural mechanisms involved in adverse outcomes.

S3A-SPPD-1 Development and Validation of a Nomogram to Predict Intracranial Hemorrhage in Neonates

Participants
Siqi Zhang, Shanxi Children's Hospital, Taiyuan, China (*Presenter*) Nothing to Disclose

PURPOSE

The aim of this study was to evaluate the prevalence of neonatal intracranial hemorrhage (ICH) using susceptibility-weighted imaging (SWI) and to develop and externally validate a nomogram for predicting the probability of ICH in neonates.

METHODS AND MATERIALS

Retrospectively collect clinical data of 1018 neonates clinically suspected craniocerebral injury, including prenatal, intrapartum and postnatal risk factors of ICH. All neonates underwent SWI to determine if there is ICH. The nomogram was developed based on the variables identified by the univariate and multivariate logistic regression analyses. Then the nomogram was validated in another independent cohort of 106 neonates. The performance of the nomogram was evaluated in terms of discrimination by the area under the receiver-operating characteristic curve (AUC), calibration by the calibration curve and clinical net benefit by the decision curve analysis (DCA).

RESULTS

267(26.2%) neonates with ICH were detected by SWI in the primary cohort, and 31(29.3%) in the validation cohort. The nomogram comprised six variables: 1 minute Apgar score, heart rate, platelet, delivery method, jaundice, and mothers with/without gestational diabetes. The AUC of the nomogram in the primary and validation cohort were 0.734 and 0.743, respectively. The calibration curve showed a good correlation between the nomogram prediction and actual observation for ICH. DCA showed the nomogram was clinically useful.

CONCLUSION

s We developed and validated an easy-to-use nomogram to predict ICH for neonates. This model could support individualized risk assessment and healthcare.

CLINICAL RELEVANCE/APPLICATION

We developed and validated a nomogram to predict the probability of neonatal ICH and confirmed it’s good performance. We believe that the application of the proposed model would enable clinicians to accurately assess the probability of neonatal ICH and make appropriate individualized risk assessment and healthcare.

Siqi Zhang, Shanxi Children's Hospital, Taiyuan, China (*Presenter*) Nothing to Disclose

PURPOSE

The aim of this study was to evaluate the prevalence of neonatal intracranial hemorrhage (ICH) using susceptibility-weighted imaging (SWI) and to develop and externally validate a nomogram for predicting the probability of ICH in neonates.

METHODS AND MATERIALS

Retrospectively collect clinical data of 1018 neonates clinically suspected craniocerebral injury, including prenatal, intrapartum and postnatal risk factors of ICH. All neonates underwent SWI to determine if there is ICH. The nomogram was developed based on the variables identified by the univariate and multivariate logistic regression analyses. Then the nomogram was validated in another independent cohort of 106 neonates. The performance of the nomogram was evaluated in terms of discrimination by the area under the receiver-operating characteristic curve (AUC), calibration by the calibration curve and clinical net benefit by the decision curve analysis (DCA).

RESULTS

267(26.2%) neonates with ICH were detected by SWI in the primary cohort, and 31(29.3%) in the validation cohort. The nomogram comprised six variables: 1 minute Apgar score, heart rate, platelet, delivery method, jaundice, and mothers with/without gestational diabetes. The AUC of the nomogram in the primary and validation cohort were 0.734 and 0.743, respectively. The calibration curve showed a good correlation between the nomogram prediction and actual observation for ICH. DCA showed the nomogram was clinically useful.

CONCLUSION

s We developed and validated an easy-to-use nomogram to predict ICH for neonates. This model could support individualized risk assessment and healthcare.

CLINICAL RELEVANCE/APPLICATION

We developed and validated a nomogram to predict the probability of neonatal ICH and confirmed it’s good performance. We believe that the application of the proposed model would enable clinicians to accurately assess the probability of neonatal ICH and make appropriate individualized risk assessment and healthcare.

S3A-SPPH-1 Development of a Deep Learning Method for Age Estimation of Cadavers Using Postmortem Vertebral CT Images

Participants
Ikuo Kawashita, PhD, Hiroshima, Japan (*Presenter*) Nothing to Disclose

PURPOSE

We developed an age estimation method for unidentified cadavers. It applies deep learning to postmortem computed tomography (PMCT) images of the vertebral bones. The purpose of this study was to determine the optimal image processing method and deep-learning model for age estimation.

METHODS AND MATERIALS

Our image database consisted of CT images of 1,120 cases (140 cases for each of 8 decades of age from the 20s to the 90s. The training set included 70 males and 70 females per decade. The evaluation set included 187 cases (112 males, 75 females; average age 64.4 years; 56 damaged, 131 undamaged). The training images were whole-body CT images obtained from positron emission tomography-CT scans; the test images were PMCT images. In preliminary experiments using 200 training images, CT-scanograms, curved planar reformation (CPR)-, maximum intensity projection (MIP)-, and curved MIP images were compared to identify suitable image processing methods for accurate age estimation. We selected the optimal models (GoogLeNet, VGG16, ResNet, DenseNet) as network structures for deep learning (Figure 1).

RESULTS

MIP was the optimal image processing method for age estimation (Figure 2). The others made little learning progress and all output the same age, only VGG16 was able to estimate the age. With combined MIP and VGG16, the intraclass correlation coefficient between the actual and estimated age of the 187 evaluation cadavers was 0.96 (95% CI: 0.95 - 0.97, $p < 0.001$), reliability was excellent. The mean absolute error (MAE) and the standard error of the estimate (SEE) between the actual and estimated age was 4.27 and 5.39 years, respectively. Shapley additive explanations visualization (SHAP) suggested that with MIP age-related changes around the thoracolumbar spine, e.g. osteophytes, intervertebral spacing, bone density, and aortic calcification, were assessed correctly (Figure 3).

CONCLUSION

s For age estimation using whole vertebral bone PMCT images, MIP yielded the best source image as the effects of gases due to decomposition were suppressed. VGG16 was the optimal network structure. The MAE was 4.27 years (margin of error +/- 10 years, 95% probability) and reliability was excellent.

CLINICAL RELEVANCE/APPLICATION

Our age estimation method using MIP images and VGG16 estimated the age of cadavers accurately. It may help to identify unknown cadavers.

S3A-SPPH-2 A Fairytale of a Fair Comparison in Deep Learning MRI Reconstruction

Participants
Chungseok Oh, (*Presenter*) Nothing to Disclose

PURPOSE

Despite the recent success in medical imaging, deep learning suffers from a generalization issue: network performance degrades when the test data have different image characteristics (e.g. resolution, SNR, etc.) from training data. This issue suggests that diversity in dataset plays a critical role in the network performance. In medical imaging, however, many of the studies still utilize a "private" dataset because no "public" dataset is available. In this study, we demonstrated that the use of a private dataset can lead to an unfair comparison between networks.

METHODS AND MATERIALS

When comparing your network with a published network, there are two options: comparing with a pre-trained network or comparing with a re-trained network. When comparing with a pre-trained network, which was trained by a different private dataset from yours, the performance comparison may not be fair. To demonstrate it, two networks, designed to perform quantitative

susceptibility mapping (QSM), were trained by datasets with different image characteristics, either resolution or preprocessing method, and their performances were compared. When comparing with a re-trained network, the re-trained network may underperform because of inadequate hyperparameter set or random seeds. For this case, we re-trained a published network (i.e. QSMnet) with a new dataset and demonstrated that the re-trained network may require hyperparameter tuning or multiple seeds.

RESULTS

[Comparison with pre-trained network] When comparing two networks trained by different datasets, each network outperformed when the training dataset has the same image characteristics as the test dataset. Therefore, the performance comparison result can easily be reversed by the image characteristics of the test dataset.[Comparison with re-trained network] When the re-trained network was hyperparameter-tuned, the performance was improved. Also, the network performances were different depending on the seed values. These results imply that the re-trained network may no longer retain its original network performance.

CONCLUSION

s We demonstrated that the use of a private dataset can lead to an unfair comparison between networks. For a fair comparison, a common test dataset and a trained network with information for reproducibility are necessary. This conclusion may also be applicable to other medical image processing tasks using private datasets.

CLINICAL RELEVANCE/APPLICATION

Performance comparison between networks is essential in academic research. This work suggests a lesson about the unfairness of comparison results which may be easily experienced in medical imaging.

S3A-SPPH-3 Temporal Deep Learning for Adhesion Detection on Cine-MRI

Participants
Bram de Wilde, MSc, (*Presenter*) Nothing to Disclose

PURPOSE

To explore the benefit of deep learning video architectures for the challenging novel task of adhesion detection in the abdomen on cine-MRI.

METHODS AND MATERIALS

Adhesions are a common cause of chronic abdominal pain, with a prevalence of up to 20% after surgery. Adhesion diagnosis is a novel application of cine-MRI, where patients induce motion in the abdomen through the Valsalva maneuver. Adhesions connect bowel loops to the anterior abdominal wall, abdominal organs, or to other bowel loops. The radiologist must analyze the movement of organs through time, to determine adhesion presence. This is challenging and requires expertise, so AI assistance could help introduce this technique in more clinics worldwide.In this study, we aim to find out if deep neural network architectures developed for video data (2D+T) are able to extract temporal information essential to detect adhesions. Adhesions were annotated with bounding boxes on 196 2D+T cine-MRI series of 85 patients. A 2D ResNet-18 was trained using only the first frame of each series (image). A 2D+T ResNet-18 was trained using the full temporal information of each series (video). Both networks analyze 49x49 pixel patches, with a third dimension of 30 time frames for the 2D+T network. The training label for each patch is positive (1) if the center pixel is inside an annotated bounding box, otherwise negative (0).Diagnostic performance for each architecture is characterized by the area under the receiver operating characteristic curve (AUC). A permutation test compared the performances using 25 individually trained models for each architecture, in a nested 5-fold cross validation scheme.

RESULTS

The 2D+T ResNet-18 architecture (mean AUC 0.70 [0.55-0.84]), was significantly better (p=0.0011) than the 2D ResNet-18 architecture (mean AUC 0.64 [0.52-0.77]).

CONCLUSION

s Adhesion detection is an exciting new problem for AI in medical imaging, because of the complex movement patterns that are featured in abdominal cine-MRI. This study provides evidence that deep learning video architectures can learn temporal patterns essential to analyze adhesions.

CLINICAL RELEVANCE/APPLICATION

Cine-MRI is a novel and uncommon modality for adhesion detection. This study paves the way for assisted diagnosis of adhesions, potentially lowering the barrier for wider adoption.

S3A-SPPH-4 UK Biobank Application of Susceptibility Source Separation (Chi-Separation) Using Deep Neural Network

Participants
Hwihun Jeong, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

?-separation has been proposed for illustrating the distribution of iron and myelin in the brain. The requirement for an R2 map hampers a wide application of ?-separation. We propose a pipeline that allows us to apply ?-separation to UK Biobank (UKB) data using R2 maps from deep neural networks.

METHODS AND MATERIALS

We scanned 20 subjects (train/validation/test: 10/1/9) using the same sequences as the UKB protocol and additional sequences for the reference R2 and R2* maps. The R2* map of the UKB protocol datasets suffered from noise and artifacts, so we developed an additional network (R2* denoising network) that infers reference R2* values from UKB GRE data. A local field map is generated using the same protocol as the UKB QSM protocol. For R2 mapping, the neural network was trained using the input of MPRAGE and T2-FLAIR to generate an R2 map. Using local field and R2' maps, iLSQR-style ?-separation was conducted to reconstruct positive and negative susceptibility, and the result was compared to the reference. Deep neural networks share the same structure as Unet with fully connected layers on the backend. The training was conducted with an L1 loss between output and reference.

RESULTS

The ?-separation maps of the proposed method demonstrate a good match to those of reference. (NRMSE = 54.4±4.7, PSNR = 21.9±0.8, and SSIM = 0.989±0.008). The zoomed-in ?pos and ?neg maps confirm that the results of the proposed method show similar structures to those of the references, revealing details of iron and myelin distribution in the brain. Particularly in the thalamus, which contains both iron and myelin, the results demonstrate details of subthalamic nuclei, agreeing with the reference.

CONCLUSION

s In this study, we developed a pipeline for reconstructing ?-separation maps from the UK Biobank protocol dataset by leveraging a deep neural network. Our results suggest that ?-separation can be applied to existing large-scale data including the UK Biobank dataset. Using this method, we will explore full UKB data, potentially benefiting from the large population dataset.

CLINICAL RELEVANCE/APPLICATION

?-separation, which is a useful methodology for estimating the distribution of iron and myelin in the brain, can be applied to a large-scale dataset.

S3A-SPPH-6 Test-Time Mix-up Augmentation for Uncertainty Estimation and Expert Assistance in Medical Image Classification

Participants
Helen Hong, PhD, PhD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Experts are often hesitant to fully trust the prediction results of deep neural networks on disease diagnosis which consists of only labels and probability values. Uncertainty estimation is a method to quantify the confident of the network in the disease prediction. We propose a method of estimating more reliable uncertainty measure through test-time mixup augmentation.

METHODS AND MATERIALS

We used an IDRiD dataset consisting of 413 training and 103 validation color fundus images of 5 diabetic retinopathy (DR) disease grades. We first train a VGG-19 on the mixup-augmented training data. In test-time, a set of mixup test data is generated by applying mixup for each test data with the randomly sampled training data. The trained CNN is then applied to the mixup test data to obtain the mixup test labels. In lesion classification, the label of each test data is determined by majority voting on the mixup test labels. In uncertainty estimation, the uncertainty of each test data is computed by the entropy of the distribution of mixup test labels.

RESULTS

In experiments, we compared the proposed TTMA method with the existing test-time affine-based augmentation (TTA) and the Monte-Carlo drop-out (MCDO) methods. The data uncertainty can be evaluated by two criteria. First, the rejection-accuracy curves can evaluate the reliability of the uncertainty by observing whether the accuracy is increasing as the uncertainty decreases. In DR grading, the proposed TTMA achieved 100% accuracy at a 95% rejection rate, meaning that the 5% of the test results with the lowest TTMA uncertainty are 100% accurate. In contrast, the TTA and MCDO achieved 68.0% and 71.6% accuracy even at a 95% rejection rate, respectively. Second, the histogram of uncertainty of correct and incorrect predictions can evaluate the uncertainty by observing whether the uncertainty distributions of two predictions are separable. In TTA and MCDO, both distributions are heavily overlapped around the zero uncertainty. However, in the proposed TTMA, the distributions are not only shifted to the higher uncertainty values thanks to the mixup perturbation, but also in relatively separable form.

CONCLUSION

s The proposed TTMA provides more reliable uncertainty measure than the existing TTA or MCDO methods thanks to the mixup perturbation. The proposed TTMA uncertainty can assist the experts to select the data requires additional review among the CNN prediction results. (This work was supported by the Korea Medical Device Development Fund grant funded by the Korea government (Project Number: 9991007550, KMDF_PR_20200901_0269))

CLINICAL RELEVANCE/APPLICATION

The proposed uncertainty measure can assist experts to decide whether to accept or revision the CNN prediction results.

S3A-SPPH-8 Automatic Tracking of Prostate Fiducials in X-Ray Images With Deep-Learning Model During Radiation Treatment

Participants
Shuang Zhou, MS, Saint Louis, MO (*Presenter*) Nothing to Disclose

PURPOSE

Automatic tracking of fiducials is needed in image-guided radiation treatments. We developed a deep-learning based fiducial detection method can automatically detect and track fiducials in x-ray images during radiation treatments.

METHODS AND MATERIALS

Total of 1870 orthogonal x-ray images acquired from 63 patients during radiation treatments were used for training (90%) and validation (10%). Additional images from 12 additional patients were used for testing. The fiducials in the x-ray images were manually labeled with a rectangle bounding-box in Microsoft COCO format. Improved YOLOX deep-learning network developed for the object detection was trained with the manually labeled x-ray images. Mean average precision (mAP) was used as the evaluation metric.

RESULTS

The YOLOX deep-learning network was able to detect fiducials in the prostate with reasonable accuracy. The average precision (AP) scores derived from the precision-recall curve range are 0.44 and 0.16 for anteroposterior and lateral x-ray, respectively. The discrepancy was due to the poor visibility of fiducials in lateral x-rays.

CONCLUSION

s The YOLOX deep-learning network can detect most prostate fiducials in x-ray images with reasonable visibility and potentially can be used for automatic tracking of the target during radiation treatment delivery.

CLINICAL RELEVANCE/APPLICATION

Automatic detection and tracking of fiducials in the treatment target can facilitate precise radiation treatment delivery.

S3A-SPPH-9 Deep Learning Identification of Severe COVID Infection in Chest Radiographs Using Multi-Institutional Data

Participants
Andre Sobiecki, PhD, MSc, (*Presenter*) Nothing to Disclose

PURPOSE

To develop a deep learning model for identifying severe COVID cases on chest radiographs (CXRs).

METHODS AND MATERIALS

We are developing a deep-learning-based approach for identifying severe COVID infection on CXRs. Our processing pipeline mainly included two convolutional neural networks: a lung segmentation model (LS) followed by a severity assessment model (LD) that classified the COVID as severe or not severe. Two datasets were used in this study: M1 - from the RICORD set in the Medical Imaging Data Resource Center (MIDRC) and M2 - collected with IRB approval from our institution. The training and validation sets for both LS and LD were from M1. The training set included 425 cases, 582 images and 30 images with manual outlines of the lungs. The validation set included 50 cases, 68 images and 7 images with manual outlines. Two test sets were used: one from M1 with 26 cases, 173 images and 39 images with manual outlines, and the other from M2 with 235 cases and 250 images. The CXRs from M1 were rated by 3 radiologists as negative, mild, moderate or severe and those from M2 were rated by one radiologist. For the LS model, we used an ImageNet pre-trained U-Net. We manually outlined the lungs in a subset of the NIH ChestX-ray database and a subset from M1 for two-stage fine-tuning of the U-Net, and for validation and testing. The trained LS model was deployed to all images in M1 and M2. Jaccard Index (JI), Dice Coefficient (Dice), Hausdorff distance (HD) and average distance (AD) were used to evaluate the segmentation quality. For the severity assessment LD model, we used the InceptionV1 model. The segmented lung images pre-processed with mean shift and scaled by the standard deviation of the gray levels were used as input to LD model.

RESULTS

For the LS model on the M1 test set , we achieved mean JI of 0.87, mean Dice of 0.93, mean HD of 28.2 mm and mean AD of 3.8 mm. For the LD model, we achieved an AUC of 0.86 on the M1 test set and 0.81 on the M2 test set.

CONCLUSION

s Our approach shows promise in identifying lungs with severe COVID infection. The current model was limited by the small training sets with severity ratings. Further improvement is expected when larger training set becomes available.

CLINICAL RELEVANCE/APPLICATION

Our deep learning approach demonstrated the potential for accurate assessment of severe COVID infection in chest x-rays, which may be useful for treatment decision support.

UK Biobank Application of Susceptibility Source Separation (Chi-Separation) Using Deep Neural Network

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - PH DPS

Participants
Hwihun Jeong, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

?-separation has been proposed for illustrating the distribution of iron and myelin in the brain. The requirement for an R2 map hampers a wide application of ?-separation. We propose a pipeline that allows us to apply ?-separation to UK Biobank (UKB) data using R2 maps from deep neural networks.

METHODS AND MATERIALS

We scanned 20 subjects (train/validation/test: 10/1/9) using the same sequences as the UKB protocol and additional sequences for the reference R2 and R2* maps. The R2* map of the UKB protocol datasets suffered from noise and artifacts, so we developed an additional network (R2* denoising network) that infers reference R2* values from UKB GRE data. A local field map is generated using the same protocol as the UKB QSM protocol. For R2 mapping, the neural network was trained using the input of MPRAGE and T2-FLAIR to generate an R2 map. Using local field and R2′ maps, iLSQR-style ?-separation was conducted to reconstruct positive and negative susceptibility, and the result was compared to the reference. Deep neural networks share the same structure as Unet with fully connected layers on the backend. The training was conducted with an L1 loss between output and reference.

RESULTS

The ?-separation maps of the proposed method demonstrate a good match to those of reference. (NRMSE = 54.4±4.7, PSNR = 21.9±0.8, and SSIM = 0.989±0.008). The zoomed-in ?pos and ?neg maps confirm that the results of the proposed method show similar structures to those of the references, revealing details of iron and myelin distribution in the brain. Particularly in the thalamus, which contains both iron and myelin, the results demonstrate details of subthalamic nuclei, agreeing with the reference.

CONCLUSION

s In this study, we developed a pipeline for reconstructing ?-separation maps from the UK Biobank protocol dataset by leveraging a deep neural network. Our results suggest that ?-separation can be applied to existing large-scale data including the UK Biobank dataset. Using this method, we will explore full UKB data, potentially benefiting from the large population dataset.

CLINICAL RELEVANCE/APPLICATION

?-separation, which is a useful methodology for estimating the distribution of iron and myelin in the brain, can be applied to a large-scale dataset.

Test-Time Mix-up Augmentation for Uncertainty Estimation and Expert Assistance in Medical Image Classification

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - PH DPS

Participants
Helen Hong, PhD, PhD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Experts are often hesitant to fully trust the prediction results of deep neural networks on disease diagnosis which consists of only labels and probability values. Uncertainty estimation is a method to quantify the confident of the network in the disease prediction. We propose a method of estimating more reliable uncertainty measure through test-time mixup augmentation.

METHODS AND MATERIALS

We used an IDRiD dataset consisting of 413 training and 103 validation color fundus images of 5 diabetic retinopathy (DR) disease grades. We first train a VGG-19 on the mixup-augmented training data. In test-time, a set of mixup test data is generated by applying mixup for each test data with the randomly sampled training data. The trained CNN is then applied to the mixup test data to obtain the mixup test labels. In lesion classification, the label of each test data is determined by majority voting on the mixup test labels. In uncertainty estimation, the uncertainty of each test data is computed by the entropy of the distribution of mixup test labels.

RESULTS

In experiments, we compared the proposed TTMA method with the existing test-time affine-based augmentation (TTA) and the Monte-Carlo drop-out (MCDO) methods. The data uncertainty can be evaluated by two criteria. First, the rejection-accuracy curves can evaluate the reliability of the uncertainty by observing whether the accuracy is increasing as the uncertainty decreases. In DR grading, the proposed TTMA achieved 100% accuracy at a 95% rejection rate, meaning that the 5% of the test results with the lowest TTMA uncertainty are 100% accurate. In contrast, the TTA and MCDO achieved 68.0% and 71.6% accuracy even at a 95% rejection rate, respectively. Second, the histogram of uncertainty of correct and incorrect predictions can evaluate the uncertainty by observing whether the uncertainty distributions of two predictions are separable. In TTA and MCDO, both distributions are heavily overlapped around the zero uncertainty. However, in the proposed TTMA, the distributions are not only shifted to the higher uncertainty values thanks to the mixup perturbation, but also in relatively separable form.

CONCLUSION

s The proposed TTMA provides more reliable uncertainty measure than the existing TTA or MCDO methods thanks to the mixup perturbation. The proposed TTMA uncertainty can assist the experts to select the data requires additional review among the CNN prediction results. (This work was supported by the Korea Medical Device Development Fund grant funded by the Korea government (Project Number: 9991007550, KMDF_PR_20200901_0269))

CLINICAL RELEVANCE/APPLICATION

The proposed uncertainty measure can assist experts to decide whether to accept or revision the CNN prediction results.

Automatic Tracking of Prostate Fiducials in X-Ray Images With Deep-Learning Model During Radiation Treatment

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - PH DPS

Participants
Shuang Zhou, MS, Saint Louis, MO (*Presenter*) Nothing to Disclose

PURPOSE

Automatic tracking of fiducials is needed in image-guided radiation treatments. We developed a deep-learning based fiducial detection method can automatically detect and track fiducials in x-ray images during radiation treatments.

METHODS AND MATERIALS

Total of 1870 orthogonal x-ray images acquired from 63 patients during radiation treatments were used for training (90%) and validation (10%). Additional images from 12 additional patients were used for testing. The fiducials in the x-ray images were manually labeled with a rectangle bounding-box in Microsoft COCO format. Improved YOLOX deep-learning network developed for the object detection was trained with the manually labeled x-ray images. Mean average precision (mAP) was used as the evaluation metric.

RESULTS

The YOLOX deep-learning network was able to detect fiducials in the prostate with reasonable accuracy. The average precision (AP) scores derived from the precision-recall curve range are 0.44 and 0.16 for anteroposterior and lateral x-ray, respectively. The discrepancy was due to the poor visibility of fiducials in lateral x-rays.

CONCLUSION

s The YOLOX deep-learning network can detect most prostate fiducials in x-ray images with reasonable visibility and potentially can be used for automatic tracking of the target during radiation treatment delivery.

CLINICAL RELEVANCE/APPLICATION

Automatic detection and tracking of fiducials in the treatment target can facilitate precise radiation treatment delivery.

Deep Learning Identification of Severe COVID Infection in Chest Radiographs Using Multi-Institutional Data

Sunday, Nov. 27 11:45AM - 12:15PM Room: Learning Center - PH DPS

Participants
Andre Sobiecki, PhD, MSc, (*Presenter*) Nothing to Disclose

PURPOSE

To develop a deep learning model for identifying severe COVID cases on chest radiographs (CXRs).

METHODS AND MATERIALS

We are developing a deep-learning-based approach for identifying severe COVID infection on CXRs. Our processing pipeline mainly included two convolutional neural networks: a lung segmentation model (LS) followed by a severity assessment model (LD) that classified the COVID as severe or not severe. Two datasets were used in this study: M1 - from the RICORD set in the Medical Imaging Data Resource Center (MIDRC) and M2 - collected with IRB approval from our institution. The training and validation sets for both LS and LD were from M1. The training set included 425 cases, 582 images and 30 images with manual outlines of the lungs. The validation set included 50 cases, 68 images and 7 images with manual outlines. Two test sets were used: one from M1 with 26 cases, 173 images and 39 images with manual outlines, and the other from M2 with 235 cases and 250 images. The CXRs from M1 were rated by 3 radiologists as negative, mild, moderate or severe and those from M2 were rated by one radiologist. For the LS model, we used an ImageNet pre-trained U-Net. We manually outlined the lungs in a subset of the NIH ChestX-ray database and a subset from M1 for two-stage fine-tuning of the U-Net, and for validation and testing. The trained LS model was deployed to all images in M1 and M2. Jaccard Index (JI), Dice Coefficient (Dice), Hausdorff distance (HD) and average distance (AD) were used to evaluate the segmentation quality. For the severity assessment LD model, we used the InceptionV1 model. The segmented lung images pre-processed with mean shift and scaled by the standard deviation of the gray levels were used as input to LD model.

RESULTS

For the LS model on the M1 test set , we achieved mean JI of 0.87, mean Dice of 0.93, mean HD of 28.2 mm and mean AD of 3.8 mm. For the LD model, we achieved an AUC of 0.86 on the M1 test set and 0.81 on the M2 test set.

CONCLUSION

s Our approach shows promise in identifying lungs with severe COVID infection. The current model was limited by the small training sets with severity ratings. Further improvement is expected when larger training set becomes available.

CLINICAL RELEVANCE/APPLICATION

Our deep learning approach demonstrated the potential for accurate assessment of severe COVID infection in chest x-rays, which may be useful for treatment decision support.

S3A-SPVA-1 Acceleration Motion Compensation Diffusion-weighted Imaging For Aortitis: Phantom and Clinical Studies

Participants
Tomoko Hyodo, MD, Osaka-sayama, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the utility of acceleration motion compensation diffusion-weighted imaging (aMC-DWI) in assessing ascending aortitis.

METHODS AND MATERIALS

A phantom experiment and a clinical study were conducted on a 1.5 T MRI scanner. Qualitative comparisons were made between the aMC-DWI and conventional DWI (cDWI) (b factor=800 s/mm2 for both) since the apparent diffusion coefficient value of aMC-DWI could not be compared in principle. In the phantom study, two experimenters independently manipulated the balloon to move the syringe filled with agar up and down in the 5mm range at 60 times per minute. The phantom images obtained using each DWI technique were graded on a 5-point scale (1=poor to 5=as good as a static image using cDWI). Mann-Whitney U tests with Bonferroni correction were used to assess differences among the sessions. The prospective clinical study was performed on patients with suspected aortitis undergoing FDG-PET/CT and whole-body diffusion-weighted MRI. Both DWI techniques were performed for the thorax in each patient. cDWI and aMC-DWI were visually scored for active inflammation of the ascending aorta (0=negative or 1=positive). Statistical analyses included calculation of diagnostic accuracy with FDG-PET/CT as the reference standard and a two-sided one-sample t-test (assuming mean difference score [aMC-DWI - cDWI]= 0).

RESULTS

In the phantom experiment, aMC-DWI showed a significantly higher median score than cDWI in both experimenters 1 (4 vs 3; P =.048) and 2 (3 vs 1; P =.048). In the clinical study, 21 patients (median age, 69 years [range, 19-84 years]; 15 women) were assessed. Eight patients were diagnosed with active arteritis (five with Takayasu's arteritis and the other with giant cell arteritis). Seven patients were found to have active ascending aortitis in FDG-PET/CT (with a median and range of maximum standardized uptake value, 3.5[2.2-4.4]). The sensitivity, specificity, and positive and negative predictive value, respectively, for detecting active inflammation in the ascending aorta were 1/7 (14 %), 13/14 (93 %), 1/2 (50 %), and 13/19(68 %) for cDWI; and 6/7 (86 %), 9/14 (64 %), 6/11 (55 %) and 9/10 (90 %) for aMC-DWI. Mean difference between two DWI techniques was significant in seven PET-positive cases (t = 3.873; P = .008; 95% CI = 0.26-1).

CONCLUSION

s The aMC technique promises to increase the utility of DWI in the assessment of ascending aortitis.

CLINICAL RELEVANCE/APPLICATION

The activity of thoracic aortitis is usually assessed by a segmental approach (the ascending, arch, and descending). With aMC-DWI, MRI may become an alternative to FDG-PET/CT.

S3B-SPBR-1 Deep Learning with 3D Convolutional Neural Networks For Prediction of BRCA Gene Mutation in High-Risk Breast Cancer Patients

Participants
Sung Eun Song, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Patients who carry a mutation in germline BRCA1/2 (gBRCA) genes might benefit from targeted therapy but genetic testing is costly. The purpose of this study was to determine the feasibility of using a deep learning (DL) approach for predicting the gBRCA mutation by using the three-dimensional (3D) MR images of breast cancer and clinical data in high-risk cancer patients.

METHODS AND MATERIALS

A total of 312 breast cancer patients who had high-risk factors and underwent gBRCA tests were retrospectively collected. A data set of 3D MR images of breast cancer from 312 subjects were manually segmented on contrast-enhanced T1-weighted subtraction images by an experienced breast radiologist. A 3D convolutional neural networks (CNNs)-based transformer architectures were trained on 80% of the data set and tested on the remaining 20%. Clinical data obtaining from biopsy were also used. The models' performances with or without clinical data were analyzed in terms of sensitivity, specificity, and areas under the receiver operating characteristic curve (AUCs) and compared by DeLongs' test.

RESULTS

Among 312 patients, 112 (35.9%) had gBRCA 1/2 pathogenic mutation. For prediction of gBRCA mutation, a 3D CNNs-based transformer architectures achieved an AUC of 0.82 (95% confidence interval [CI]: 0.69, 0.96) in the train set and that of 0.81 (95%CI:0.69, 0.95) in the test set, respectively. Adding the clinical data did not improve an AUC of DL model (AUCs: 0.83 and 0.81 in both of train and test sets; P= .14 and .15, respectively). The DL model achieved 72% sensitivity and 80% specificity in the train set and 74% sensitivity and 86% specificity in the test set.

CONCLUSION

s Using 3D MR images, DL models can effectively predict the gBRCA mutation without clinical data.

CLINICAL RELEVANCE/APPLICATION

Artificial intelligence may provide an early detection of gBRCA mutation for breast cancer patients who had high-risk factors.

S3B-SPBR-2 Automatic Assessment of The Quality of Breast Positioning in Mammography Using Deep Learning-based Methods

Participants
Huei-yi Tsai, MD, MS, (*Presenter*) Nothing to Disclose

PURPOSE

Breast positioning assessment is an important component of mammographic quality control. The aim of this study is to develop deep learning-based automated analytic tools to assess breast positioning, focusing on the completeness of breast tissue in the images.

METHODS AND MATERIALS

Assessing metrics: 1. Completeness of breast tissue, classifying into three degrees (inadequate, acceptable, and perfect); 2. Measuring the length of the posterior nipple line (PNL) on the CC view and MLO view; 3. Length of pectoral muscle to PNL. Datasets: Screening mammography were retrospectively enrolled. The images showing breast implant or breast distortion due to tumor or previous operation were excluded. A total of 479 mammography with 1,916 images (958 CC view and 958 MLO view) were labeled by two radiologists for the completeness of breast tissue after a consensus meeting. Manual annotation of nipple and pectoral muscle was also performed. The data was then randomly subdivided into training, validation, and test datasets.Model training and metrics computation: For classification of the completeness of breast tissue in the image, a ConvMixer model was used for patch embedding and feature extraction, followed by Random Forest classification. For MLO view, before ConvMixer model, the pectoral muscle was first localized by using You Only Look Once (YOLO)-v5 model and removed from the diagonal line of the bounding box. YOLO-v5 was trained to detect the nipple and pectoral muscle in mammograms. The length of PNL and the length

from the inferior extent of pectoral muscle to PNL were then calculated by automatic drawing a vertical line from nipple to the posterior image border/pectoral muscle. Intraclass correlation coefficient (ICC) was used to investigate the correlation between model and manual measurements.

RESULTS

For classification of the completeness of breast tissue, the AUCs of the three degrees (inadequate, acceptable, and perfect) were 0.97 (95%CI: 0.96-0.98), 0.79 (95%CI: 0.77-0.81), and 0.92 (95%CI: 0.91-0.93). The mean average precisions of YOLO-v5 model for nipple and pectoral muscle detection were 0.995 and 0.863, respectively. The ICC for the length of PNL between model and manual measurements was 0.997 for CC view and 0.984 for MLO view. The ICC for the length of pectoral muscle to PNL between model and manual measurements was 0.981.

CONCLUSION

s The proposed deep learning-based methods allowed for automatic and accurate assessment of the quality of breast positioning in mammography.

CLINICAL RELEVANCE/APPLICATION

The deep learning-based methods have the potential to be part of an automated image quality assessment system.

S3B-SPBR-3 Attention-Based Deep Learning for Breast Lesions Classification on Contrast Enhanced Spectral Mammography: A Multicenter Study

Participants
Ning Mao, Yantai, China (*Presenter*) Nothing to Disclose

PURPOSE

This study aims to develop an attention-based deep learning model for distinguishing benign from malignant breast lesions on Contrast Enhanced Spectral Mammography (CESM).

METHODS AND MATERIALS

Preoperative CESM images of 1239 patients, which were definitely diagnosed on pathology in a multicenter cohort, were divided into training and validation sets, internal and external test sets. The regions of interest of the breast lesions were outlined manually by a senior radiologist. We adopted three conventional convolutional neural networks (CNNs), namely, DenseNet 121, Xception, and ResNet 50, as the backbone architectures and incorporated the convolutional block attention module (CBAM) into them for classification. The performance of the models was analyzed in terms of the receiver operating characteristic (ROC) curve, accuracy, the positive predictive value (PPV), the negative predictive value (NPV), the F1 score, the precision recall curve (PRC), and heat maps. The final models were compared with the diagnostic performance of conventional CNNs, radiomics models, and radiologists with specialized breast imaging experience.

RESULTS

The best-performing deep learning model, that is, the CBAM-based Xception, achieved an area under the ROC curve (AUC) of 0.970, a sensitivity of 0.848, a specificity of 1.000, and an accuracy of 0.891 on the external test set, which was higher than those of other CNNs, radiomics models, and radiologists. The PRC and the heat maps also indicated the favorable predictive performance of the attention-based CNN model. The diagnostic performance of radiologists improved with deep learning assistance.

CONCLUSION

s Using an attention-based deep learning model based on CESM images can help to distinguishing benign from malignant breast lesions, and the diagnostic performance of radiologists improved with deep learning assistance.

CLINICAL RELEVANCE/APPLICATION

We developed an attention-based deep learning model using CESM to noninvasively distinguish between benign and malignant breast lesions. In addition, the diagnostic performance of radiologists improved with deep learning assistance.Therefore, it has high clinical applicability and promotion value.

S3B-SPBR-4 A Regional Interpretation of Mammography Phantom Object by Evaluating ACR Phantom Images using a Deep Learning Model

Participants
Kyung Mi Lee, MD, PhD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Mammography is the initial examination to detect breast cancer symptoms, and quality control of mammography devices is crucial to maintain accurate diagnosis and to safeguard against degradation of performance. The objective of this study was to assist radiologists in mammography phantom image evaluation by developing and validating an interpretable deep learning model capable of objectively evaluating the quality of standard phantom images for mammography.

METHODS AND MATERIALS

A total of 2,208 mammography phantom images were collected for periodic accreditation of the scanner from 1,755 institutions. The dataset was randomly split into training (1,808 images) and testing (400 images) datasets. To develop an interpretable model that contains two deep learning networks in series, five processing steps were performed: mammography phantom detection, phantom object detection, post-processing, score evaluation, and a report with a comment.

RESULTS

For phantom detection, the accuracy and mean intersection over union (mIOU) were 1.00 and 0.938 in the test dataset, respectively. During phantom object detection, a total of 6,369 out of 6,400 objects were detected as the correct object class, and the accuracy and mIOU were 0.995 and 0.813, respectively. The predicted score for each object showed a consensus of 97.40% excluding fifth object in the fiber group, fourth object in the specks and mass groups. A score difference of 240 objects

was evaluated for the fiber group, 171 for the specks group, and 207 for the mass group. The highest difference in scores for the 0.5 point difference was found to be 145 objects at the fifth object in the fiber group (36.80% in itself), 149 objects at the fourth object of the specks (38.21%), and 163 objects in the fourth mass group (41.06%).

CONCLUSION

s The interpretable deep learning model using large-scale data from multiple centers shows high performance and reasonable object scoring, successfully validating the reliability and feasibility of mammography phantom image quality management.

CLINICAL RELEVANCE/APPLICATION

Deep learning algorithm with phantom image evaluator can demonstrate to be used to assess quality control for mammography, CT and MRI as a practical method for early and precision diagnosis.

S3B-SPBR-5 Real-time Decision Support by Light-weighted AI Model Trained with Large-scale Data for Breast Cancer Diagnosis Using Ultrasound

Participants
Jaeil Kim, PhD, Daegu, Korea, Republic Of (*Presenter*) Stockholder, BeamWorks, Inc.

PURPOSE

Although many of artificial intelligence (AI) models for ultrasound (US) diagnosis have been introduced, real-time decision support by AI is still challenging, due to its high computation cost. We aimed to evaluate the technical feasibility of real-time decision support by light-weighted AI model trained with large-scale data for breast cancer diagnosis using US.

METHODS AND MATERIALS

Using a large-scale data over 400,000 breast US images, we developed an AI decision support model based on weakly-supervised learning. In order to achieve the real-time processing of the developed AI model, we implemented a quantization method which can reduce inference time and memory usage while maintaining diagnostic accuracy. For the evaluation of the real-time decision support, US examinations were prospectively recorded from May 2021 in biopsy-proven breast cancer patients. A total of 8 video clips were simulated and tested with our light-weighted AI model. Diagnostic performance and inference time to return AI diagnosis were measured according to two hardware configurations (1: Intel Core i7 2.90 GHz with a GPU and 2: Intel Core i9 2.30Hz without GPU). Frame-wise ground truth labeling for malignancy/non-malignancy was performed by an experienced radiologist with reference to pathologic and radiologic reports.

RESULTS

Our light-weighted AI model diagnosed breast US images in the video clips in real-time and simultaneously produced score for cancer with cancer-relevant maps. Of the 8 examinations with breast cancer patients, our maps correctly highlighted the cancer in all examinations. For a total of 19,231 images with 4,525 malignant images and 14,706 non-malignant images, extracted from the video clips, the diagnostic performance was 0.93 of AUC and sensitivity/specificity was 85.4%/85.2%, respectively. Mean time to return AI diagnosis for each image was 0.03 seconds in hardware configuration 1 with GPU and 0.06 seconds in configuration 2 without GPU.

CONCLUSION

s With our development of light-weighted AI model trained with a large-scale data, real-time decision support is feasible to diagnose breast cancer using US with high detection and diagnostic performances.

CLINICAL RELEVANCE/APPLICATION

Real-time decision support for breast US diagnosis can help sonographers/radiologists to detect and differentiate the breast lesions among high volume of time-series images.

S3B-SPBR-6 Real-World Retrospective Cohort Studies of Artificial Intelligence (AI) Readers in Population Breast Cancer Screening

Participants
Helen Frazer, FRANZCR, Fitzroy, Australia (*Presenter*) Nothing to Disclose

PURPOSE

To assess an AI reader in various breast cancer screening operating modes in real-world retrospective cohort studies.

METHODS AND MATERIALS

We curated two datasets from a population breast cancer screening program. First, we established a cancer-rich dataset comprising 10,917 cancer images from 4,680 screening episodes (4,647 clients) and 69,775 non-cancer images from 40,364 screening episodes (39,704 clients), which we used for AI model training and testing. Second, we compiled an independent two-year sequential population cohort of women screened in 2016-2017 comprising 497,288 screening episodes (494,246 clients) and 2,094,424 images. This second dataset was used for the retrospective cohort studies. Five candidate CNN models (ECAResNet269d, ResNet152d, ResNet200d, ResNet101d, Xception41) were trained and tested on the cancer-rich set. The ensemble of the five CNN models achieved an AUROC of 0.877 (95% CI 0.873, 0.881) on the 2016-2017 population dataset and was used for the retrospective cohort simulation study. The study assessed application of the AI model in three operating modes: i) first pass read to remove easy normal mammograms; ii) second reader replacement with comparable/better accuracy; iii) final pass read to detect missed cancers. The simulation included all 497,288 screening episodes of the 2016-2017 retrospective cohort, real-world reader and screening outcomes for comparison, and real-world unit costs. The simulation model produced key classification outcomes (TP, FP, TN, FN) for each retrospective AI operating mode with a range of thresholds, as well as cost implications.

RESULTS

The best result was the operating mode of second reader replacement. It demonstrated superior performance to current screening outcomes with 396,173 fewer human reads, 3,103 fewer unnecessary recalls, 51 fewer missed cancers and a 16.9% reduction in reading and assessment costs (threshold set at 0.1).

CONCLUSION

s Our retrospective cohort studies using the simulation model demonstrated that the use of an AI model for second reader replacement can achieve better screening outcomes, with fewer false negatives and fewer false positives at lower cost, than the current screening process.

CLINICAL RELEVANCE/APPLICATION

Retrospective and prospective cohort studies with real-world clinical data and consideration of operating modes are necessary to evaluate AI readers in population breast cancer screening programs.

S3B-SPBR-7 Comparison of Mammography Artificial Intelligence Algorithms for 5-year Breast Cancer Risk Prediction

Participants
Vignesh Arasu, MD, Vallejo, CA (*Presenter*) Nothing to Disclose

PURPOSE

We examined the ability of mammography artificial intelligence (AI) algorithms, most trained for computer-aided detection (CAD) of visible breast cancer on mammograms, to predict 5-year future risk. We compared 5 AI algorithms -- 3 commercial CAD algorithms (representing 1/3 of the FDA/CE cleared devices) and 2 well known open source algorithms -- relative to the Breast Cancer Surveillance Consortium clinical risk model (BCSC v2)

METHODS AND MATERIALS

In this case-cohort study, women with a screening mammogram in 2016 at a large managed care organization with no evidence of cancer on final imaging assessment were followed through September 2021. Women were excluded with a prior history of breast cancer or highly penetrant gene mutation. From the 324,009 eligible women, a random subcohort of 13,628 (4.2%) were selected; 193 had incident cancer. All 4,391 additional incident cancers were also included. AI scores were generated from the index 2016 mammogram. Discrimination was assessed with time-varying area under the curve [AUC(t)].

RESULTS

For incident cancers at 0 to 1 year (interval cancer risk), the AUC(t) for BCSC was 0.62 (95% CI 0.59, 0.66), and AI algorithms all had significantly higher AUC(t)s, ranging from 0.67-0.71 ($P < .05$). For incident cancers at >1 to 5 years (5-year future cancer risk), the BCSC AUC(t) was 0.61 (95% CI 0.60, 0.62), and the AI algorithms AUC(t)s ranged from 0.63 to 0.67, all significantly higher than BCSC. Combined BCSC and AI models demonstrated AUC(t)s for interval cancer risk of 0.67-0.73 and for 5-year future cancer risk of 0.66-0.68.

CONCLUSION

s The evaluated AI mammography algorithms had significantly higher discrimination than the BCSC clinical risk model for interval and 5-year future cancer risk. Combined AI and BCSC models had slightly higher discrimination than AI alone.

CLINICAL RELEVANCE/APPLICATION

Mammography AI algorithms provide a new approach for improving breast cancer risk prediction beyond clinical variables such as age, family history, or the traditional imaging risk biomarker of breast density. Most CAD algorithms, trained for detection at shorter time horizons can also predict longer-term risk. Breast imaging practices may incorporate CAD AI for both diagnostic assistance and future risk stratification.

Automatic Assessment of The Quality of Breast Positioning in Mammography Using Deep Learning-based Methods

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - BR DPS

Participants
Huei-yi Tsai, MD, MS, (*Presenter*) Nothing to Disclose

PURPOSE

Breast positioning assessment is an important component of mammographic quality control. The aim of this study is to develop deep learning-based automated analytic tools to assess breast positioning, focusing on the completeness of breast tissue in the images.

METHODS AND MATERIALS

Assessing metrics: 1. Completeness of breast tissue, classifying into three degrees (inadequate, acceptable, and perfect); 2. Measuring the length of the posterior nipple line (PNL) on the CC view and MLO view; 3. Length of pectoral muscle to PNL. Datasets: Screening mammography were retrospectively enrolled. The images showing breast implant or breast distortion due to tumor or previous operation were excluded. A total of 479 mammography with 1,916 images (958 CC view and 958 MLO view) were labeled by two radiologists for the completeness of breast tissue after a consensus meeting. Manual annotation of nipple and pectoral muscle was also performed. The data was then randomly subdivided into training, validation, and test datasets.Model training and metrics computation: For classification of the completeness of breast tissue in the image, a ConvMixer model was used for patch embedding and feature extraction, followed by Random Forest classification. For MLO view, before ConvMixer model, the pectoral muscle was first localized by using You Only Look Once (YOLO)-v5 model and removed from the diagonal line of the bounding box. YOLO-v5 was trained to detect the nipple and pectoral muscle in mammograms. The length of PNL and the length from the inferior extent of pectoral muscle to PNL were then calculated by automatic drawing a vertical line from nipple to the posterior image border/pectoral muscle. Intraclass correlation coefficient (ICC) was used to investigate the correlation between model and manual measurements.

RESULTS

For classification of the completeness of breast tissue, the AUCs of the three degrees (inadequate, acceptable, and perfect) were 0.97 (95%CI: 0.96-0.98), 0.79 (95%CI: 0.77-0.81), and 0.92 (95%CI: 0.91-0.93). The mean average precisions of YOLO-v5 model for nipple and pectoral muscle detection were 0.995 and 0.863, respectively. The ICC for the length of PNL between model and manual measurements was 0.997 for CC view and 0.984 for MLO view. The ICC for the length of pectoral muscle to PNL between model and manual measurements was 0.981.

CONCLUSION

s The proposed deep learning-based methods allowed for automatic and accurate assessment of the quality of breast positioning in mammography.

CLINICAL RELEVANCE/APPLICATION

The deep learning-based methods have the potential to be part of an automated image quality assessment system.

Attention-Based Deep Learning for Breast Lesions Classification on Contrast Enhanced Spectral Mammography: A Multicenter Study

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - BR DPS

Participants
Ning Mao, Yantai, China (*Presenter*) Nothing to Disclose

PURPOSE

This study aims to develop an attention-based deep learning model for distinguishing benign from malignant breast lesions on Contrast Enhanced Spectral Mammography (CESM).

METHODS AND MATERIALS

Preoperative CESM images of 1239 patients, which were definitely diagnosed on pathology in a multicenter cohort, were divided into training and validation sets, internal and external test sets. The regions of interest of the breast lesions were outlined manually by a senior radiologist. We adopted three conventional convolutional neural networks (CNNs), namely, DenseNet 121, Xception, and ResNet 50, as the backbone architectures and incorporated the convolutional block attention module (CBAM) into them for classification. The performance of the models was analyzed in terms of the receiver operating characteristic (ROC) curve, accuracy, the positive predictive value (PPV), the negative predictive value (NPV), the F1 score, the precision recall curve (PRC), and heat maps. The final models were compared with the diagnostic performance of conventional CNNs, radiomics models, and radiologists with specialized breast imaging experience.

RESULTS

The best-performing deep learning model, that is, the CBAM-based Xception, achieved an area under the ROC curve (AUC) of 0.970, a sensitivity of 0.848, a specificity of 1.000, and an accuracy of 0.891 on the external test set, which was higher than those of other CNNs, radiomics models, and radiologists. The PRC and the heat maps also indicated the favorable predictive performance of the attention-based CNN model. The diagnostic performance of radiologists improved with deep learning assistance.

CONCLUSION

s Using an attention-based deep learning model based on CESM images can help to distinguishing benign from malignant breast lesions, and the diagnostic performance of radiologists improved with deep learning assistance.

CLINICAL RELEVANCE/APPLICATION

We developed an attention-based deep learning model using CESM to noninvasively distinguish between benign and malignant breast lesions. In addition, the diagnostic performance of radiologists improved with deep learning assistance.Therefore, it has high clinical applicability and promotion value.

S3B-SPBR-4

A Regional Interpretation of Mammography Phantom Object by Evaluating ACR Phantom Images using a Deep Learning Model

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - BR DPS

Participants
Kyung Mi Lee, MD, PhD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Mammography is the initial examination to detect breast cancer symptoms, and quality control of mammography devices is crucial to maintain accurate diagnosis and to safeguard against degradation of performance. The objective of this study was to assist radiologists in mammography phantom image evaluation by developing and validating an interpretable deep learning model capable of objectively evaluating the quality of standard phantom images for mammography.

METHODS AND MATERIALS

A total of 2,208 mammography phantom images were collected for periodic accreditation of the scanner from 1,755 institutions. The dataset was randomly split into training (1,808 images) and testing (400 images) datasets. To develop an interpretable model that contains two deep learning networks in series, five processing steps were performed: mammography phantom detection, phantom object detection, post-processing, score evaluation, and a report with a comment.

RESULTS

For phantom detection, the accuracy and mean intersection over union (mIOU) were 1.00 and 0.938 in the test dataset, respectively. During phantom object detection, a total of 6,369 out of 6,400 objects were detected as the correct object class, and the accuracy and mIOU were 0.995 and 0.813, respectively. The predicted score for each object showed a consensus of 97.40% excluding fifth object in the fiber group, fourth object in the specks and mass groups. A score difference of 240 objects was evaluated for the fiber group, 171 for the specks group, and 207 for the mass group. The highest difference in scores for the 0.5 point difference was found to be 145 objects at the fifth object in the fiber group (36.80% in itself), 149 objects at the fourth object of the specks (38.21%), and 163 objects in the fourth mass group (41.06%).

CONCLUSION

s The interpretable deep learning model using large-scale data from multiple centers shows high performance and reasonable object scoring, successfully validating the reliability and feasibility of mammography phantom image quality management.

CLINICAL RELEVANCE/APPLICATION

Deep learning algorithm with phantom image evaluator can demonstrate to be used to assess quality control for mammography, CT and MRI as a practical method for early and precision diagnosis.

Real-time Decision Support by Light-weighted AI Model Trained with Large-scale Data for Breast Cancer Diagnosis Using Ultrasound

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - BR DPS

Participants
Jaeil Kim, PhD, Daegu, Korea, Republic Of (*Presenter*) Stockholder, BeamWorks, Inc.

PURPOSE

Although many of artificial intelligence (AI) models for ultrasound (US) diagnosis have been introduced, real-time decision support by AI is still challenging, due to its high computation cost. We aimed to evaluate the technical feasibility of real-time decision support by light-weighted AI model trained with large-scale data for breast cancer diagnosis using US.

METHODS AND MATERIALS

Using a large-scale data over 400,000 breast US images, we developed an AI decision support model based on weakly-supervised learning. In order to achieve the real-time processing of the developed AI model, we implemented a quantization method which can reduce inference time and memory usage while maintaining diagnostic accuracy. For the evaluation of the real-time decision support, US examinations were prospectively recorded from May 2021 in biopsy-proven breast cancer patients. A total of 8 video clips were simulated and tested with our light-weighted AI model. Diagnostic performance and inference time to return AI diagnosis were measured according to two hardware configurations (1: Intel Core i7 2.90 GHz with a GPU and 2: Intel Core i9 2.30Hz without GPU). Frame-wise ground truth labeling for malignancy/non-malignancy was performed by an experienced radiologist with reference to pathologic and radiologic reports.

RESULTS

Our light-weighted AI model diagnosed breast US images in the video clips in real-time and simultaneously produced score for cancer with cancer-relevant maps. Of the 8 examinations with breast cancer patients, our maps correctly highlighted the cancer in all examinations. For a total of 19,231 images with 4,525 malignant images and 14,706 non-malignant images, extracted from the video clips, the diagnostic performance was 0.93 of AUC and sensitivity/specificity was 85.4%/85.2%, respectively. Mean time to return AI diagnosis for each image was 0.03 seconds in hardware configuration 1 with GPU and 0.06 seconds in configuration 2 without GPU.

CONCLUSION

s With our development of light-weighted AI model trained with a large-scale data, real-time decision support is feasible to diagnose breast cancer using US with high detection and diagnostic performances.

CLINICAL RELEVANCE/APPLICATION

Real-time decision support for breast US diagnosis can help sonographers/radiologists to detect and differentiate the breast lesions among high volume of time-series images.

Real-World Retrospective Cohort Studies of Artificial Intelligence (AI) Readers in Population Breast Cancer Screening

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - BR DPS

Participants
Helen Frazer, FRANZCR, Fitzroy, Australia (*Presenter*) Nothing to Disclose

PURPOSE

To assess an AI reader in various breast cancer screening operating modes in real-world retrospective cohort studies.

METHODS AND MATERIALS

We curated two datasets from a population breast cancer screening program. First, we established a cancer-rich dataset comprising 10,917 cancer images from 4,680 screening episodes (4,647 clients) and 69,775 non-cancer images from 40,364 screening episodes (39,704 clients), which we used for AI model training and testing. Second, we compiled an independent two-year sequential population cohort of women screened in 2016-2017 comprising 497,288 screening episodes (494,246 clients) and 2,094,424 images. This second dataset was used for the retrospective cohort studies. Five candidate CNN models (ECAResNet269d, ResNet152d, ResNet200d, ResNet101d, Xception41) were trained and tested on the cancer-rich set. The ensemble of the five CNN models achieved an AUROC of 0.877 (95% CI 0.873, 0.881) on the 2016-2017 population dataset and was used for the retrospective cohort simulation study. The study assessed application of the AI model in three operating modes: i) first pass read to remove easy normal mammograms; ii) second reader replacement with comparable/better accuracy; iii) final pass read to detect missed cancers. The simulation included all 497,288 screening episodes of the 2016-2017 retrospective cohort, real-world reader and screening outcomes for comparison, and real-world unit costs. The simulation model produced key classification outcomes (TP, FP, TN, FN) for each retrospective AI operating mode with a range of thresholds, as well as cost implications.

RESULTS

The best result was the operating mode of second reader replacement. It demonstrated superior performance to current screening outcomes with 396,173 fewer human reads, 3,103 fewer unnecessary recalls, 51 fewer missed cancers and a 16.9% reduction in reading and assessment costs (threshold set at 0.1).

CONCLUSION

s Our retrospective cohort studies using the simulation model demonstrated that the use of an AI model for second reader replacement can achieve better screening outcomes, with fewer false negatives and fewer false positives at lower cost, than the current screening process.

CLINICAL RELEVANCE/APPLICATION

Retrospective and prospective cohort studies with real-world clinical data and consideration of operating modes are necessary to evaluate AI readers in population breast cancer screening programs.

S3B-SPBR-7

Comparison of Mammography Artificial Intelligence Algorithms for 5-year Breast Cancer Risk Prediction

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - BR DPS

Participants
Vignesh Arasu, MD, Vallejo, CA (*Presenter*) Nothing to Disclose

PURPOSE

We examined the ability of mammography artificial intelligence (AI) algorithms, most trained for computer-aided detection (CAD) of visible breast cancer on mammograms, to predict 5-year future risk. We compared 5 AI algorithms -- 3 commercial CAD algorithms (representing 1/3 of the FDA/CE cleared devices) and 2 well known open source algorithms -- relative to the Breast Cancer Surveillance Consortium clinical risk model (BCSC v2)

METHODS AND MATERIALS

In this case-cohort study, women with a screening mammogram in 2016 at a large managed care organization with no evidence of cancer on final imaging assessment were followed through September 2021. Women were excluded with a prior history of breast cancer or highly penetrant gene mutation. From the 324,009 eligible women, a random subcohort of 13,628 (4.2%) were selected; 193 had incident cancer. All 4,391 additional incident cancers were also included. AI scores were generated from the index 2016 mammogram. Discrimination was assessed with time-varying area under the curve [AUC(t)].

RESULTS

For incident cancers at 0 to 1 year (interval cancer risk), the AUC(t) for BCSC was 0.62 (95% CI 0.59, 0.66), and AI algorithms all had significantly higher AUC(t)s, ranging from 0.67-0.71 ($P < .05$). For incident cancers at >1 to 5 years (5-year future cancer risk), the BCSC AUC(t) was 0.61 (95% CI 0.60, 0.62), and the AI algorithms AUC(t)s ranged from 0.63 to 0.67, all significantly higher than BCSC. Combined BCSC and AI models demonstrated AUC(t)s for interval cancer risk of 0.67-0.73 and for 5-year future cancer risk of 0.66-0.68.

CONCLUSION

s The evaluated AI mammography algorithms had significantly higher discrimination than the BCSC clinical risk model for interval and 5-year future cancer risk. Combined AI and BCSC models had slightly higher discrimination than AI alone.

CLINICAL RELEVANCE/APPLICATION

Mammography AI algorithms provide a new approach for improving breast cancer risk prediction beyond clinical variables such as age, family history, or the traditional imaging risk biomarker of breast density. Most CAD algorithms, trained for detection at shorter time horizons can also predict longer-term risk. Breast imaging practices may incorporate CAD AI for both diagnostic assistance and future risk stratification.

Cardiac Sunday Poster Discussions - B

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - CA DPS

Sub-Events

S3B-SPCA-1 Diagnostic Performance of Myocardial Native T1 and T2 Mapping in Differentiating Between Acute Myocarditis, Acute Myocardial Infarction and Takotsubo

Participants
Giulia Cundari, MD, Rome, Italy (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the diagnostic perfomance of myocardial native T1 (nT1) and T2 mapping in the differentiation between three acute cardiac conditions causing acute chest pain (ACP): acute myocardial infarction (MI), acute myocarditis (AM) and Takotsubo syndrome (TTS) by using cardiac magnetic resonance (CMR).

METHODS AND MATERIALS

166 patients with ACP and troponin increase who underwent CMR within 30 days from the onset of symptoms were retrospectively enrolled: 76/166 (45.8%) AM, 29/166 (17.5%) early-MI (onset-to-CMR= 10 days), 37/166 (22.3%) late-MI (onset-to-CMR: 11-30 days) and 24/166 (14.5%) TTS. Thirty healthy controls were also included in the analysis. CMR protocol included MOLLI and T2-3pt-GRE for the evaluation of nT1 and T2 mapping respectively. For each patient, the maximum segmental value (Max-), the average value among all the segments with increased mapping values (Ave-) and the global value for all the segments (Glo-) were calculated both in nT1 and for T2 maps. nT1 and T2 thresholds were calculated as > 95th percentile of controls values. Statistical analysis was performed using SPSS and included ANOVA, Kruskal-Wallis, and ROC curve analysis. Parameters were considered statistically significant when <0.05.

RESULTS

Using ANOVA, the comparisons between the groups with each mapping parameter (Ave-,Max- and Glo-T1 and T2) were statistically significant (p<.001). Significant differences have been found in the paired comparison between AM vs. controls and AM vs. e-MI/l-MI/TTS (p<.001 for all). No significant difference was found in the paired comparison between e-MI, l-MI, and TTS (p>.05). ROC curve analysis showed excellent performance in discriminating between ACP patients vs. controls for all the parameters (p<.001 for all); fair in differentiating between AM vs e-MI/l-MI/TTS using glo-T1, Ave-T1, Ave-T2 and Max-T2, good for Max-T1 and poor for Glo-T2. Diagnostic performance was very good in distinguishing controls vs. AM for glo-T1, Ave-T1, Max-T1, Ave-T2 and Max-T2 and good for Glo-T2.

CONCLUSION

s nT1 and T2 mapping play a role in the detection of acute cardiac conditions, and differentiation between AM versus myocardial infarction or TTS. Max- and Ave-T1 and T2 showed a greater diagnostic performance as compared to Glo-T1 and T2.

CLINICAL RELEVANCE/APPLICATION

The use of mapping sequences can help in the diagnosis of MI, AM and TTS in the acute setting, even without the use of contrast agent.

S3B-SPCA-2 Efficacy of Super-Resolution Deep-Learning Reconstruction for the Assessments of Obstructive Coronary Artery Disease on Cardiac CT

Participants
Yasunori Nagayama, MD, Kumamoto, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the image quality of super-resolution deep-learning reconstruction (SR-DLR) for coronary CT angiography (CCTA) in patients with coronary artery disease (CAD).

METHODS AND MATERIALS

This retrospective study included 48 patients with obstructive CAD (=50% stenosis in at least one coronary vessel) who underwent CCTA on a 320-row scanner. The images were reconstructed with hybrid iterative reconstruction (HIR, AIDR 3D), model-based iterative reconstruction (MBIR, FIRST), normal-resolution DLR (NR-DLR, AiCE), and SR-DLR (PIQE) using dedicated cardiac parameters. For each image series, CT attenuation at the left main artery, proximal and distal segments of the right coronary artery, left anterior descending artery (LAD), and left circumflex artery was quantified. Image noise was quantified as the standard deviation of CT attenuation in the subcutaneous fat at the level of the proximal and distal coronary arteries. The contrast-to-noise ratio (CNR) was calculated as the ratio of the attenuation differences between the coronary lumen and adjacent pericoronary fat and image noise. At the coronary segments with calcified plaques, blooming artifact was quantified using following formula: [(measured external coronary section diameter with calcified plaque - measured lumen diameter)/measured external coronary

section diameter with calcified plaque] × 100. The image sharpness, image noise, delineation of coronary lumens, calcified and noncalcified plaques, cardiac muscle, valves, and diagnostic confidence were subjectively scored on a 5-point scale (1, insufficient; 5, excellent). The quantitative parameters and qualitative scores were compared among the four reconstruction algorithms using the Kruskal-Wallis and Steel-Dwass tests.

RESULTS

SR-DLR yielded significantly lower quantitative image noise and blooming artifact with higher CNR at all coronary segments relative to HIR, MBIR, and NR-DLR images (all $P < 0.05$). The best subjective scores for all evaluation criteria were attained at SR-DLR images, with significant differences from all other reconstruction algorithms ($P < 0.05$).

CONCLUSION

s SR-DLR considerably improves the subjective and objective image qualities and diagnostic confidence of CCTA in patients with obstructive CAD.

CLINICAL RELEVANCE/APPLICATION

SR-DLR improves the spatial resolution while reducing noise and blooming, thereby allowing the accurate interpretation of CCTA performed in patients with obstructive CAD.

S3B-SPCA-3 A Pilot Study of combining 2nd Order Flow Compensated Diffusion and Computed DWI to Detect the Myocardial Infarction without Exogenous Contrast Agents

Participants
Rui Chen, Guangzhou, China (*Presenter*) Nothing to Disclose

PURPOSE

Cardiac diffusion weighted imaging (DWI) could provide essential information for diagnosis and clinical decision in patients with myocardial infarction without exogenous contrast agents. Higher b-value DWI could improve the detection rate of myocardial infarction, but it is challenging for image acquisition in cardiac DWI because of the low signal-to-noise ratio. The present study aimed to combine the 2nd order motion compensated diffusion with computed DWI to overcome these challenges.

METHODS AND MATERIALS

The graphical abstract (A) showed the proposed solution in the present study. To decrease the motion impact on cardiac DWI images, the 2nd order flow compensated diffusion (mcDWI) was used for image acquisition. Computed diffusion (cDWI) was implemented to generate higher b-value DWI images. To our knowledge, no published studies have combined mcDWI and cDWI in cardiac imaging. We called the combination of these two techniques as m2cDWI, and obtained the high b-value cardiac DWI images for the first time. To evaluate the feasibility of m2cDWI, we compared the m2cDWI images and origin DWI images with late gadolinium enhancement (LGE) imaging.

RESULTS

In the graphical abstract (B), the subendocardial enhancement seen in LGE might be more clearly shown in the m2cDWI images (b = 800, b=1200, b = 1600) than the origin DWI images (b = 400). It showed that the m2cDWI images seemed to be more sensitive to myocardial infarction.

CONCLUSION

s The m2cDWI could obtain higher b-value cardiac DWI images and improve the detection rate of myocardial infarction without exogenous contrast agents.

CLINICAL RELEVANCE/APPLICATION

In the present study, a novel scheme m2cDWI was proposed to obtain higher b value cardiac diffusion by combining mcDWI and cDWI, which was more sensitive to myocardial infarction. It could also have the potential improve the detection rate of of other microscopic structural remodeling without exogenous contrast agents.

S3B-SPCH-2 Quantitative Evaluation of Airway Disease in Rheumatoid Arthritis Using Ultra-high-resolution CT

Participants
Tae Iwasawa, MD, PhD, Yokohama, Japan (*Presenter*) Support, Canon Medical Systems Corporation;Support, Ziosoft Inc;Speaker, FUJIFILM Holdings Corporation;Speaker, Boehringer Ingelheim GmbH

PURPOSE

Airway disease is an important feature of rheumatoid arthritis (RA). In this study, we quantitatively evaluated bronchial dilatation in patients with RA using ultra-high-resolution CT (U-HRCT).

METHODS AND MATERIALS

This multicenter study was approved by the institutional review board, and the requirement for informed consent was waived. We collected clinical data, pulmonary function test results, and U-HRCT images of patients diagnosed with RA. All CT scans were performed using a 160-row U-HRCT scanner (Aquilion Precision, Canon Medical Systems, Otawara, Tochigi, Japan). CT scans were performed at 120 kVp, 0.25 × 160 collimation, using automatic exposure control. Two kinds of images were reconstructed: (1) U-HRCT mode (1024 × 1024 matrix size, 0.25-mm slice thickness, and deep learning reconstruction algorithm for the lung, Fig.1a) and (2) normal-resolution image (512 × 512 matrix size, 0.5-mm slice thickness, and iterative reconstruction method). We produced bronchial 3-dimensional images of U-HRCT using a workstation (Ziostation 2) (Fig.1.b), measured the airway volume in the right lower lobe (AWVrl), and calculated the ratio to the right lower lobe volume (AWV%rl= AWVrl/ volume of the right lower lobe × 100). We further measured the extension of interstitial lung diseases (ILD) in normal resolution images using a software (QZIP-ILD, Ziosoft, Inc, Tokyo, Japan) (Fig.1c). We compared AWV%rl with extension ILD, pulmonary function test results, and Krebs von den Lungen-6 (KL-6) using Spearman's rank correlation.

RESULTS

Overall, 151 patients (106 female) were enrolled, with a median age of 77. Fifty-one patients had a history of smoking and 119 had received with disease-modifying antirheumatic drugs and steroids at CT examinations. AWVrl% showed a significant negative correlation with forced vital capacity (%pred) (r=-0.383), diffusing capacity of the lung for carbon monoxide (DLCO %pred) (r=-0.412) (Fig.1d), and significant positive correlation with the extent of fibrotic lesion (%) (r=0.742), and KL-6 (r=0.697) (Fig.1e) ($p<0.001$, respectively).

CONCLUSION

s AWV%rl is a useful parameter to evaluate airway disease in RA.

CLINICAL RELEVANCE/APPLICATION

Bronchiolitis and bronchiectasis are significant features of the RA lung. U-HRCT enables clinicians to extract peripheral bronchi and measure AWVrl%, which is easier than measuring intra-bronchial area and wall-thickness.

S3B-SPCH-3 Limiting CT-based Severity Staging of COPD to a Single Inspiratory Acquisition Using Convolutional Neural Networks

Participants
Amanda Lee, (*Presenter*) Nothing to Disclose

PURPOSE

Several methods for computed tomography (CT)-based severity staging of chronic obstructive pulmonary disease (COPD) utilize both inspiratory and expiratory acquisitions, which are not the clinical standard and increase patients' exposure to ionizing radiation. We assess the feasibility of using a convolutional neural network (CNN) to stage COPD using only inspiratory images.

METHODS AND MATERIALS

This retrospective study is HIPAA-compliant and IRB-approved with waived requirement for written informed consent. We sampled 7,822 inspiratory lung CT series and spirometry measurements (forced expiratory volume in one second [FEV1], FEV1 to forced vital capacity ratio [FEV1/FVC], percent predicted FEV1 [FEV1pp]) from the COPDGene Phase I cohort. Severity stages were determined according to the Global Initiative for Obstructive Lung Disease (GOLD) stages. A 3D residual attention network was trained to

predict spirometry measurements using inspiratory images as input. CNN-predicted spirometry measurements were then used to estimate GOLD stage. Agreement between CNN-predicted and true spirometry measurements was assessed using intraclass correlation (ICC) and Bland Altman analysis. Accuracy for predicting GOLD stage, within one GOLD stage, and GOLD 0 vs. 1-4 was calculated.

RESULTS

FEV1, FEV1/FVC, and FEV1pp ICCs were 0.84, 0.85, and 0.79 and Bland Altman bias and limits of agreement were 0.01 [-0.97, 0.98]; gt; -0.01 [-0.17, 0.17]; and -1.03 [-32.21, 30.16], respectively. Accuracies were 0.63, 0.90, and 0.84 for GOLD stage, within one GOLD stage, and GOLD 0 vs. 1-4. Our model improves upon existing inspiratory models with accuracies of 0.51, 0.75, and 0.77, respectively, and achieves comparable accuracy to an existing inspiratory-expiratory model with GOLD 0 vs. 1-4 accuracy of 0.89.

CONCLUSION

s Inspiratory images can be used to accurately stage COPD severity within one stage. Accuracies are comparable to those achieved by competing methods, which use both inspiratory and expiratory series, suggesting inspiratory series contain the majority of information needed for imaging-based staging.

CLINICAL RELEVANCE/APPLICATION

The proposed model can be used to lower patients' CT radiation exposure, improve accessibility to CT-based staging, and align current methods to the clinical standard.

S3B-SPCH-4 Narrowing the Differential Diagnosis of Cystic Lesions in Smoking Related Lung Diseases with Expiratory CT Acquisition

Participants
Matheus Zanon, MD, MSc, Porto Alegre, Brazil (*Presenter*) Nothing to Disclose

PURPOSE

to assess the respiratory changes in the size of pulmonary cysts in paired inspiratory and expiratory CT scans from patients with cysts from honeycombing fibrosis, pulmonary Langerhans cell histiocytosis (PLCH), and paraseptal emphysema.

METHODS AND MATERIALS

smokers with cystic we retrospectively reviewed inspiratory and expiratory CT scans from lesions from paraseptal emphysema, honeycombing, and PLCH. Diagnosis should have been confirmed by histopathology. Blinded to the final diagnosis, two senior thoracic radiologists measured the diameters of the three largest cysts on paired inspiratory and expiratory CT scans.

RESULTS

A total of 72 patients and 216 lesions were included. The intraclass correlation coefficients demonstrated excellent reliability (ICC= 0.91). PLCH and honeycombing presented a decrease in the mean diameter of the cystic lesions (PLCH, d = 60.9%; p = 0.001; honeycombing, d = 47.5%; p = 0.014). Conversely, paraseptal emphysema did not show any changes (d = 5.2%; p = 0.34).

CONCLUSION

s our results demonstrate that cysts in smokers with PLCH and honeycombing fibrosis get smaller during expiratory CT scans, whereas the size of cystic-like lesions due to paraseptal emphysema and bullae tend to remain constant during respiratory cycles.

CLINICAL RELEVANCE/APPLICATION

presence of cyst-airway communication could narrow the differential diagnosis of cysts in smoking-related lung diseases, avoiding misinterpretation of honeycombing as paraseptal emphysema, and vice-versa.

S3B-SPCH-6 HRCT and Post-lymphangiographic CT (PLCT) In Lymphangiomyomatosis: A Retrospective Study

Participants
Xingpeng Li, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the imaging features and clinical value of chest high-resolution CT (HRCT) and post lymphangiographic CT (PLCT) in lymphangiomyomatosis.

METHODS AND MATERIALS

Fifty-six patients diagnosed as lymphangiomyomatosis were recruited in this retrospective study from December of 2008 to April of 2019. All patients underwent HRCT, and 45 underwent PLCT. All the imaging data were blinded reviewed by two radiologists respectively, with the imaging features of abnormal thoracic, abdominal and pelvic manifestations, abnormal distribution of contrast agents throughout the whole body.Statistical analyses were performed with the constituent ratio in the classified variable data.

RESULTS

HRCT findings of 56 patients showed diffuse thin-walled air cysts of different sizes in both lungs, the lung ground glass density 16 cases, 8 cases within the lung nodules, atelectasis 32 cases, bronchus enlargement of blood vessel bundle 12 cases , interlobular septal thickening 25 cases, mediastinal fat increased density 30 cases,pericardial effusion 6 cases, mediastinal lymph node enlargement 9 cases,pleural effusion 45 cases, pneumothorax 12 cases. PLCT findings of 45 patients showed abnormal iodine oil from different parts of the deposit: 24 cases of the end of thoracic duct,7 cases with right lymphatic catheter, 7 cases were intrapulmonary and 7 cases were hilum,mediastinum 20 cases, pericardium 1 case, pleural cavity 7 cases, Intercostal 17 cases, axillary 6 cases, diaphragmatic around 32 cases, 27 cases of spinal column, abdominal pelvic 45 cases, double iliac 41 cases, bilateral inguinal 36 cases, perineum 3 cases. In addition, 3 patients had hepatic angiomyolipoma, 8 patients had renal angiomyolipoma, 4 patients had diffuse intestinal wall thickening, and 31 patients had abdominal and pelvic effusion.

CONCLUSION

s HRCT and PLCT demonstrates capability in abnormalities of the thoracic, abdominal and pelvic and detection of location, distribution and range of abnormal lymphatics, which is useful for diagnosis and therapeutic adoptions for lymphangiomyomatosis.

CLINICAL RELEVANCE/APPLICATION

Lymphangiomyomatosis is an autoimmune disease involving multiple organs and systems.It is necessary to evaluate the systematic lymphatic circulation abnormality for with HRCT and PLCT in patients with SLE, which is very important for therapeutic options.

S3B-SPCH-7 Dark-Field Chest Radiography Outperforms Conventional Radiography for the Diagnosis and Staging of Pulmonary Emphysema

Awards
Trainee Research Prize - Resident

Participants
Theresa Urban, MSc, Garching, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Dark-field chest radiography visualizes the condition of the lungs' alveolar structure by measuring the coherent ultra-small-angle scattering of X-rays. Here, we compare dark-field chest radiography with conventional radiography for the diagnosis and staging of pulmonary emphysema.

METHODS AND MATERIALS

Subjects were included after a medically indicated CT scan of the thorax, showing either no lung impairments or different stages of emphysema. To establish a ground truth, all CTs were assessed separately by three radiologists assigning visual scores based on the Fleischner society classification scheme for emphysema severity (absent, trace, mild, moderate, confluent, advanced destructive).Participants were imaged at a commercial chest radiography device, yielding a conventional attenuation image, and at a clinical prototype for dark-field chest radiography, yielding both an attenuation and a dark-field image. Three independent blinded readers assessed the conventional attenuation image and both attenuation and dark-field image from the prototype for presence and severity of emphysema (no emphysema, mild emphysema, moderate emphysema, severe emphysema).Statistical analysis included evaluation of receiver-operator-characteristics and pair-wise comparison of adjacent Fleischner groups using an AUC-based z-test with a significance level of 0.05.

RESULTS

A total of 90 patients (56 males) were included, with a mean age of 65 ± 12 years.The dark-field images show a distinct decrease of signal strength with emphysema severity. Compared to conventional images (AUC = 0.74), readers were significantly better able to identify emphysema with images from the dark-field prototype (AUC = 0.85, $p < 0.05$). While ratings of adjacent emphysema severity groups with conventional radiographs were only different for trace and mild emphysema, ratings based on images from the dark-field prototype were different for trace and mild, mild and moderate, and moderate and confluent emphysema.

CONCLUSION

s Compared to conventional chest radiography, dark-field chest radiography provides improved capability for identification and staging of emphysema.

CLINICAL RELEVANCE/APPLICATION

Dark-field chest radiography improves the detection of emphysematous changes in the lung, demonstrating its high diagnostic value for lung assessment.

S3B-SPCH-8 Lung Imaging at 0.55T MRI for Interstitial Lung Disease Assessment in Patients with Pulmonary Sarcoidosis

Participants
Hanns-Christian Breit, MD, Basel, Switzerland (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the potential of lung MR imaging at 0.55T in patients with pulmonary sarcoidosis.

METHODS AND MATERIALS

We performed a prospective study with 7 patients (4 male, 3 female, 42±9 years) . All patients underwent a routine chest CT (SOMATOM Definition Edge, Siemens Healthineers, arms overhead position) followed by MRI on a 0.55T whole-body scanner (MAGNETOM Free.Max, Siemens Healthineers, gradient amplitude 26 mT/m, gradient slew rate 45 T/m/s) using a 6-channel chest array coil and a 6-channel spine coil. All patients had sarcoidosis with proven pulmonary involvement.Morphological lung imaging was performed by using a free-breathing 3D half-radial dual-echo sequence termed bSTAR (TA = 5:30 min, TE1/TE2/TR = 0.08/2.1/2.2 ms, field-of-view = 34×34×34cm3, flip angle = 25°, bandwidth = 1002 Hz/pixel) with a 1.3 mm isotropic resolution, a commercial axial breath-hold balanced steady state free precession (bSSFP) (TA = 0:48min, TE/TR = 2.3/4.6 ms, field-of-view = 380 x 304 mm, 6 mm slice thickness, flip angle = 90°). Furthermore, functional lung MRI using matrix pencil (MP) method for the evaluation of the fractional ventilation and pulmonary perfusion was performed using bSSFP (TA = 1:06 min, TE/TR = 1.20/2.66ms, field-of-view?=? 450×450?mm2, 12-mm slice thickness, flip angle = 80°).

RESULTS

In 4 patients, bihilar and mediastinal lymphadenopathy was seen on both CT and MRI. All 7 patients showed CT findings compatible with pulmonary sarcoidosis (perilymphatic nodules with associated partially thickened interlobular septa, airspace opacities, signs of pulmonary fibrosis). All findings were delineable in the morphologic MRI sequences, although the resolution of the perilymphatic micronodules was inferior. In line with these findings, functional MRI images showed a reduced perfusion and ventilation in the affected areas.

CONCLUSION

s Lung imaging at 0.55T MRI is a promising tool for visualizing morphologic changes in patients with sarcoidosis. Additional

s Lung imaging at 0.55T MRI is a promising tool for visualizing morphologic changes in patients with sarcoidosis. Additional information on perfusion and ventilation can be obtained using functional imaging. Further quantitative analyzes might be performed in the further to assess the full potential of this new method.

CLINICAL RELEVANCE/APPLICATION

Pulmonary MRI may be an attractive alternative to CT for diagnosis and follow-up of pulmonary sarcoidosis. Unlike CT, pulmonary MRI can provide additional functional information on pulmonary perfusion and ventilation

S3B-SPGI-1 Fully automated 3D organ segmentation in assessing hepatic steatosis on pre-contrast and post-contrast abdominal CT: diagnostic performances of various CT attenuation-based parameters

Participants
Jeongin Yoo, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the clinical utility of fully automated 3D organ segmentation in assessing hepatic steatosis on pre-contrast and post-contrast CT images, using MR spectroscopy (MRS)-derived proton density fat fraction (PDFF) as the reference standard.

METHODS AND MATERIALS

This retrospective study included 489 potential living liver donors (291 men; mean age: 37.1 years) with abdominal CT scans and MRS-PDFF. Using a deep learning-based fully automated 3D organ segmentation algorithm, mean volumetric CT attenuation of the liver and spleen were measured on pre-contrast (liver(L)_pre and spleen(S)_pre) and post-contrast (portal venous phase) images (L_post and S_post), respectively. Mean attenuation of the liver and spleen were also quantified using a conventional method, 2D manually-defined circular region-of-interest (ROI)-based measurement, and their agreements with volumetric measurements were assessed using the Bland-Altman analysis and intraclass correlation coefficient (ICC). Diagnostic performances for detecting MRS-PDFF =5% or =10% of CT attenuation-based parameters (L_pre, liver-minus-spleen(L-S)_pre, L_post, and L-S_post) were evaluated using receiver operating characteristic (ROC) curve analysis, and compared between volumetric and manual measurements using z-statistics.

RESULTS

According to MRS-PDFF, 143 (29.2%) and 51 (10.4%) subjects had =5% and =10% hepatic steatosis, respectively. Volumetric and ROI-based attenuation measurements showed good agreements both for liver and spleen, with mean differences of -4.1 HU (ICC=0.980) and -3.4 HU (ICC=0.915) on pre-contrast CT; and -1.4 HU (ICC=0.992) and -7.7 HU (ICC=0.968) on post-contrast CT, respectively. L_pre, L-S_pre, L_post, and L-S_post of volumetric measurements showed areas under the ROC curve (AUCs) of 0.786, 0.827, 0.748, and 0.807 for =5% steatosis; and 0.893, 0.921, 0.842, and 0.883 for =10% steatosis, respectively, which were comparable to those of ROI-based measurements (AUCs: 0.748-0.828; and 0.837-0.908, all Ps>0.05).

CONCLUSION

s Fully automated 3D segmentation analysis of the liver and spleen provides quantitative CT attenuation-based parameters that work well for assessing hepatic steatosis both on pre-contrast and post-contrast CT.

CLINICAL RELEVANCE/APPLICATION

Using the fully automated organ segmentation tool, CT volumetric attenuation data of liver and spleen can be obtained which can detect and grade hepatic steatosis. By allowing large population data collection on hepatic steatosis, it may be used for screening risk groups for metabolic disease and predicting the prognosis of various diseases.

S3B-SPGI-10 The establishment of a classification model for the acute ileus and perforation on abdominal radiographic image based on deep learning

Participants
Kexin Wang, (*Presenter*) Nothing to Disclose

PURPOSE

Establish an automatic triage system to classify whether typical imaging features of ileus or perforation exists on an abdominal radiography based on deep learning neural network.

METHODS AND MATERIALS

In the study for establishment of classification model aimed to diagnose ileus in X-ray plain image, we included 1697 consecutive patients (median age, 55 years; men, 1154) from January 1st 2018 to August 30th 2020 in our PACS/RIS database, who were divided into training dataset (n=1355), validation dataset (n=169) and testing dataset (n=173). As the model for classify image about whether perforation is existed, 271 patients were included, separated into training dataset (n=214), validation dataset (n=30) and testing dataset (n=27) randomly. The above-mentioned data were used to train classification models based on MedicalNet. Accuracy, misclassification, recall, specificity, precision, and F1-score were calculated and used to evaluate the

performance of models.

RESULTS

In the testing dataset of ileus model, 75 cases were classified as positive, while 98 cases were negative. The accuracy, misclassification, recall, specificity, precision, and F1-score were 94.8%, 4.3%, 0.949, 0.933, and 0.957, respectively. In the testing dataset of perforation diagnostic model, 11 cases were classified as positive, while 16 cases were negative. The accuracy, misclassification, recall, specificity, precision, and F1-score were 96.3%, 3.7%, 0.917, 1, 1, and 0.957, respectively.

CONCLUSION

s For the abdomen radiographs of patients with acute abdomen, the AI algorithm can be used in triage of the patients suspected of ileus and perforation.

CLINICAL RELEVANCE/APPLICATION

Automatic and rapid detection of patients with the acute abdomen on abdominal radiography in the ER, facilitating patient management and improving safety.

S3B-SPGI-2 Prediction Histological Grades and Ki-67 Expression of Hepatocellular Carcinoma Based on Sonazoid Contrast Enhanced Ultrasound Radiomics Signatures

Participants
Yi Dong, MD, PhD, Shanghai, China (*Presenter*) Nothing to Disclose

PURPOSE

Tumor histopathological grades and Ki-67 expression are key aspects concerning to prognosis of patients with hepatocellular carcinoma (HCC) lesions. The aim of this study is to investigate whether radiomics model derived from Sonazoid contrast enhanced (S-CEUS) images could predict histological grades and Ki-67 expression in HCC lesions.

METHODS AND MATERIALS

This prospective study included 101 (training cohort: n = 71; validation cohort: n = 30) patients with surgical resection and histopathological confirmed HCC lesions. Radiomics features were extracted from B mode and Kupffer phase of S-CEUS images. Maximum relevance minimum redundancy (MRMR) and Least Absolute Shrinkage and Selection Operator (LASSO) were used for feature selection and stepwise multivariate logit regression model was trained for prediction. Model accuracy, sensitivity and specificity in both training and testing datasets were used to evaluate performance.

RESULTS

Prediction model derived from Kupffer phase images (CE-model) displayed a significantly better performance for the prediction of stage III HCC patients, with an area under the receiver operating characteristic curve (AUROC) of 0.869 in the training dataset, and 0.865 in testing set. CE-model demonstrated well generalizability in identifying HCC patients with elevated Ki-67 expression (> 10 %) with a training AUROC of 0.873 and testing AUROC of 0.768, with noticeably higher specificity of 93.3% and 80.0% in training and testing datasets.

CONCLUSION

s Radiomic model constructed from Kupffer phase of S-CEUS images have potential for predicting Ki-67 expression and histological stages in patients with HCC.

CLINICAL RELEVANCE/APPLICATION

Radiomic model constructed from Kupffer phase of S-CEUS images could be used to provide valuable information for predicting histopathologic stages and Ki-67 expression in patients with HCC.

S3B-SPGI-3 Detection of Colon Cancer on CT using Machine Learning

Participants
Robert Harris, PhD, (*Presenter*) Scientist, Virtual Radiologic Corporation

PURPOSE

Colorectal cancer is among the most common cancers diagnosed in the U.S. The survival rate is greatly influenced by how early the disease is caught, with a 5-year survival rate of 91% in patients with localized cancer. However, less than half of patients are diagnosed at this early stage. Our teleradiology institution processes approximately 3 million CT studies each year, during which a small number of masses suspicious for colon cancer are missed on the initial CT read and discovered during quality assurance (QA) review. We hypothesized that we could train a machine learning algorithm to identify masses suspicious for colon cancer on CT images and use this model as part of a QA process to notify radiologists if a suspicious mass has been potentially missed.

METHODS AND MATERIALS

Natural language processing (NLP) of radiology CT reports was used retrospectively to identify 99 studies containing colorectal masses suspicious for cancer. An axial image series from each of these studies was annotated by a Board Certified radiologist by segmenting masses suspicious for cancer. These segmentations were converted into bounding boxes, with 1,085 annotated images used as positives and 2,170 axial CT images with no colon masses used as negatives in the training dataset. A yolo-v3 bounding box model was used for training. A test dataset was created using 16 CT studies containing a suspicious colorectal mass that had been missed on the initial read and later found by QA, along with 16 CT studies with no suspicious pathology. The trained model was run on this test dataset. The model was also integrated with our teleradiology practice workflow to classify prospective studies during a four-week period.

RESULTS

The model achieved an AUC of 0.930 on the test dataset, with a sensitivity of 50% and specificity of 100%. For prospective data, 17,451 abdominal CT studies were inferenced, of which 40 were NLP-positive for suspicion of colorectal cancer. The model correctly identified 22 of these for a sensitivity of 55.0% and specificity of 92.3%.

CONCLUSION

s An artificial intelligence model was trained to identify masses suspicious for colorectal cancer on CT imaging. This model was able to identify half of our practice's previously missed suspicious colon masses and performs equally well on prospective data. This model is currently undergoing iterative retraining and will be used to screen CT data for missed findings.

CLINICAL RELEVANCE/APPLICATION

At least 20 colorectal masses suspicious for cancer are missed on CT imaging each year at our practice due to our high volume of CT imaging. A machine learning model capable of identifying these missed findings shortly after image interpretation can be used to correct missed diagnoses and improve patient care.

S3B-SPGI-5 Prior-judgement-based 2D Deep Transfer Learning Improves MRI Prediction of Preoperative T-staging in Rectal Cancer

Participants
Min Hou, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate whether the addition of expert radiologists' prior selection of imaging slice in 2D deep transfer learning model could achieve better predictive performance than the 2D model without prior information and subjective assessment of expert radiologists.

METHODS AND MATERIALS

A total of 788 consecutive RC patients with pathologically proven T-staging results in our institution were retrospectively enrolled in this study. All patients were randomly divided into the training cohort (n = 670) and the testing cohort (n = 118). We established an ImageNet pre-trained ResNet18 model for the pretreatment prediction on tumor T-staging. Then two tumor-derived deep learning (DL) diagnostic models were developed: Model1 based on the slice selected by radiologists which they reckon to compromise the deepest invasion depth of the tumor, and Model2 based on the slice of maximum tumor cross-section. The diagnostic performance of the DL models were compared to each other and to the subjective assessment of expert radiologists by receiver operating characteristic (ROC). The sensitivity, specificity, and accuracy were calculated.

RESULTS

The diagnostic performance of Model1 [the area under the curve (AUC) 91.7%, sensitivity 0.907, specificity 0.761, and accuracy 0.855] was significantly higher than that of Model2 (AUC 80.0%, sensitivity 0.815, specificity 0.693, and accuracy 0.772) for predicting RC T-staging ($P<0.05$). Both the DL models achieved superior predictive performance than the expert radiologists ($P<0.05$).

CONCLUSION

s We introduced a novel 2D deep transfer learning model for preoperative assessing the T-staging category of rectal cancer, and found that the performance of the DL model was significantly improved based on expert radiologists' prior selected slice of the deepest invasion depth of tumor.

CLINICAL RELEVANCE/APPLICATION

The accuracy of T-staging prediction among RC patients has been a prime concern in tailoring preoperative treatment strategy. We firstly established a 2D deep transfer learning model with satisfying predictive performance, and found that the performance could be significantly improved by using radiologists' prior judgment.

S3B-SPGI-6 A Novel Multimodal Deep Learning Model for PreoperativePrediction of Microvascular Invasion and Outcome in Hepatocellular Carcinoma

Participants
Fang Wang, Hangzhou, China (*Presenter*) Nothing to Disclose

PURPOSE

Accurate preoperative identification of the positive propensity of microvascular invasion (MVI) can relieve the pressure from personalized treatment adaptation and improve the poor prognosis for hepatocellular carcinoma (HCC). This study aimed to develop and validate a novel multimodal deep learning (DL) model for MVI status prediction based on contrast-enhanced computed tomography (CT) and multi-parameter magnetic resonance imaging (MRI).

METHODS AND MATERIALS

This retrospective study enrolled 397 patients from two institutions with pathologically-confirmed HCC. All patients underwent both CT and MRI examinations preoperative. Patients from institution I (n = 297) were included as training cohort and patients from institution II (n = 100) served as an independent validation set. To predict the presence of MVI, the clinical model (C) and the CT/MRI radiological models (RCT, RMRI) were established by support vector machine (SVM), and DL models (DLCT_ALL, DLMRI_ALL, DLCT+MRI) based on single or multi-modality medical images were developed by convolutional neural network (CNN) ResNet18, and the comprehensive model (CALL) involving multi-modality DL features and clinical and radiological features was constructed using SVM algorithm. In addition, the prognostic value of the DL models for recurrence-free survival (RFS) was further explored.

RESULTS

The DLCT+MRI model exhibited superior predicted efficiency over single-modality models, especially over the DLCT_ALL model (area under receiver operating characteristics curve [AUC]: 0.819 vs. 0.742, net reclassification index [NRI] > 0, integrated discrimination improvement [IDI] > 0). Besides, the DLMRI_ALL model improved the performance over the RMRI model (AUC: 0.794 vs. 0.766, NRI > 0, IDI < 0), but no such difference was found between the DLCT_ALL model and the RCT model (AUC: 0.742 vs. 0.710, NRI<0, IDI<0). And the diagnostic performance of the C model was worse than any other models. Furthermore, both DLCT+MRI and CALL models revealed the prognostic power in the stratification of RFS ($P<0.001$).

CONCLUSION

s The proposed DLCT+MRI model showed robust capability in predicting the risk of MVI occurrence and outcomes for HCC patients, which might help surgeons decide the extent of operation in precise medicine. Besides, the performance of multi-modality DL model was better than any single modality, especially for CT.

CLINICAL RELEVANCE/APPLICATION

MVI plays a crucial role in the personalized treatment strategy of HCC, yet a high level of diagnostic expertise tends to be localized in minority reference centers. One promising solution is the adoption of the deep learning model based on multi-modality medical images to improve the accuracy of preoperative prediction of MVI.

S3B-SPGI-7 Prediction of Microvascular Invasion in Hepatocellular Carcinoma Using Artificial Intelligence: A systematic review and meta-analysis of 12,216 patients

Participants
Pedram Keshavarz, MD, Los Angeles, CA (*Presenter*) Nothing to Disclose

PURPOSE

To review the developed microvascular invasion (MVI) predictive models using radiomics, non-radiomics, and Convolutional Neural Network (CNN) in patients with hepatocellular carcinoma (HCC).

METHODS AND MATERIALS

A systematic search of PubMed, Scopus, Embase, Web of Science, and Google Scholar was performed. The random-effect models were utilized to calculate pool sensitivity, specificity, predictive values, summary ROC curves, and AUC based on the "Standards for Reporting Diagnostic accuracy studies" (STARD) guidelines. The heterogeneity between studies was examined using Cochrane's Q and I2 tests.

RESULTS

The meta-analysis study cohort included 47 studies comprising 12,216 cases including 15, 26 and 10 studies in the radiomics, non-radiomics, and CNN subcohorts respectively. Four studies reported two models. The pooled specificity, sensitivity, and AUC of the radiomics, non-radiomics and CNN subcohorts were 0.76 (95% CI: 0.69-0.82, I2 = 87%), 0.79 (95% CI: 0.73-0.85, I2 = 84%), 0.85 and 0.81 (95% CI: 0.76-0.85, I2 = 79%), 0.73 (95% CI: 0.65-0.79, I2 = 82%), 0.84 and 0.81 (95% CI: 0.76-0.85, I2 = 49%, and 0.83 (95% CI: 0.78-0.88, I2 = 60%), and AUC of 0.89, respectively. Meta-regression and sub-group analysis showed significant differences in performance of CNN models in patients with multiple vs single HCC tumors (specificity 0.78, 95% CI: 0.72-0.83, I2 = 37%, sensitivity 0.82, 95% CI: 0.74-0.88, I2 = 46%, AUC: 0.85) without significant differences between studies using different imaging modalities (MRI vs. CT).

CONCLUSION

s Based on the meta-analysis, the CNN subcohort had the best pooled prediction of MVI, compared to radiomics and non-radiomics sub-cohorts, especially in patients with multiple HCC lesions.

CLINICAL RELEVANCE/APPLICATION

CNN-based deep learning models have high performance for the prediction of MVI in HCC patients, although the long-term outcomes and multicentral validation are required to provide a reliable and robust prediction tool that translates into clinical utilization.

S3B-SPGI-9 DeePSC - Automated decision support for the diagnosis of primary sclerosing cholangitis

Awards
Trainee Research Prize - Resident

Participants
Haissam Ragab, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To develop a deep learning-based clinical decision support system for the automated diagnosis of primary sclerosing cholangitis (PSC) on 2D-MRCP images that surpasses the predictive performance of the average radiologist.

METHODS AND MATERIALS

In this retrospective study, 2D-MRCP datasets of 342 patients with confirmed diagnosis of PSC and another 264 control subjects without any history of chronic liver disease obtained at 1.5 and 3 T were included. For external validation, another 37 MRCP datasets (20 PSC/17 non-PSC) from a different scanner and manufacturer (3 T, Siemens) were included.The binary classification task was performed with a multi-view deep convolutional neural network (CNN) specialized on simultaneously processing seven 2D-MRCP images taken from different rotational angles from the same patient. The diagnostic performance of our model was eventually compared to that of four board-certified radiologists at different levels of training and with varying experience in reading MRCP.

RESULTS

The model showed high performance with an accuracy, sensitivity, and specificity of 82 %, 81 %, and 83 % on the unseen 3 T test dataset, and 82 %, 82 %, and 82 % on the unseen 1.5 T test dataset, respectively. For comparison, the average diagnostic performance of the four radiologists was 75 %, 77 %, and 72 % for accuracy, sensitivity, and specificity, respectively, on the 3 T images as well as 72 %, 73 %, and 70 % on the 1.5 T images. When comparing individually, the model achieved similar values to the best radiologist in all metrics on the 1.5 T data as well as in 3 T sensitivity, and scored second best in 3 T accuracy and specificity. On the external dataset, the model achieved near perfect values for accuracy (94 %), sensitivity (100 %) and specificity (88 %).

CONCLUSION

s The proposed multi-view CNN outperformed the average predictions provided by four radiologists on all metrics and datasets and even performed on par with the best radiologist on the 1.5 T dataset. The high performance on the external dataset suggests generalizability of the developed algorithm. Our results show that automated classification of PSC-compatible findings based on 2D-MRCP is achievable with high accuracy for both 1.5 and 3 T.

CLINICAL RELEVANCE/APPLICATION

The proposed algorithm might serve as a clinical decision support system to improve the expert diagnosis of PSC-compatible features on 2D-MRCP image data.

Fully automated 3D organ segmentation in assessing hepatic steatosis on pre-contrast and post-contrast abdominal CT: diagnostic performances of various CT attenuation-based parameters

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - GI DPS

Participants
Jeongin Yoo, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the clinical utility of fully automated 3D organ segmentation in assessing hepatic steatosis on pre-contrast and post-contrast CT images, using MR spectroscopy (MRS)-derived proton density fat fraction (PDFF) as the reference standard.

METHODS AND MATERIALS

This retrospective study included 489 potential living liver donors (291 men; mean age: 37.1 years) with abdominal CT scans and MRS-PDFF. Using a deep learning-based fully automated 3D organ segmentation algorithm, mean volumetric CT attenuation of the liver and spleen were measured on pre-contrast (liver(L)_pre and spleen(S)_pre) and post-contrast (portal venous phase) images (L_post and S_post), respectively. Mean attenuation of the liver and spleen were also quantified using a conventional method, 2D manually-defined circular region-of-interest (ROI)-based measurement, and their agreements with volumetric measurements were assessed using the Bland-Altman analysis and intraclass correlation coefficient (ICC). Diagnostic performances for detecting MRS-PDFF =5% or =10% of CT attenuation-based parameters (L_pre, liver-minus-spleen(L-S)_pre, L_post, and L-S_post) were evaluated using receiver operating characteristic (ROC) curve analysis, and compared between volumetric and manual measurements using z-statistics.

RESULTS

According to MRS-PDFF, 143 (29.2%) and 51 (10.4%) subjects had =5% and =10% hepatic steatosis, respectively. Volumetric and ROI-based attenuation measurements showed good agreements both for liver and spleen, with mean differences of -4.1 HU (ICC=0.980) and -3.4 HU (ICC=0.915) on pre-contrast CT; and -1.4 HU (ICC=0.992) and -7.7 HU (ICC=0.968) on post-contrast CT, respectively. L_pre, L-S_pre, L_post, and L-S_post of volumetric measurements showed areas under the ROC curve (AUCs) of 0.786, 0.827, 0.748, and 0.807 for =5% steatosis; and 0.893, 0.921, 0.842, and 0.883 for =10% steatosis, respectively, which were comparable to those of ROI-based measurements (AUCs: 0.748-0.828; and 0.837-0.908, all Ps>0.05).

CONCLUSION

s Fully automated 3D segmentation analysis of the liver and spleen provides quantitative CT attenuation-based parameters that work well for assessing hepatic steatosis both on pre-contrast and post-contrast CT.

CLINICAL RELEVANCE/APPLICATION

Using the fully automated organ segmentation tool, CT volumetric attenuation data of liver and spleen can be obtained which can detect and grade hepatic steatosis. By allowing large population data collection on hepatic steatosis, it may be used for screening risk groups for metabolic disease and predicting the prognosis of various diseases.

We established an ImageNet pre-trained ResNet18 model for the pretreatment prediction on tumor T-staging. Then two tumor-derived deep learning (DL) diagnostic models were developed: Model1 based on the slice selected by radiologists which they reckon to compromise the deepest invasion depth of the tumor, and Model2 based on the slice of maximum tumor cross-section. The diagnostic performance of the DL models were compared to each other and to the subjective assessment of expert radiologists by receiver operating characteristic (ROC). The sensitivity, specificity, and accuracy were calculated.

RESULTS

The diagnostic performance of Model1 [the area under the curve (AUC) 91.7%, sensitivity 0.907, specificity 0.761, and accuracy 0.855] was significantly higher than that of Model2 (AUC 80.0%, sensitivity 0.815, specificity 0.693, and accuracy 0.772) for predicting RC T-staging ($P<0.05$). Both the DL models achieved superior predictive performance than the expert radiologists ($P<0.05$).

CONCLUSION

s We introduced a novel 2D deep transfer learning model for preoperative assessing the T-staging category of rectal cancer, and found that the performance of the DL model was significantly improved based on expert radiologists' prior selected slice of the deepest invasion depth of tumor.

CLINICAL RELEVANCE/APPLICATION

The accuracy of T-staging prediction among RC patients has been a prime concern in tailoring preoperative treatment strategy. We firstly established a 2D deep transfer learning model with satisfying predictive performance, and found that the performance could be significantly improved by using radiologists' prior judgment.

S3B-SPGI-6

A Novel Multimodal Deep Learning Model for PreoperativePrediction of Microvascular Invasion and Outcome in Hepatocellular Carcinoma

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - GI DPS

Participants
Fang Wang, Hangzhou, China (*Presenter*) Nothing to Disclose

PURPOSE

Accurate preoperative identification of the positive propensity of microvascular invasion (MVI) can relieve the pressure from personalized treatment adaptation and improve the poor prognosis for hepatocellular carcinoma (HCC). This study aimed to develop and validate a novel multimodal deep learning (DL) model for MVI status prediction based on contrast-enhanced computed tomography (CT) and multi-parameter magnetic resonance imaging (MRI).

METHODS AND MATERIALS

This retrospective study enrolled 397 patients from two institutions with pathologically-confirmed HCC. All patients underwent both CT and MRI examinations preoperative. Patients from institution I (n = 297) were included as training cohort and patients from institution II (n = 100) served as an independent validation set. To predict the presence of MVI, the clinical model (C) and the CT/MRI radiological models (RCT, RMRI) were established by support vector machine (SVM), and DL models (DLCT_ALL, DLMRI_ALL, DLCT+MRI) based on single or multi-modality medical images were developed by convolutional neural network (CNN) ResNet18, and the comprehensive model (CALL) involving multi-modality DL features and clinical and radiological features was constructed using SVM algorithm. In addition, the prognostic value of the DL models for recurrence-free survival (RFS) was further explored.

RESULTS

The DLCT+MRI model exhibited superior predicted efficiency over single-modality models, especially over the DLCT_ALL model (area under receiver operating characteristics curve [AUC]: 0.819 vs. 0.742, net reclassification index [NRI] > 0, integrated discrimination improvement [IDI] > 0). Besides, the DLMRI_ALL model improved the performance over the RMRI model (AUC: 0.794 vs. 0.766, NRI > 0, IDI < 0), but no such difference was found between the DLCT_ALL model and the RCT model (AUC: 0.742 vs. 0.710, NRI<0, IDI<0). And the diagnostic performance of the C model was worse than any other models. Furthermore, both DLCT+MRI and CALL models revealed the prognostic power in the stratification of RFS (P<0.001).

CONCLUSION

s The proposed DLCT+MRI model showed robust capability in predicting the risk of MVI occurrence and outcomes for HCC patients, which might help surgeons decide the extent of operation in precise medicine. Besides, the performance of multi-modality DL model was better than any single modality, especially for CT.

CLINICAL RELEVANCE/APPLICATION

MVI plays a crucial role in the personalized treatment strategy of HCC, yet a high level of diagnostic expertise tends to be localized in minority reference centers. One promising solution is the adoption of the deep learning model based on multi-modality medical images to improve the accuracy of preoperative prediction of MVI.

S3B-SPGI-7

Prediction of Microvascular Invasion in Hepatocellular Carcinoma Using Artificial Intelligence: A systematic review and meta-analysis of 12,216 patients

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - GI DPS

Participants
Pedram Keshavarz, MD, Los Angeles, CA (*Presenter*) Nothing to Disclose

PURPOSE

To review the developed microvascular invasion (MVI) predictive models using radiomics, non-radiomics, and Convolutional Neural Network (CNN) in patients with hepatocellular carcinoma (HCC).

METHODS AND MATERIALS

A systematic search of PubMed, Scopus, Embase, Web of Science, and Google Scholar was performed. The random-effect models were utilized to calculate pool sensitivity, specificity, predictive values, summary ROC curves, and AUC based on the "Standards for Reporting Diagnostic accuracy studies" (STARD) guidelines. The heterogeneity between studies was examined using Cochrane's Q and I2 tests.

RESULTS

The meta-analysis study cohort included 47 studies comprising 12,216 cases including 15, 26 and 10 studies in the radiomics, non-radiomics, and CNN subcohorts respectively. Four studies reported two models. The pooled specificity, sensitivity, and AUC of the radiomics, non-radiomics and CNN subcohorts were 0.76 (95% CI: 0.69-0.82, I2 = 87%), 0.79 (95% CI: 0.73-0.85, I2 = 84%), 0.85 and 0.81 (95% CI: 0.76-0.85, I2 = 79%), 0.73 (95% CI: 0.65-0.79, I2 = 82%), 0.84 and 0.81 (95% CI: 0.76-0.85, I2 = 49%, and 0.83 (95% CI: 0.78-0.88, I2 = 60%), and AUC of 0.89, respectively. Meta-regression and sub-group analysis showed significant differences in performance of CNN models in patients with multiple vs single HCC tumors (specificity 0.78, 95% CI: 0.72-0.83, I2 = 37%, sensitivity 0.82, 95% CI: 0.74-0.88, I2 = 46%, AUC: 0.85) without significant differences between studies using different imaging modalities (MRI vs. CT).

CONCLUSION

s Based on the meta-analysis, the CNN subcohort had the best pooled prediction of MVI, compared to radiomics and non-radiomics sub-cohorts, especially in patients with multiple HCC lesions.

CLINICAL RELEVANCE/APPLICATION

CNN-based deep learning models have high performance for the prediction of MVI in HCC patients, although the long-term outcomes and multicentral validation are required to provide a reliable and robust prediction tool that translates into clinical utilization.

DeePSC - Automated decision support for the diagnosis of primary sclerosing cholangitis

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - GI DPS

Awards
Trainee Research Prize - Resident

Participants
Haissam Ragab, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To develop a deep learning-based clinical decision support system for the automated diagnosis of primary sclerosing cholangitis (PSC) on 2D-MRCP images that surpasses the predictive performance of the average radiologist.

METHODS AND MATERIALS

In this retrospective study, 2D-MRCP datasets of 342 patients with confirmed diagnosis of PSC and another 264 control subjects without any history of chronic liver disease obtained at 1.5 and 3 T were included. For external validation, another 37 MRCP datasets (20 PSC/17 non-PSC) from a different scanner and manufacturer (3 T, Siemens) were included.The binary classification task was performed with a multi-view deep convolutional neural network (CNN) specialized on simultaneously processing seven 2D-MRCP images taken from different rotational angles from the same patient. The diagnostic performance of our model was eventually compared to that of four board-certified radiologists at different levels of training and with varying experience in reading MRCP.

RESULTS

The model showed high performance with an accuracy, sensitivity, and specificity of 82 %, 81 %, and 83 % on the unseen 3 T test dataset, and 82 %, 82 %, and 82 % on the unseen 1.5 T test dataset, respectively. For comparison, the average diagnostic performance of the four radiologists was 75 %, 77 %, and 72 % for accuracy, sensitivity, and specificity, respectively, on the 3 T images as well as 72 %, 73 %, and 70 % on the 1.5 T images. When comparing individually, the model achieved similar values to the best radiologist in all metrics on the 1.5 T data as well as in 3 T sensitivity, and scored second best in 3 T accuracy and specificity. On the external dataset, the model achieved near perfect values for accuracy (94 %), sensitivity (100 %) and specificity (88 %).

CONCLUSION

s The proposed multi-view CNN outperformed the average predictions provided by four radiologists on all metrics and datasets and even performed on par with the best radiologist on the 1.5 T dataset. The high performance on the external dataset suggests generalizability of the developed algorithm. Our results show that automated classification of PSC-compatible findings based on 2D-MRCP is achievable with high accuracy for both 1.5 and 3 T.

CLINICAL RELEVANCE/APPLICATION

The proposed algorithm might serve as a clinical decision support system to improve the expert diagnosis of PSC-compatible features on 2D-MRCP image data.

S3B-SPGU-2 Improved Detection of Renal Stones using Photon Counting Detector (PCD) CT

Participants
Andrea Esquivel Mora, MD, San Jose, Costa Rica (*Presenter*) Nothing to Disclose

PURPOSE

To compare photon-counting detector (PCD) CT to dual-energy CT (DECT) with conventional energy-integrating detectors (EIDs) for renal stone detection.

METHODS AND MATERIALS

After IRB approval and informed written consent, patients with renal stones detected using DECT underwent a research PCD-CT exam using similar acquisition settings. Inclusion criteria: (1) archived DECT projection data, (2) no more than 10 renal stones, and (3) at least one stone with a maximum dimension of 3 mm or smaller. For each patient, two DECT mixed images were reconstructed via filtered backprojection (FBP) with (1) a 512 matrix, Qr40 kernel, slice thickness of 1 mm and (2), a 512 matrix, Br40 kernel, and slice thickness of 2 mm. Likewise, for each patient, two PCD-CT virtual monoenergetic images (VMIs) at 70 keV were reconstructed with (1) a 1024 matrix, Qr68 kernel with IR strength 3, and slice thickness of 2 mm and (2), a 1024 matrix, Br68 kernel with IR strength 4, and slice thickness of 0.4 mm. Two radiologists blinded to CT system, slice thickness, and kernel independently compared the de-identified, randomized images in a side-by-side manner to evaluate the visibility of each renal stone using a 4-point Likert score (1=Definitely present, 2=Probably present, 3=Questionably present, 4=Not seen), with disagreements resolved by a genitourinary radiologist. To generate a reference standard for stone presence, a stone was considered definitely present if a consensus score of 1 was assigned for at least one of the four reconstructions, and not present otherwise.

RESULTS

Twenty-one patients underwent a DECT exam with EID followed by a PCD CT (mean age 66 years [range, 48-74]; CTDIvol of PCD [15.65 ± 14.17 mGy], CTDIvol of DECT [15.93 ± 14.17 mGy]). 121 renal stones were characterized as definitely present (mean maximum dimension 2.84 ± 2.61 mm, interquartile range: [1.1 mm, 2.7 mm]); 86 of these stones were 3 mm or less. The sensitivity of conventional DECT was 61.2% (74/121; 95% CI: 51.9-69.9) at 2 mm and 65.3% (79/121; 95% CI: 56.1-73.7) at 1 mm. Sensitivity of PCD CT was 73.6% (89/121; 95% CI: 64.8-81.2) at 2 mm and 95.9% (116/121; 95% CI: 90.6-98.6) at 0.4 mm. For stones 3 mm or smaller, PCD at 0.4 mm slice thickness (sensitivity 94.2% [81/86]) was significantly more sensitive than DECT at either slice thickness (at 2 mm: 47.7% [41/86], P=.005; at 1 mm: 53.5% [46/86], P=.01) or PCD at 2 mm (62.8% [54/86], P <.001).

CONCLUSION

s PCD CT with high resolution reconstruction enabled detection of renal stones 3 mm and smaller that were not seen or characterized by DECT with conventional EIDs.

CLINICAL RELEVANCE/APPLICATION

PCD CT facilitates more accurate detection of small renal stones, which has implications for patient counseling and triage.

S3B-SPGU-3 Prostate Imaging-Reporting and Data System Version 2 Release Has Improved Biopsy Accuracy Regarding Tumor Grade: An Experience of Single, Tertiary Institution

Participants
Sung Yoon Park, (*Presenter*) Nothing to Disclose

PURPOSE

Before Prostate Imaging-Reporting and Data System Version 2 (PI-RADSv2) release, there was a significant discrepancy in tumor grade between prostate biopsy and surgery. We investigated changes of prostate biopsy accuracy regarding tumor grade before and after PI-RADSv2 release in single, tertiary institution.

METHODS AND MATERIALS

We retrospectively evaluated 1191 patients before (2013 cohort, n=394) and 5 years after PI-RADSv2 release (2020 cohort, n=797) who had biopsy-proven prostate cancer (PCa), magnetic resonance imaging (MRI), and surgery. The highest tumor grade of each biopsy and surgical specimens was recorded, respectively. We compared the concordant, underestimated, and overestimated biopsy rates regarding tumor grade compared to surgery between two cohorts, respectively. For patients who underwent both prostate MRI and biopsy at our institution, we investigated the proportion of prebiopsy MRI, age, and prostate-specific antigen of patients, and performed logistic regression for analyzing which parameters are associated with concordant biopsy.

RESULTS

Concordant and underestimated biopsy rates were significantly different between two cohorts: concordance rates were 47.2% in 2013 and 54.5% in 2020 (p=.019); underestimated rates were 46.3% in 2013 and 36.4% in 2020 (p=.003). However, overestimated biopsy rates between two cohorts were similar (p=.993). The proportion of prebiopsy MRI was significantly higher in 2020 than 2013 (80.9% versus 4.9%; p<.001), and it was independently associated with concordant biopsy result in multivariate analysis (odds ratio=1.486; 95% confidence interval, 1.057-2.089; p=.022).

CONCLUSION

s There was a significant change in the proportion of prebiopsy MRI before and after PI-RADSv2 release in patients who underwent surgery for PCa. This change appears to improve biopsy accuracy regarding tumor grade by reducing underestimation.

CLINICAL RELEVANCE/APPLICATION

We demonstrated the change in clinical pathway and improvement of biopsy accuracy before and after PI-RADSv2 release. Current data will serve as evidence for supporting MRI-directed biopsy pathway.

S3B-SPHN-1 Spectral Shaping in Ultra-High-Resolution Photon-Counting and Energy-Integrating Detector CT of the Temporal Bone by Means of Tin Prefiltration

Participants
Henner Huflage, MD, Wuerzburg, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the dose saving potential of spectral shaping via tin prefiltration in photon-counting detector CT (PCD-CT) of the temporal bone.

METHODS AND MATERIALS

Deploying dose-matched scan protocols with and without tin prefiltration on a PCD-CT and EID-CT system (low-/intermediate-/full-dose: 4.8/7.6-7.7/27.0-27.1 mGy), twelve ultra-high-resolution examinations were performed on each of five cadaveric heads. While 120 kVp were applied for standard imaging, the protocols with spectral shaping used the highest potential available with tin prefiltration (EID-CT: Sn 150 kVp, PCD-CT: Sn 140 kVp). Contrast-to-noise ratios and dose saving potential by spectral shaping were computed for each scanner. Three radiologists independently assessed the image quality of each examination.

RESULTS

Regardless of tin prefiltration, PCD-CT with low (171.2±10.3 HU) and intermediate dose (134.7±4.5 HU) produced less image noise than full-dose EID-CT (177.0±14.2 HU; $p<0.001$). Targeting matched image noise to 120 kVp EID-CT, mean dose reduction of 79.3±3.9% could be realized in 120 kVp PCD-CT. Subjective image quality of PCD-CT was better than EID-CT on each dose level ($p<0.050$). While no distinction was found between dose-matched PCD-CT with and without tin prefiltration ($p=0.928$), Sn 150 kVp EID-CT provided better image quality than 120 kVp EID-CT at high and intermediate dose levels ($p>0.050$). The majority of low-dose EID-CT examinations was considered not diagnostic, whereas PCD-CT scans of the same dose level received satisfactory or better ratings. Interrater reliability was excellent (ICC: 0.903).

CONCLUSION

s PCD-CT provides superior image quality and significant dose savings compared to EID-CT for ultra-high-resolution examinations of the temporal bone. Aiming for matched image noise, high-voltage scan protocols with tin prefiltration facilitate additional dose saving in EID-CT, whereas superior inherent denoising decreases the dose reduction potential of spectral shaping in PCD-CT.

CLINICAL RELEVANCE/APPLICATION

In ultra-high-resolution photon-counting detector CT of the temporal bone, the denoising effect of spectral shaping through tin prefiltration is less pronounced than in energy-integrating detector CT.

S3B-SPHN-2 Improved Cochlear Implant Electrode Localization Using Co-registration of Pre- and Post-Operative CT

Participants
Paul Farnsworth, DO, Saint Cloud, FL (*Presenter*) Nothing to Disclose

PURPOSE

A primary objective of cochlear implant surgery is an atraumatic electrode array insertion, preventing the implant from violating the basilar membrane and osseous spiral lamina with transscalar migration of the array from the scala tympani into the scala vestibuli, disrupting the cochlear duct. Accurate localization of electrode and can be difficult on post-operative imaging secondary to artifact. Here, we describe the use of co-registered pre- and post-operative multi-detector CT images to determine scalar location of the cochlear implant and determine depth of electrode insertion.

METHODS AND MATERIALS

Pre- and post-operative temporal bone CT examinations were retrospectively reviewed after co-registration and overlay of both exams. Images were evaluated by 2 neuroradiologists for scalar location of electrodes tip (+/- scalar translocation), tip fold over, and depth of insertion. Any disagreements between reviewers were resolved via consensus. Depth of insertion was expressed in radial degrees beyond the round window. For purposes of statistical analysis, depth of insertion was considered to represent agreement if the discrepancy was <90 degrees difference between reviewers. Electronic medical records of patients were searched for intra-operative and post-operative complications.

RESULTS

Thirty-four patients were included in the final cohort: Thirteen (38.2%) females and 21 (61.8%) males. Fourteen (41.2%) had right

Thirty-four patients were included in the final cohort. Thirteen (38.2%) females and 21 (61.8%) males. Fourteen (41.2%) had right sided cochlear implants and 20 (58.8%) had left. Transscalar migration was present in 3 (8.8%) cases (one case demonstrated tip fold over), with initial disagreement between reviewers regarding transscalar migration in 1/34 patients (2.9%). Agreement regarding depth of insertion between the two reviewers was present in 31 (91.1%) cases. The average depth of insertion was 495° (range = 285-720).

CONCLUSION

s Co-registeration of pre- and post-operative CT examinations provides a useful technique for accurate localization of cochlear implant electrode arrays.

CLINICAL RELEVANCE/APPLICATION

Fused co-registration of pre-operative and post-operative temporal bone CT images can reduce artifact and permit a more accurate localization of the electrode array with implications for improvement in surgical technique and electrode array design.

S3B-SPHN-3 Comparison of 3D Virtual Surgical Planning and Conventional Methods for Mandibular and Maxillary Free Flap Reconstruction

Participants
Mohammad Khalil, MD, (*Presenter*) Nothing to Disclose

PURPOSE

This study aims to compare the rate of bony union in 3D virtual surgical planning (VSP) and conventional methods (CM) for reconstruction.

METHODS AND MATERIALS

The postoperative CT of patients who underwent mandibular or maxillary reconstruction with fibular or scapular free flap from 2014 to 2021 were retrospectively reviewed. The reconstruction was performed using either 3D VSP with 3D printed models and cutting guides derived from the preoperative CT or CM. A neuroradiologist and a neuroradiology fellow, blinded to the type of surgical planning and clinical outcomes, classified the radiographic union as complete, partial or non-union. Statistical significance was determined using chi-square test.

RESULTS

124 patients were included with 55 patients in the VSP group and 69 patients in the CM group for a total of 325 appositions. When assessing appositions individually, complete and partial bony union was higher in the VSP group (74.8%; 17.9%, respectively) than in the CM group (64.9%; 16.1%, respectively) and non-union was higher in the CM group (33%) than in the VSP group (7.3%) ($p<0.01$). Patients in the VSP group had a higher rate of complete or partial union across all their appositions (85.5%) than in the CM group (69.6%) and non-union across all appositions was higher in patients in the CM group (30.4%) than in the VSP group (14.5%) ($p=0.04$).

CONCLUSION

s 3D VSP is associated with better bony union rates. Thus, it has the potential to improve clinical outcomes and could be considered as part of the routine preoperative surgical planning.

CLINICAL RELEVANCE/APPLICATION

The improvement of preoperative surgical planning techniques in mandibular and maxillary free flap reconstruction contributes to favorable functional and cosmetic outcomes. Virtual surgical planning and 3D printing of models and cutting guides allows for precise reconstruction to achieve adequate bony alignment and higher rate of union in comparison to conventional methods.

Contrast-to-noise ratios and dose saving potential by spectral shaping were computed for each scanner. Three radiologists independently assessed the image quality of each examination.

RESULTS

Regardless of tin prefiltration, PCD-CT with low (171.2±10.3 HU) and intermediate dose (134.7±4.5 HU) produced less image noise than full-dose EID-CT (177.0±14.2 HU; $p<0.001$). Targeting matched image noise to 120 kVp EID-CT, mean dose reduction of 79.3±3.9% could be realized in 120 kVp PCD-CT. Subjective image quality of PCD-CT was better than EID-CT on each dose level ($p<0.050$). While no distinction was found between dose-matched PCD-CT with and without tin prefiltration ($p=0.928$), Sn 150 kVp EID-CT provided better image quality than 120 kVp EID-CT at high and intermediate dose levels ($p>0.050$). The majority of low-dose EID-CT examinations was considered not diagnostic, whereas PCD-CT scans of the same dose level received satisfactory or better ratings. Interrater reliability was excellent (ICC: 0.903).

CONCLUSION

s PCD-CT provides superior image quality and significant dose savings compared to EID-CT for ultra-high-resolution examinations of the temporal bone. Aiming for matched image noise, high-voltage scan protocols with tin prefiltration facilitate additional dose saving in EID-CT, whereas superior inherent denoising decreases the dose reduction potential of spectral shaping in PCD-CT.

CLINICAL RELEVANCE/APPLICATION

In ultra-high-resolution photon-counting detector CT of the temporal bone, the denoising effect of spectral shaping through tin prefiltration is less pronounced than in energy-integrating detector CT.

S3B-SPHN-2

Improved Cochlear Implant Electrode Localization Using Co-registration of Pre- and Post-Operative CT

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - HN DPS

Participants
Paul Farnsworth, DO, Saint Cloud, FL (*Presenter*) Nothing to Disclose

PURPOSE

A primary objective of cochlear implant surgery is an atraumatic electrode array insertion, preventing the implant from violating the basilar membrane and osseous spiral lamina with transscalar migration of the array from the scala tympani into the scala vestibuli, disrupting the cochlear duct. Accurate localization of electrode and can be difficult on post-operative imaging secondary to artifact. Here, we describe the use of co-registered pre- and post-operative multi-detector CT images to determine scalar location of the cochlear implant and determine depth of electrode insertion.

METHODS AND MATERIALS

Pre- and post-operative temporal bone CT examinations were retrospectively reviewed after co-registration and overlay of both exams. Images were evaluated by 2 neuroradiologists for scalar location of electrodes tip (+/- scalar translocation), tip fold over, and depth of insertion. Any disagreements between reviewers were resolved via consensus. Depth of insertion was expressed in radial degrees beyond the round window. For purposes of statistical analysis, depth of insertion was considered to represent agreement if the discrepancy was <90 degrees difference between reviewers. Electronic medical records of patients were searched for intra-operative and post-operative complications.

RESULTS

Thirty-four patients were included in the final cohort: Thirteen (38.2%) females and 21 (61.8%) males. Fourteen (41.2%) had right sided cochlear implants and 20 (58.8%) had left. Transscalar migration was present in 3 (8.8%) cases (one case demonstrated tip fold over), with initial disagreement between reviewers regarding transscalar migration in 1/34 patients (2.9%). Agreement regarding depth of insertion between the two reviewers was present in 31 (91.1%) cases. The average depth of insertion was 495° (range = 285-720).

CONCLUSION

s Co-registeration of pre- and post-operative CT examinations provides a useful technique for accurate localization of cochlear implant electrode arrays.

CLINICAL RELEVANCE/APPLICATION

Fused co-registration of pre-operative and post-operative temporal bone CT images can reduce artifact and permit a more accurate localization of the electrode array with implications for improvement in surgical technique and electrode array design.

S3B-SPHN-3

Comparison of 3D Virtual Surgical Planning and Conventional Methods for Mandibular and Maxillary Free Flap Reconstruction

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - HN DPS

Participants
Mohammad Khalil, MD, (*Presenter*) Nothing to Disclose

PURPOSE

This study aims to compare the rate of bony union in 3D virtual surgical planning (VSP) and conventional methods (CM) for reconstruction.

METHODS AND MATERIALS

The postoperative CT of patients who underwent mandibular or maxillary reconstruction with fibular or scapular free flap from 2014 to 2021 were retrospectively reviewed. The reconstruction was performed using either 3D VSP with 3D printed models and cutting guides derived from the preoperative CT or CM. A neuroradiologist and a neuroradiology fellow, blinded to the type of surgical planning and clinical outcomes, classified the radiographic union as complete, partial or non-union. Statistical significance was determined using chi-square test.

RESULTS

124 patients were included with 55 patients in the VSP group and 69 patients in the CM group for a total of 325 appositions. When assessing appositions individually, complete and partial bony union was higher in the VSP group (74.8%; 17.9%, respectively) than in the CM group (64.9%; 16.1%, respectively) and non-union was higher in the CM group (33%) than in the VSP group (7.3%) ($p<0.01$). Patients in the VSP group had a higher rate of complete or partial union across all their appositions (85.5%) than in the CM group (69.6%) and non-union across all appositions was higher in patients in the CM group (30.4%) than in the VSP group (14.5%) ($p=0.04$).

CONCLUSION

s 3D VSP is associated with better bony union rates. Thus, it has the potential to improve clinical outcomes and could be considered as part of the routine preoperative surgical planning.

CLINICAL RELEVANCE/APPLICATION

The improvement of preoperative surgical planning techniques in mandibular and maxillary free flap reconstruction contributes to favorable functional and cosmetic outcomes. Virtual surgical planning and 3D printing of models and cutting guides allows for precise reconstruction to achieve adequate bony alignment and higher rate of union in comparison to conventional methods.

Sub-Events

S3B-SPIN-1 Improvement of Radiomics Reproducibility using Deep Learning-based Image Conversion between CT Reconstruction Algorithms

Participants
Heejin Lee, BEng, Seongnam-Si, Korea, Republic Of (*Presenter*) Student, Seoul National University

PURPOSE

To evaluate the effect of deep learning-based image conversion between CT reconstruction algorithms, in improving radiomics reproducibility in hepatocellular carcinomas (HCC).

METHODS AND MATERIALS

This retrospective study included 78 patients who underwent four-phase liver CTs consisting of non-contrast, late arterial (LAP), portal venous (PVP), and delayed phase (DP) images, reconstructed using both filtered back projection (FBP) and advanced modeled iterative reconstruction (ADMIRE). PVP images of the first 34 consecutive patients were used in training the convolutional neural network (CNN) model to convert images from FBP to ADMIRE and vice versa. All LAP, PVP, and DP images of the following 14 and 30 consecutive patients with HCCs were used for validation and testing, respectively. The radiomic features were extracted from the largest HCC in each patient using a semi-automatic segmentation tool on original and converted images. We used concordance correlation coefficients (CCCs) to evaluate the radiomics reproducibility for original FBP (oFBP) vs. original ADMIRE (oADMIRE), oFBP vs. converted FBP (cFBP), and oADMIRE vs. converted ADMIRE (cADMIRE).

RESULTS

In the test group, the CCC and the proportion of reproducible features (CCC = 0.85) for oFBP vs. oADMIRE were 0.65 and 32.9% (524/1595) at LAP, 0.65 and 35.9% (573/1595) at PVP, and 0.69 and 43.8% (699/1595) at DP. For oFBP vs. cFBP, the values increased to 0.92 and 83.9% (1339/1595) at LAP, 0.89 and 71.0% (1133/1595) at PVP, and 0.90 and 79.7% (1271/1595) at DP. Likewise, for oADMIRE vs. cADMIRE, the values increased to 0.87 and 68.1% (1086/1595) at LAP, 0.91 and 82.1% (1309/1595) at PVP, and 0.89 and 76.2% (1216/1595) at DP.

CONCLUSION

s The CNN-based image conversion between two different CT reconstruction algorithms improved the radiomics reproducibility for HCCs.

CLINICAL RELEVANCE/APPLICATION

This study promoted the reproducibility and generalizability of different CT reconstruction algorithms in radiomics research for clinical diagnosis and prediction of prognosis.

S3B-SPIN-2 Understanding the Role of Imaging Factors in The Variability of CT-based Texture Analysis (CTTA) Metrics

Participants
Bino A. Varghese, PhD, Los Angeles, CA (*Presenter*) Nothing to Disclose

PURPOSE

To assess the reproducibility of radiomic features derived from computed tomography (CT) images by varying dose, reconstruction algorithms and slice thickness using scans of a uniform water phantom, anthropomorphic liver phantom, and a human liver in vivo.

METHODS AND MATERIALS

Scans were acquired on a 16 cm detector GE Revolution CT scanner with variations across three different slice thicknesses: 0.625mm, 1.25mm and 2.5mm, three different dose levels: CTDIvol of 13,86 mGy for the standard dose, 40 % reduced dose and 60 % reduction and two different reconstruction algorithms: a deep learning image reconstruction (DLIR-high) algorithm and a hybrid iterative reconstruction (IR) algorithm ASiR-V50% (AV50) were explored, varying one at a time. To assess the effect of non-linear modifications of image by AV50 and DLIR-high, images of the water phantom were also reconstructed using filtered back projection. The texture panel comprised of 70 features belonging to first-order CT texture analysis (CTTA) metrics. Beta coefficients of each of the radiomic metrics were extracted from the images of all the ROIs across all scans.

RESULTS

Across all scans, imaging and reconstruction settings, CTTA metrics including but not limited to coefficient of variation (CV), inter-quartile range (IQR) and standard deviation (SD) showed statistically significant linear trend with reduction in dose and slice

thickness. For example, when the standard dose was reduced by 60% the IQR increased from 14.98±4.58 to 20.1±6.72 ($p<0.01$). However, this trend was not reported in all features when using filtered back projection reconstruction. Lower values of CV, IQR and SD were observed in DLIR-high reconstructions compared to AV50 and FBP. The Poisson statistics were more stringently followed in FBP than DLIR-H and AV50.

CONCLUSION

s Variation in image noise due to dose reduction algorithms, tube current, and slice thickness show a consistent trend across phantom and patient scans. Prospective evaluation across multiple centers, preferably with human subjects, is needed for establishing quality assurance and control required for the clinical translation of radiomics.

CLINICAL RELEVANCE/APPLICATION

Understanding the relationships between radiomic metrics and imaging variables may help improving imaging quality by compensating one variable for another for e.g., increasing dose for reducing slice thickness etc.

S3B-SPIN-3 Accurately Segment Rectal Tumor From Multi-parametric Magnetic Imaging: A Deep Learning Based Method

Participants
Meng Dou, Chengdu, China (*Presenter*) Nothing to Disclose

PURPOSE

Accurate segmentation of rectal tumor from multi-parametric Magnetic Resonance Imaging (MRI) images is the basis of rectal cancer diagnosis. Multiparametric MRI images can also provide detailed information of the physical characteristics of rectum tumors. However, manual delineation of rectal tumors is a time-consuming procedure, as it requires a high level of expertise. In this study, we propose and evaluate a deep learning-based method for automatic segmentation of rectal cancers on multi-parametric MRI images.

METHODS AND MATERIALS

In this retrospective study, 156 patients with locally advanced rectal cancer were collected and divided into a training cohort (100), a validation cohort (30), and a test cohort (26). For each patient, three types of MRIs including T2-weighted imaging, apparent diffusion coefficient-weighted (ADC), and diffusion-weighted MRI (DWI) were exported from the PACS system. All manual segmentations were performed by two radiologists with 10 years experience of diagnosis of rectal cancer using ITK-SNAP software. In addition, the DWI and ADC images were registered to T2 images using a rigid transformation. We explore three pretrained Convnext-tiny models as the backbone to extract different levels of semantic features for each type of MRI image. Then, an attention-based fusion module was proposed to fuse the semantic information from the different backbones. After that, this fusion feature was concatenated with the context feature, generated by fusing different levels of semantic feature, and was input into a self-attention module and generate the final probability map.

RESULTS

As shown in Tab 1, compared with other methods, our method attains a performance of 0.845 in terms of dice value on the test set, which outperforms the Attention-UNet by 1.35%. The qualitative results of our method show that our method can produce accurate segmentation results with fewer mis-segmentation pixels.

CONCLUSION

s In this study, we develop a deep learning-based model to accurately segment the primary tumor area from multi-parametric MRI images and evaluate its' performance with other advanced segmentation methods. The results proved that our method can produce accurate segmentation results, especially at the tumor margins.

CLINICAL RELEVANCE/APPLICATION

Accurate segmentation of rectal tumor from multi-parametric MRI images is the basis of rectal cancer diagnosis. However, manual delineation of rectal tumors is a time-consuming and subjective procedure. Thus, there is a high demand for accurate and reliable automatic segmentation methods.

S3B-SPIN-4 Multi-planar Deep Learning Pelvic MRI Segmentation using Geometric Conditional Loss Functions

Participants
Melina Hosseiny, MD, Los Angeles, CA (*Presenter*) Nothing to Disclose

PURPOSE

Deep learning is a powerful tool for segmentation of anatomic structures in medical images, but typically requires substantial training data that can be time-consuming to obtain. For enhanced prostate MRI, we sought to develop a single algorithm accomplishing two tasks: 1) provide spatial orientation for oblique plane prescription, handled in sagittal sections, and 2) divide the prostate into central and peripheral zones, handled in axial sections. To that end, two datasets were aggregated by 3D image re-slicing to be used for training based on conditional loss functions to address missing labels and encode geometric relationships.

METHODS AND MATERIALS

We retrospectively collected pelvic MRI from 656 patients. The urinary bladder, prostate, and point locations of the prostate's apex and base were annotated on T2 sagittal images in 391 patients. The prostate gland and its peripheral zone were segmented on T2 axial images in 265 patients. Datasets were then divided by patient, into train (80%), validation (10%) and test (10%) cohorts. Three modified U-Nets were trained: CNN1 using sagittal annotations, CNN2 using axial annotations, and the proposed CNN using both, while incorporating custom conditional loss functions. Model performance for segmentation and localization were assessed by Dice score and L2 distance error respectively.

RESULTS

Median Dice for prostate segmentation improved from 80.3 (IQR 76.0-81.8) by CNN1 to 88.2 (IQR, 84.2-89.0) by the proposed CNN (p-value<0.05, Wilcoxon test). Median L2 errors decreased from 5.7 (IQR 4.5-6.9) mm and 6.5 (IQR 5.6-7.7) mm by CNN1 to 3.6 (IQR 2.6-4.7) mm and 3.5 (IQR 2.4-4.5) mm by the proposed CNN. Results of central and peripheral zone segmentation on axial

sections did not significantly change between CNN2 and the proposed CNN.

CONCLUSION

s Aggregating training data developed for multiple tasks in multiple imaging planes is possible by the use of 3D image re-slicing and conditional loss functions to handle missing labels and encode geometric relationships. These can be used to train a multi-task deep learning algorithm which surpasses the performance of CNNs trained only on data for individual tasks.

CLINICAL RELEVANCE/APPLICATION

Deep learning algorithms can be trained with small, partially-annotated datasets for segmentation tasks in multiple planes, to potentially automate image analysis tasks.

S3B-SPIN-5 Multi-site Brain MRI Analysis using Deep Learning-Harmonization Protocols

Participants
Zhifan Jiang, PhD, Washington, DC (*Presenter*) Nothing to Disclose

PURPOSE

Insufficient training data can compromise the robustness of deep learning models trained on medical images. Rare pediatric diseases, such as optic pathway gliomas secondary to neurofibromatosis type 1 (NF1-OPGs), often have this challenge. Therefore, multiple sites must collaborate when acquiring imaging data like magnetic resonance imaging (MRI), even though they use different device manufacturers and protocols. We designed a deep learning framework to simultaneously address the challenges of MRI data harmonization and analysis, specially targeting segmentation of optic nerves, chiasm and optic tract, referred to as the anterior visual pathway (AVP), for children with NF1-OPG.

METHODS AND MATERIALS

The proposed method builds a semi-supervised model based on multiple generative adversarial networks to: (i) harmonize images from multiple sources sharing latent spaces, (ii) generate a latent protocol, and (iii) segment anatomical structures, i.e., the AVP in this application. T1-weighted MRI data were collected from three institutions and acquired with different imaging protocols and scanners: Site A (General Electric), Site B (Siemens) and Site C (Philips). The average voxel size across sites was A (0.43×0.59×0.43 mm), B (0.91×0.83×0.83 mm) and C (0.63×0.96×0.62 mm). The framework was evaluated on MRIs from 180 subjects with NF1-OPG using manual segmentations as ground truth.

RESULTS

The proposed framework demonstrated a strong performance in the AVP segmentation task. Results showed that the average Dice volume overlap was 80.63±6.17%. In comparison, the inter-observer variability for manual segmentations was 75.00±6.00%. The average normalized surface distance between our method and ground truth was 0.28±0.20 mm. The AVP volume was similar between the automatic segmentation and ground truth (p-value=0.14). Although this method was focused on the segmentation of AVP, however, the method can be applied to other quantitative imaging tasks with data resources from multiple sites.

CONCLUSION

s We present a framework for harmonization of MRI acquired with different scanners and protocols, which demonstrated high quality segmentation of AVP. Deep learning models can help provide reliable data analysis on small and diverse imaging datasets by utilizing image harmonization.

CLINICAL RELEVANCE/APPLICATION

Deep neural network-optimized protocols harmonize the presentation and analysis of multi-site MRI data, which may assist clinical trials and routine care with consistent data for their examination.

S3B-SPIN-6 Contrast Media Dynamics Determine CT Radiomics Profiles and Machine-learning-based Tumor Identification in Oncologic Imaging

Participants
Martin Watzenboeck, MD, Vienna, Austria (*Presenter*) Nothing to Disclose

PURPOSE

The reproducibility of radiomics features extracted from CT examinations depends on several physiological and technical factors including inspiration depth, examination protocol, slice thickness and the reconstruction kernel. Particularly in oncologic imaging, the use of contrast-agent dynamics might affect the stability of radiomics features. Our aim was to evaluate the impact of contrast-agent timing on radiomics feature profiles using CT perfusion of prostate and lung cancers.

METHODS AND MATERIALS

We extracted 1204 radiomics features from healthy prostate parenchyma and tumors in seven patients with biopsy-proven peripheral prostate cancer, and from tumors in seven patients with biopsy-proven NSCLC, who received dynamic contrast-enhanced perfusion CT with high temporal resolution. Features showing significant differences between contrast phases were identified using linear mixed models. We used a L2-penalized logistic regression classifier to predict class labels for tumor and healthy segments for patients with prostate cancer.

RESULTS

The timing of the contrast enhancement peak in the reference vessel and tumor varied between patients. After normalizing for individual enhancement patterns by defining seven individual phases based on the reference vessel, 19, 467 and 128 features (1204 total features) showed significant temporal dynamics in healthy prostate parenchyma, prostate tumors and lung tumors, respectively. While machine learning classifiers could not differentiate well between healthy and tumor segments early after contrast-agent application (AUC 0.63, 95% CI 0.31-0.95), a high predictive accuracy was achieved during the arterial phase (AUC 0.92, 95% CI 0.76-1).

CONCLUSION

s Radiomic profiles of tumor segments in prostate CT are highly dependent oncontrast perfusion timing. Accordingly, machine

s radiomic profiles of tumor segments in prostate CT are highly dependent on contrast perfusion timing. Accordingly, machine learning based classification accuracy highly depends on contrast-agent phase.

CLINICAL RELEVANCE/APPLICATION

Our data highlights the need for careful design of radiomic studies when contrast media are involved, as a substantial number of radiomics features is contrast perfusion dependent and prone to bias. When using contrast enhanced scans for radiomics studies care should be taken to ensure a standardized perfusion timing for radiomics analysis, which is tumor specific.

Results of central and peripheral zone segmentation on axial sections did not significantly change between CNN2 and the proposed CNN.

CONCLUSION

s Aggregating training data developed for multiple tasks in multiple imaging planes is possible by the use of 3D image re-slicing and conditional loss functions to handle missing labels and encode geometric relationships. These can be used to train a multi-task deep learning algorithm which surpasses the performance of CNNs trained only on data for individual tasks.

CLINICAL RELEVANCE/APPLICATION

Deep learning algorithms can be trained with small, partially-annotated datasets for segmentation tasks in multiple planes, to potentially automate image analysis tasks.

S3B-SPIN-5

Multi-site Brain MRI Analysis using Deep Learning-Harmonization Protocols

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - IN DPS

Participants
Zhifan Jiang, PhD, Washington, DC (*Presenter*) Nothing to Disclose

PURPOSE

Insufficient training data can compromise the robustness of deep learning models trained on medical images. Rare pediatric diseases, such as optic pathway gliomas secondary to neurofibromatosis type 1 (NF1-OPGs), often have this challenge. Therefore, multiple sites must collaborate when acquiring imaging data like magnetic resonance imaging (MRI), even though they use different device manufacturers and protocols. We designed a deep learning framework to simultaneously address the challenges of MRI data harmonization and analysis, specially targeting segmentation of optic nerves, chiasm and optic tract, referred to as the anterior visual pathway (AVP), for children with NF1-OPG.

METHODS AND MATERIALS

The proposed method builds a semi-supervised model based on multiple generative adversarial networks to: (i) harmonize images from multiple sources sharing latent spaces, (ii) generate a latent protocol, and (iii) segment anatomical structures, i.e., the AVP in this application. T1-weighted MRI data were collected from three institutions and acquired with different imaging protocols and scanners: Site A (General Electric), Site B (Siemens) and Site C (Philips). The average voxel size across sites was A (0.43×0.59×0.43 mm), B (0.91×0.83×0.83 mm) and C (0.63×0.96×0.62 mm). The framework was evaluated on MRIs from 180 subjects with NF1-OPG using manual segmentations as ground truth.

RESULTS

The proposed framework demonstrated a strong performance in the AVP segmentation task. Results showed that the average Dice volume overlap was 80.63±6.17%. In comparison, the inter-observer variability for manual segmentations was 75.00±6.00%. The average normalized surface distance between our method and ground truth was 0.28±0.20 mm. The AVP volume was similar between the automatic segmentation and ground truth (p-value=0.14). Although this method was focused on the segmentation of AVP, however, the method can be applied to other quantitative imaging tasks with data resources from multiple sites.

CONCLUSION

s We present a framework for harmonization of MRI acquired with different scanners and protocols, which demonstrated high quality segmentation of AVP. Deep learning models can help provide reliable data analysis on small and diverse imaging datasets by utilizing image harmonization.

CLINICAL RELEVANCE/APPLICATION

Deep neural network-optimized protocols harmonize the presentation and analysis of multi-site MRI data, which may assist clinical trials and routine care with consistent data for their examination.

S3B-SPIN-6

Contrast Media Dynamics Determine CT Radiomics Profiles and Machine-learning-based Tumor Identification in Oncologic Imaging

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - IN DPS

Participants
Martin Watzenboeck, MD, Vienna, Austria (*Presenter*) Nothing to Disclose

PURPOSE

The reproducibility of radiomics features extracted from CT examinations depends on several physiological and technical factors including inspiration depth, examination protocol, slice thickness and the reconstruction kernel. Particularly in oncologic imaging, the use of contrast-agent dynamics might affect the stability of radiomics features. Our aim was to evaluate the impact of contrast-agent timing on radiomics feature profiles using CT perfusion of prostate and lung cancers.

METHODS AND MATERIALS

We extracted 1204 radiomics features from healthy prostate parenchyma and tumors in seven patients with biopsy-proven peripheral prostate cancer, and from tumors in seven patients with biopsy-proven NSCLC, who received dynamic contrast-enhanced perfusion CT with high temporal resolution. Features showing significant differences between contrast phases were identified using linear mixed models. We used a L2-penalized logistic regression classifier to predict class labels for tumor and healthy segments for patients with prostate cancer.

RESULTS

The timing of the contrast enhancement peak in the reference vessel and tumor varied between patients. After normalizing for individual enhancement patterns by defining seven individual phases based on the reference vessel, 19, 467 and 128 features (1204 total features) showed significant temporal dynamics in healthy prostate parenchyma, prostate tumors and lung tumors, respectively. While machine learning classifiers could not differentiate well between healthy and tumor segments early after contrast-agent application (AUC 0.63, 95% CI 0.31-0.95), a high predictive accuracy was achieved during the arterial phase (AUC 0.92, 95% CI 0.76-1).

CONCLUSION

s Radiomic profiles of tumor segments in prostate CT are highly dependent oncontrast perfusion timing. Accordingly, machine learning based classification accuracy highly depends on contrast-agent phase.

CLINICAL RELEVANCE/APPLICATION

Our data highlights the need for careful design of radiomic studies when contrast media are involved, as a substantial number of radiomics features is contrast perfusion dependent and prone to bias. When using contrast enhanced scans for radiomics studies care should be taken to ensure a standardized perfusion timing for radiomics analysis, which is tumor specific.

S3B-SPIR

Interventional Sunday Poster Discussions - B

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - IR DPS

Sub-Events

S3B-SPIR-1 Evaluation of The Prediction for The Change of Future Liver Volume after Portal Vein Embolization (PVE) using 2D Perfusion Angiography (2D-PA)

Participants
Hiroki Yano, MD, (*Presenter*) Nothing to Disclose

PURPOSE

2D-PA application equipped with the angiography unit can visualize the chronological flow of contrast through vessels as a color coded image and enables visible and quantitative blood flow evaluation. Among the several parameters of the 2D-PA, area under the curve (AUC) is considered as the total blood volume in the measured liver parenchyma.The purpose of this study is to investigate the relationship between the change of liver volume and the parameter of 2D-PA during pre and post PVE.

METHODS AND MATERIALS

Thirty six patients who underwent PVE between 2006 and 2022 were included in this retrospective case-control study. Percutaneous transhepatic portography was performed pre and post embolization with the same volume and rate of contrast injection as 2D-PA mode. Regions of interest (ROI) are placed in each lobes of the liver, and AUC (AUC-left ; remnant liver, -right ; embolized liver) are measured pre- and post-PVE, respectively. AUC ratio (AUCR =AUC pre-left/right) was calculated. In order to reflect each lobes blood flow in the liver parenchyma as purely as possible in 2D-PA, ROI were set on the right side outside the diaphragm and the left side outside the umbilical point.Enhanced CT examinations were performed before and 3 weeks after PVE for volumetry of liver parenchyma. Future remnant liver volume (FRLV), embolized liver volume (ELV), and total liver volume (TLV) were measured, and ELVR (=ELV/TLV), FRLVR (=FRLV/TLV), degree of hypertrophy (DH=FRLVR post/pre), degree of reduction (DR=1-ELVR post/pre) were calculated respectively. The relationships between the change of AUC and FRLR each live volume were also evaluated by Pearson's correlation coefficient(R, $P<0.05$).

RESULTS

Post AUC-left was significantly increased compared to pre AUC-left. No significant correlation was found between DH and AUCR. A positive correlation was found between DR and AUCR (R=0.418, p=0.0111), FRLVR post and AUCR (R=0.616, p=0.0000632). Furthermore, ROC analysis between AUCR and FRLVR post exceeds 40% or not, the area under the curve was 0.885 (sensitivity 78.8%, specificity 85.2%), when cutoff value of AUCR was 0.455.)

CONCLUSION

s The AUC ratio of both liver lobes in 2D-PA before PVE correlates with the embolized liver volume rate and future remnant liver volume rate of 3 weeks after PVE.

CLINICAL RELEVANCE/APPLICATION

PVE is sometimes performed for hypertrophy before hepatectomy to avoid postoperative acute liver failure, but the precise prediction for the degree of hypertrophy of liver parenchyma is unclear. The AUC ratio of pre 2D-PA may help predicting the degree of future remnant liver volume.

S3B-SPIR-2 Genicular Artery Embolization as a Treatment for Symptomatic Knee Osteoarthritis: A Systematic Review and Meta-analysis

Participants
Yan Epelboym, MPH, (*Presenter*) Nothing to Disclose

PURPOSE

Genicular artery embolization (GAE) is a minimally invasive therapy for symptomatic osteoarthritis (OA) in patients with knee pain refractory to conservative management. The purpose of this study was to evaluate current evidence on the effectiveness of GAE for OA related knee pain.

METHODS AND MATERIALS

Using three databases (Embase, PubMed, and Web of Science), we performed a systematic review to identify studies evaluating treatment of knee OA with GAE. Studies were screened by 2 of the investigators independently, first by study title, and from those the abstracts were reviewed, followed by a full-text review to select the final cohort. Exclusion criteria included studies of hemarthrosis, review articles, or republished data in the case of already-included patients.The primary outcome measure was change in pain scale score at 6 months; changes at 1, 3, and 12 months were secondary outcomes. We computed Hedge's g as a measure of effect size, a version of standardized mean difference (change per standard deviation) that includes a correction for small samples, selecting Visual Analog Scale (VAS) first if available and Knee Injury and Osteoarthritis Outcome Score (KOOS) and

Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) if VAS was not available. To estimate pooled change in pain a meta-analysis was performed using a random effects model with restricted maximum likelihood.

RESULTS

The initial search yielded 581 studies. After screening titles, abstracts, and the full text, 8 studies met the inclusion and exclusion criteria for this study. The inter-reader agreement at the title review stage was k = 0.681 (substantial), abstract stage was k = 0.655 (substantial), and full-text review stage was k = 0.94 (almost perfect).Eight studies with 276 treated knees were included. Seven studies were cohort studies without control groups, categorized as level II evidence. One randomized controlled trial with a sham intervention group was categorized as level I evidence. Of the 276 treated knees, 241 (87%) demonstrated Kellgren Lawrence grade I-III OA. The estimated standardized mean change (Hedges' g) from baseline to six months, was -1.4 (95% CI: (-2.1, -0.8)). The estimated standardized mean change in pain scores for secondary outcomes was -1.3 (95% CI: (-1.6, -0.97)) at one month, -1.2 (95% CI: (-1.54, -0.84)) at three months and -1.25 (95% CI: (-2.0, -0.6)) at twelve months.

CONCLUSION

s GAE provides durable reductions in pain scores for patients with symptomatic knee OA. The effect size of GAE on pain appears to be greater than published effects for oral non-steroidal anti-inflammatories and intra-articular corticosteroid injections.

CLINICAL RELEVANCE/APPLICATION

GAE is a promising treatment for OA related knee pain.

S3B-SPIR-3 Impact of Computed Tomography Angiography on Lower Gastrointestinal Bleeding Primary Endovascular Intervention Outcomes

Participants
Olivia Little, BS, Savannah, GA (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the impact of pre-procedural computed tomography angiography (CTA) on treatment success, hospitalization length of stay (LOS), and mortality of patients undergoing primary endovascular intervention (PEI) for lower gastrointestinal bleeding (LGIB).

METHODS AND MATERIALS

Using ICD-9 codes, all LGIB encounters and associated procedures in the 2005-2015 National Inpatient Sample databases were identified. Patients treated with conservative management or those who received nuclear scintigraphy were excluded. LGIB encounters initially treated with either angiography and/or embolization (PEI) and were not re-treated with PEI or another intervention were classified as successfully treated. In patients that underwent pre-procedural CTA versus those who did not, differences in mortality, mean LOS, and successful LGIB treatment were assessed with chi-square test, ANOVA, and student's t-test.

RESULTS

Of 224,640 LGIB encounters captured, 5,983 LGIB encounters treated with PEI met our inclusion/exclusion criteria. Overall mean age, gender, race/ethnicity was 69 years, 53% female, and 73% Caucasian. PEI definitively treated LGIB in 61.6% of LGIB encounters. Compared to patients who did not undergo CTA prior to PEI, pre-intervention CTA was associated with a greater incidence of definitive treatment success after PEI (70.8% vs 29.2%; Odds-Ratio (OR)=1.5 [95%CI 1.1-2.2], p<0.02). There was no significant difference in LOS (8.3±9.6 vs 7.7±8.8 days; p=0.5) or mortality (6.9% vs 8.1%; p=0.7) between encounters involving vs. not involving CTA prior to PEI.

CONCLUSION

s CTA utilization prior to LGIB PEI is associated with a higher incidence of successful treatment but does not impact LOS nor incidence of mortality.

CLINICAL RELEVANCE/APPLICATION

When utilized for the management of lower gastrointestinal bleeding, pre-intervention CTA is associated with a higher incidence of definitive treatment success after primary endovascular intervention but does impact the length of hospital stay nor incidence of mortality.

S3B-SPIR-4 Treatment Patterns in Chronic Venous Disease: Endovenous vs. Open Vein Stripping: Where Are We Today?

Participants
Brian D'Amore, BS, (*Presenter*) Nothing to Disclose

PURPOSE

Chronic venous disease (CVD) affects over 30 million patients in the United States with an annual incidence of 1.9% in males and 2-6% in females. Advances in minimally-invasive treatments allow faster recovery times and lower complications with endovenous treatment options when compared to traditional vein stripping. Yet, surgical interventions persist both as primary and salvage CVD therapy. The purpose of this study was to compare the relative utilization of vein stripping and endovenous treatments, including thermal and laser ablation.

METHODS AND MATERIALS

Endovenous treatment (including thermal and laser ablation) and vein stripping data was obtained from the American College of Surgeons - National Surgical Quality Improvement Program (NSQIP) based on CPT codes (36475-9, 37700, 37718, 37722, and 37735) between 2011-2017. Demographics were extracted for each patient, including race, gender and age. Utilization trends were computed, and percent change was calculated for each procedure.

RESULTS

We identified 22,114 patients who underwent treatment for chronic superficial venous insufficiency between 2011-2017. Thermal

ablation was the most frequently performed procedure with 49.5% (n=10,941) patients receiving this treatment, followed by vein stripping at 35.0% (n=7744) and laser ablation at 15.5% (n=3429). Volume increased by 6.3% for thermal ablation and 1.1% for vein stripping, while it decreased by 18.5% for laser ablation. Lastly, thermal ablation increased in males by 24.6% and decreased in females by 1.3%. It also increased in patients aged 65 and older by 24.6% and decreased in patients less than 65 by 3.03%.

CONCLUSION

s Although thermal ablation was the most performed procedure for superficial CVD between 2011-2017, vein stripping volume was still greater than expected. Trends in thermal ablation increased significantly for males when compared to females and for patients aged 65 and older when compared to patients less than 65.

CLINICAL RELEVANCE/APPLICATION

The transition from vein stripping to endovenous procedures may be slower than originally presumed and total volume of procedures is lower than expected based on disease prevalence.

S3B-SPIR-5 The Role of Boosting Algorithms in Machine Learning in Predicting the Treatment Outcome of High-Intensity Focused Ultrasound Ablation of Uterine Fibroids: Most Informative Perfusion MRI Features

Participants
Bilgin Keserci, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

To comparatively evaluate the role of boosting algorithms in machine learning to find the most informative perfusion MRI features in predicting the treatment outcome of High-Intensity Focused Ultrasound (HIFU) ablation with an immediate nonperfused volume (NPV) ratio of at least 90%.

METHODS AND MATERIALS

A total of 73 women with symptomatic uterine fibroids who underwent HIFU treatment were classified according to T1 perfusion-based classification as group A (n = 47, if the time-SI curve of lesion was lower than that of myometrium) and group B (n = 26, if the time-SI curve of lesion was equal to or higher than that of myometrium). In this study, myometrium was chosen as an internal reference. An ensemble feature ranking model was introduced based on the score values ??assigned to the 21 perfusion MRI features by three different boosting algorithms including Adaptive boosting (Adaboost), Category boosting (Catboost) and Gradient boosting (GBM), to find the most informative perfusion MRI features. The relationship between perfusion MRI features and the immediate NPV ratio of 90% was evaluated using Pearson's correlation coefficients. The diagnostic ability of Boosting algorithms was performed by means of standard performance metrics, including the area under the receiver operating characteristic curve (AUROC), accuracy, sensitivity, and specificity in eight folds cross-validation.

RESULTS

For the most informative perfusion MRI features, the AUROC ranged from 0.838 to 0.916, accuracy ranged from 0.84 to 0.96, specificity of 0.833, and sensitivity ranged from 0.842 to 1.0. The GBM algorithm showed the best predictive performance with an AUROC of 0.95 and accuracy of 0.92, followed by the Catboost and Adaboost algorithms, which yielded an AUROC of 0.864 and 0.838, and accuracy of 0.88 and 0.84, respectively. The best classifier performance with the best-performing features from each perfusion MRI group, Ktrans ratio of fibroid to myometrium, The ratio of area under the curve of fibroid to myometrium, the ratio of maximum relative enhancement of fibroid to myometrium, the ratio of relative enhancement of fibroid to myometrium and the ratio of maximum enhancement of fibroid to myometrium, was achieved using GBM.

CONCLUSION

s The preliminary findings in this study suggest that the most informative perfusion MRI features should considered in predicting the treatment outcome of HIFU ablation to achieve an immediate NPV ratio of 90%.

CLINICAL RELEVANCE/APPLICATION

The best boosting algorithm performance with the best-performing perfusion MRI features should be considered by the treating physician in the screening phase to predict the treatment outcome of HIFU ablation to achieve an immediate NPV ratio of 90%.

S3B-SPIR-6 Sustained Clinical Improvement After Prostate Artery Embolization (PAE) for Symptomatic Benign Prostate Hyperplasia (BPH): Results from a Single Center, Retrospective Analysis

Participants
Vijay Chockalingam, BS, (*Presenter*) Nothing to Disclose

PURPOSE

To validate if short term clinical results of Prostate Artery Embolization (PAE) in Benign Prostate Hyperplasia (BPH) are sustained over time.

METHODS AND MATERIALS

In an IRB approved, single center, retrospective study, 120 patients (Mean age 70.6 years ±9.7 years) who underwent PAE were identified. Technical success was defined as successful embolization on at least one side. Baseline IPSS (International Prostate Symptom Score) was obtained for each patient. Clinical success was evaluated as change in IPSS in short-term (< 1 year), medium-term (1-2 years) and long-term (3 or more years) follow-up. To determine change in IPSS between pre-PAE procedure and follow-up post-PAE procedure, IPSS was analyzed through a multilevel model using time as a fixed effect and patient ID as a random effect to account for within-patient correlations. Prostate shrinkage was also evaluated and changes in prostate size between baseline and post-PAE procedure were analyzed.

RESULTS

Between February 2014 and May 2021, 56 patients were accounted for in the pre-procedure baseline measurement, which showed an average IPSS of 22.1 (95% CI 20.4-23.9). Technical success was seen in 90.1% of patients in the study. Short-term (n=21), mid-term (n=24), and long-term (n=11) follow-up of these patients showed average IPSS scores of 10.2 (95% CI 7.3-13.1), 9.7 (95% CI 6.7-12.7), and 6.1 (95% CI 4.2-8.0). The results show a statistically significant (p = 0.000) and dramatic drop in IPSS of

13.5 points in the short term. The trend post-embolization, although not statistically significant (p = 0.321) shows that IPSS scores remain decreased over-time. Prostate size decreased from pre-PAE procedure (n=35) to post-PAE procedure follow up (n=27) from an average of 138.7 cc to 89.9 cc (p = 0.000).

CONCLUSION

s The short term, statistically significant drop in IPSS after PAE appears to be sustained in the medium and long term study period in our study, with all available data. Although these results suggest a sustained long term clinical success of the procedure, large multi-center studies are needed.

CLINICAL RELEVANCE/APPLICATION

PAE has emerged as a minimally invasive technique to treat BPH that involves a reduced hospital stay and less adverse effects compared to current gold standard approaches, all while maintaining significant symptom reduction over long term follow-up.

S3B-SPIR-7 In-vitro Characterization of Drug Eluting Superabsorbent Polymer Microspheres: Absorption and Eluting Capacity of Contrast Material, Antibiotics and/or Analgesics

Participants
Akiko Narita, MD, PhD, Nagakute, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Superabsorbent polymer microspheres (SAP-MS) have a property of absorbing fluids to swell. Therefore, drug-loaded SAP-MS will become visible, antibacterial and/or analgesic. The purpose of this study was to examine the characteristics of drug-loaded SAP-MS.

METHODS AND MATERIALS

SAP-MS were suspended in the drug solution (a) antibiotics (Cefazolin) (b) analgesics (Lidocaine) (c) contrast material (Iopamidol) and Cefazolin (d) Iopamidol and Lidocaine (e) Iopamidol, Cefazolin and Lidocaine. 1) Change of the diameter of each drug-loaded SAP-MS was observed by a stereomicroscope for three hours. 2) Absorption capacity of each drug-loaded SAP-MS were assessed by measuring the concentration of drug solution using high performance liquid chromatography (HPLC) sequentially. 3) Filtered each drug-loaded SAP-MS were mixed with 100ml of saline and drug eluting capacity of each drug-loaded SAP-MS were evaluated using HPLC over time.

RESULTS

1) Diameter of drug-loaded SAP-MS increased for about 15 minutes and came to an equilibrium. Finally, the diameter was (a) 3.9 times (b) 5.0 times (c) 2.2 times (d) 5.5 times (e) 3.6 times larger than its original size. 2) The concentration of drug solution did not change and the amount of drug solution decreased. 3) Each drug was released into 10 minutes and came to an equilibrium. The concentration of each drug in the mixture was increased by (a) Cefazolin: 1.82 mg/ml (b) Lidocaine: 0.06 mg/ml (c) Iopamidol: 1.34 mg/ml, Cefazolin: 0.17 mg/ml (d) Iopamidol: 4.51 mg/ml, Lidocaine: 0.11 mg/ml (e) Iopamidol: 2.70 mg/ml, Cefazolin: 1.10 mg/ml, Lidocaine: 0.03 mg/ml.

CONCLUSION

s SAP-MS can absorb each drug as much as it swells. And drug-loaded SAP-MS release contrast material, antibiotics and analgesics.

CLINICAL RELEVANCE/APPLICATION

Visible, antibiotic and/or analgesic microspheres will contribute to safe and useful embolization, in addition, relief of pain and prevention infection like abscess.

S3B-SPIR-8 Bariatric Arterial Embolization with Radiopaque Hydrogel Microspheres Suppresses Weight Gain and Fundal Ghrelin Levels in Swine

Participants
Yingli Fu, Baltimore, MD (*Presenter*) Nothing to Disclose

PURPOSE

Octreotide is a somatostatin analogue with beneficial effect on ghrelin suppression and weight loss. The purpose of this study is to evaluate the effect of octreotide-eluting, lipiodol-impregnated, alginate microspheres (OLMs) on the safety and efficacy of bariatric arterial embolization (BAE) in swine.

METHODS AND MATERIALS

X-ray-visible OLMs were produced from lipiodol-impregnated alginate (2% w/v) solution containing 10 mg/ml octreotide using an electrostatic droplet generator. BAE was performed in 6 healthy, growing swine (mean weight: 22.2 kg) by selective infusion of X-ray-visible OLMs (n = 3) or saline (n = 3) into the right gastric artery (RGA) and the left gastroepiploic artery (LGEA) under X-ray guidance. Weight was obtained in all animals at baseline and weekly up to 8 weeks post embolization. Cone-beam CT (CBCT) images of the stomachs were acquired immediately after embolization and at 8 weeks prior to sacrifice to assess the embolization coverage of the fundus, and the visibility and distribution of OLMs. All animals were euthanized for gross and histological examination of stomach mucosal integrity at 8 weeks. Ghrelin-expressing cells (GECs) in the stomach were assessed immunohistochemically and analyzed using the Mann-Whitney U test.

RESULTS

OLMs were monodispersed with diameter of 185 ± 6 μm. BAE with OLMs was successfully performed in all animals. The OLMs can be visualized both on fluoroscopy and CBCT images during the embolization procedure. The post-procedural percentage of weight gain was lower in BAE-treated animals as compared to controls (BAE vs. control: 39.4% ± 12.9 vs. 61.0% ± 3.2 at 8 weeks). The GECs were significantly decreased in the gastric fundus of OLM- embolized animals compared to control animals (BAE vs. control: 14.9 ± 3.6 vs. 24.3 ± 5.4, $p < 0.0001$). Superficial healed mucosal ulcers were observed in one OLM-embolized animal along the stomach fundus and body.

CONCLUSION

s BAE with octreotide-eluting, lipiodol/alginate microspheres can be safely performed in all animals and significantly suppress the percentage of weight gain and fundal ghrelin levels.

CLINICAL RELEVANCE/APPLICATION

BAE with octreotide-eluting, lipiodol/alginate microspheres may be useful for treating obesity.

S3B-SPIR-9 New TRUS Techniques and Imaging Features of PI-RADS 4 or 5: Influence on Tumor Targeting

Participants
Byung Kwan Park, MD, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

To determine if the new transrectal ultrasound (TRUS) techniques and imaging features contribute to targeting Prostate Imaging and Reporting and Data System (PI-RADS) 4 or 5.

METHODS AND MATERIALS

Between December 2018 and February 2020, 115 men underwent cognitive biopsy by radiologist A, who was familiar with the new TRUS findings and biopsy techniques. During the same period, 179 men underwent magnetic resonance imaging-TRUS image fusion or cognitive biopsy by radiologist B, who was unfamiliar with the new biopsy techniques. Prior to biopsy, both radiologists knew MRI findings such as the location, size, and shape of PI-RADS 4 or 5. We recorded how many target biopsies were performed without systematic biopsy and how many of these detected higher Gleason score (GS) than those detected by systematic biopsy. The numbers of biopsy cores were also obtained. Fisher Exact or Mann-Whitney test was used for statistical analysis.

RESULTS

For PI-RADS 4, target biopsy alone was performed in 0% (0/84) by radiologist A and 0.8% (1/127) by radiologist B ($p>0.9999$). Target biopsy yielded higher GSs in 57.7% (30/52) by radiologist A and 29.5% (23/78) by radiologist B ($p = 0.0019$). For PI-RADS 5, target biopsy alone was performed in 29.0% (9/31) by radiologist A and 1.9% (1/52) by radiologist B ($p = 0.0004$). Target biopsy yielded higher GSs in 50.0% (14/28) by radiologist A and 18.2% (8/44) by radiologist B ($p = 0.0079$). Radiologist A sampled fewer biopsy cores than radiologist B ($p = 0.0008$ and 0.0023 for PI-RADS 4 and 5), respectively.

CONCLUSION

s PI-RADS 4 or 5 can be more precisely targeted if the new TRUS biopsy techniques are applied.

CLINICAL RELEVANCE/APPLICATION

The new TRUS biopsy techniques help to not only target PI-RADS 4 or 5 lesions more precisely but also to reduce the number of biopsy cores needed. Moreover, systematic biopsy can be omitted in PI-RADS 5 patients who do not stop taking aspirin because of cardiovascular disease.

S3B-SPIR-1

Evaluation of The Prediction for The Change of Future Liver Volume after Portal Vein Embolization (PVE) using 2D Perfusion Angiography (2D-PA)

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - IR DPS

Participants
Hiroki Yano, MD, (*Presenter*) Nothing to Disclose

PURPOSE

2D-PA application equipped with the angiography unit can visualize the chronological flow of contrast through vessels as a color coded image and enables visible and quantitative blood flow evaluation. Among the several parameters of the 2D-PA, area under the curve (AUC) is considered as the total blood volume in the measured liver parenchyma.The purpose of this study is to investigate the relationship between the change of liver volume and the parameter of 2D-PA during pre and post PVE.

METHODS AND MATERIALS

Thirty six patients who underwent PVE between 2006 and 2022 were included in this retrospective case-control study. Percutaneous transhepatic portography was performed pre and post embolization with the same volume and rate of contrast injection as 2D-PA mode. Regions of interest (ROI) are placed in each lobes of the liver, and AUC (AUC-left ; remnant liver, -right ; embolized liver) are measured pre- and post-PVE, respectively. AUC ratio (AUCR =AUC pre-left/right) was calculated. In order to reflect each lobes blood flow in the liver parenchyma as purely as possible in 2D-PA, ROI were set on the right side outside the diaphragm and the left side outside the umbilical point.Enhanced CT examinations were performed before and 3 weeks after PVE for volumetry of liver parenchyma. Future remnant liver volume (FRLV), embolized liver volume (ELV), and total liver volume (TLV) were measured, and ELVR (=ELV/TLV), FRLVR (=FRLV/TLV), degree of hypertrophy (DH=FRLVR post/pre), degree of reduction (DR=1-ELVR post/pre) were calculated respectively. The relationships between the change of AUC and FRLR each live volume were also evaluated by Pearson's correlation coefficient(R, $P<0.05$).

RESULTS

Post AUC-left was significantly increased compared to pre AUC-left. No significant correlation was found between DH and AUCR. A positive correlation was found between DR and AUCR (R=0.418, p=0.0111), FRLVR post and AUCR (R=0.616, p=0.0000632). Furthermore, ROC analysis between AUCR and FRLVR post exceeds 40% or not, the area under the curve was 0.885 (sensitivity 78.8%, specificity 85.2%), when cutoff value of AUCR was 0.455.)

CONCLUSION

s The AUC ratio of both liver lobes in 2D-PA before PVE correlates with the embolized liver volume rate and future remnant liver volume rate of 3 weeks after PVE.

CLINICAL RELEVANCE/APPLICATION

PVE is sometimes performed for hypertrophy before hepatectomy to avoid postoperative acute liver failure, but the precise prediction for the degree of hypertrophy of liver parenchyma is unclear. The AUC ratio of pre 2D-PA may help predicting the degree of future remnant liver volume.

Genicular Artery Embolization as a Treatment for Symptomatic Knee Osteoarthritis: A Systematic Review and Meta-analysis

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - IR DPS

Participants
Yan Epelboym, MPH, (*Presenter*) Nothing to Disclose

PURPOSE

Genicular artery embolization (GAE) is a minimally invasive therapy for symptomatic osteoarthritis (OA) in patients with knee pain refractory to conservative management. The purpose of this study was to evaluate current evidence on the effectiveness of GAE for OA related knee pain.

METHODS AND MATERIALS

Using three databases (Embase, PubMed, and Web of Science), we performed a systematic review to identify studies evaluating treatment of knee OA with GAE. Studies were screened by 2 of the investigators independently, first by study title, and from those the abstracts were reviewed, followed by a full-text review to select the final cohort. Exclusion criteria included studies of hemarthrosis, review articles, or republished data in the case of already-included patients.The primary outcome measure was change in pain scale score at 6 months; changes at 1, 3, and 12 months were secondary outcomes. We computed Hedge's g as a measure of effect size, a version of standardized mean difference (change per standard deviation) that includes a correction for small samples, selecting Visual Analog Scale (VAS) first if available and Knee Injury and Osteoarthritis Outcome Score (KOOS) and Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) if VAS was not available. To estimate pooled change in pain a meta-analysis was performed using a random effects model with restricted maximum likelihood.

RESULTS

The initial search yielded 581 studies. After screening titles, abstracts, and the full text, 8 studies met the inclusion and exclusion criteria for this study. The inter-reader agreement at the title review stage was k = 0.681 (substantial), abstract stage was k = 0.655 (substantial), and full-text review stage was k = 0.94 (almost perfect).Eight studies with 276 treated knees were included. Seven studies were cohort studies without control groups, categorized as level II evidence. One randomized controlled trial with a sham intervention group was categorized as level I evidence. Of the 276 treated knees, 241 (87%) demonstrated Kellgren Lawrence grade I-III OA. The estimated standardized mean change (Hedges' g) from baseline to six months, was -1.4 (95% CI: (-2.1, -0.8)). The estimated standardized mean change in pain scores for secondary outcomes was -1.3 (95% CI: (-1.6, -0.97)) at one month, -1.2 (95% CI: (-1.54, -0.84)) at three months and -1.25 (95% CI: (-2.0, -0.6)) at twelve months.

CONCLUSION

s GAE provides durable reductions in pain scores for patients with symptomatic knee OA. The effect size of GAE on pain appears to be greater than published effects for oral non-steroidal anti-inflammatories and intra-articular corticosteroid injections.

CLINICAL RELEVANCE/APPLICATION

GAE is a promising treatment for OA related knee pain.

Impact of Computed Tomography Angiography on Lower Gastrointestinal Bleeding Primary Endovascular Intervention Outcomes

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - IR DPS

Participants
Olivia Little, BS, Savannah, GA (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the impact of pre-procedural computed tomography angiography (CTA) on treatment success, hospitalization length of stay (LOS), and mortality of patients undergoing primary endovascular intervention (PEI) for lower gastrointestinal bleeding (LGIB).

METHODS AND MATERIALS

Using ICD-9 codes, all LGIB encounters and associated procedures in the 2005-2015 National Inpatient Sample databases were identified. Patients treated with conservative management or those who received nuclear scintigraphy were excluded. LGIB encounters initially treated with either angiography and/or embolization (PEI) and were not re-treated with PEI or another intervention were classified as successfully treated. In patients that underwent pre-procedural CTA versus those who did not, differences in mortality, mean LOS, and successful LGIB treatment were assessed with chi-square test, ANOVA, and student's t-test.

RESULTS

Of 224,640 LGIB encounters captured, 5,983 LGIB encounters treated with PEI met our inclusion/exclusion criteria. Overall mean age, gender, race/ethnicity was 69 years, 53% female, and 73% Caucasian. PEI definitively treated LGIB in 61.6% of LGIB encounters. Compared to patients who did not undergo CTA prior to PEI, pre-intervention CTA was associated with a greater incidence of definitive treatment success after PEI (70.8% vs 29.2%; Odds-Ratio (OR)=1.5 [95%CI 1.1-2.2], p<0.02). There was no significant difference in LOS (8.3±9.6 vs 7.7±8.8 days; p=0.5) or mortality (6.9% vs 8.1%; p=0.7) between encounters involving vs. not involving CTA prior to PEI.

CONCLUSION

s CTA utilization prior to LGIB PEI is associated with a higher incidence of successful treatment but does not impact LOS nor incidence of mortality.

CLINICAL RELEVANCE/APPLICATION

When utilized for the management of lower gastrointestinal bleeding, pre-intervention CTA is associated with a higher incidence of definitive treatment success after primary endovascular intervention but does impact the length of hospital stay nor incidence of mortality.

Treatment Patterns in Chronic Venous Disease: Endovenous vs. Open Vein Stripping: Where Are We Today?

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - IR DPS

Participants
Brian D'Amore, BS, (*Presenter*) Nothing to Disclose

PURPOSE

Chronic venous disease (CVD) affects over 30 million patients in the United States with an annual incidence of 1.9% in males and 2-6% in females. Advances in minimally-invasive treatments allow faster recovery times and lower complications with endovenous treatment options when compared to traditional vein stripping. Yet, surgical interventions persist both as primary and salvage CVD therapy. The purpose of this study was to compare the relative utilization of vein stripping and endovenous treatments, including thermal and laser ablation.

METHODS AND MATERIALS

Endovenous treatment (including thermal and laser ablation) and vein stripping data was obtained from the American College of Surgeons - National Surgical Quality Improvement Program (NSQIP) based on CPT codes (36475-9, 37700, 37718, 37722, and 37735) between 2011-2017. Demographics were extracted for each patient, including race, gender and age. Utilization trends were computed, and percent change was calculated for each procedure.

RESULTS

We identified 22,114 patients who underwent treatment for chronic superficial venous insufficiency between 2011-2017. Thermal ablation was the most frequently performed procedure with 49.5% (n=10,941) patients receiving this treatment, followed by vein stripping at 35.0% (n=7744) and laser ablation at 15.5% (n=3429). Volume increased by 6.3% for thermal ablation and 1.1% for vein stripping, while it decreased by 18.5% for laser ablation. Lastly, thermal ablation increased in males by 24.6% and decreased in females by 1.3%. It also increased in patients aged 65 and older by 24.6% and decreased in patients less than 65 by 3.03%.

CONCLUSION

s Although thermal ablation was the most performed procedure for superficial CVD between 2011-2017, vein stripping volume was still greater than expected. Trends in thermal ablation increased significantly for males when compared to females and for patients aged 65 and older when compared to patients less than 65.

CLINICAL RELEVANCE/APPLICATION

The transition from vein stripping to endovenous procedures may be slower than originally presumed and total volume of procedures is lower than expected based on disease prevalence.

The Role of Boosting Algorithms in Machine Learning in Predicting the Treatment Outcome of High-Intensity Focused Ultrasound Ablation of Uterine Fibroids: Most Informative Perfusion MRI Features

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - IR DPS

Participants
Bilgin Keserci, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

To comparatively evaluate the role of boosting algorithms in machine learning to find the most informative perfusion MRI features in predicting the treatment outcome of High-Intensity Focused Ultrasound (HIFU) ablation with an immediate nonperfused volume (NPV) ratio of at least 90%.

METHODS AND MATERIALS

A total of 73 women with symptomatic uterine fibroids who underwent HIFU treatment were classified according to T1 perfusion-based classification as group A (n = 47, if the time-SI curve of lesion was lower than that of myometrium) and group B (n = 26, if the time-SI curve of lesion was equal to or higher than that of myometrium). In this study, myometrium was chosen as an internal reference. An ensemble feature ranking model was introduced based on the score values ??assigned to the 21 perfusion MRI features by three different boosting algorithms including Adaptive boosting (Adaboost), Category boosting (Catboost) and Gradient boosting (GBM), to find the most informative perfusion MRI features. The relationship between perfusion MRI features and the immediate NPV ratio of 90% was evaluated using Pearson's correlation coefficients. The diagnostic ability of Boosting algorithms was performed by means of standard performance metrics, including the area under the receiver operating characteristic curve (AUROC), accuracy, sensitivity, and specificity in eight folds cross-validation.

RESULTS

For the most informative perfusion MRI features, the AUROC ranged from 0.838 to 0.916, accuracy ranged from 0.84 to 0.96, specificity of 0.833, and sensitivity ranged from 0.842 to 1.0. The GBM algorithm showed the best predictive performance with an AUROC of 0.95 and accuracy of 0.92, followed by the Catboost and Adaboost algorithms, which yielded an AUROC of 0.864 and 0.838, and accuracy of 0.88 and 0.84, respectively. The best classifier performance with the best-performing features from each perfusion MRI group, Ktrans ratio of fibroid to myometrium, The ratio of area under the curve of fibroid to myometrium, the ratio of maximum relative enhancement of fibroid to myometrium, the ratio of relative enhancement of fibroid to myometrium and the ratio of maximum enhancement of fibroid to myometrium, was achieved using GBM.

CONCLUSION

s The preliminary findings in this study suggest that the most informative perfusion MRI features should considered in predicting the treatment outcome of HIFU ablation to achieve an immediate NPV ratio of 90%.

CLINICAL RELEVANCE/APPLICATION

The best boosting algorithm performance with the best-performing perfusion MRI features should be considered by the treating physician in the screening phase to predict the treatment outcome of HIFU ablation to achieve an immediate NPV ratio of 90%.

S3B-SPIR-6

Sustained Clinical Improvement After Prostate Artery Embolization (PAE) for Symptomatic Benign Prostate Hyperplasia (BPH): Results from a Single Center, Retrospective Analysis

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - IR DPS

Participants
Vijay Chockalingam, BS, (*Presenter*) Nothing to Disclose

PURPOSE

To validate if short term clinical results of Prostate Artery Embolization (PAE) in Benign Prostate Hyperplasia (BPH) are sustained over time.

METHODS AND MATERIALS

In an IRB approved, single center, retrospective study, 120 patients (Mean age 70.6 years ±9.7 years) who underwent PAE were identified. Technical success was defined as successful embolization on at least one side. Baseline IPSS (International Prostate Symptom Score) was obtained for each patient. Clinical success was evaluated as change in IPSS in short-term (< 1 year), medium-term (1-2 years) and long-term (3 or more years) follow-up. To determine change in IPSS between pre-PAE procedure and follow-up post-PAE procedure, IPSS was analyzed through a multilevel model using time as a fixed effect and patient ID as a random effect to account for within-patient correlations. Prostate shrinkage was also evaluated and changes in prostate size between baseline and post-PAE procedure were analyzed.

RESULTS

Between February 2014 and May 2021, 56 patients were accounted for in the pre-procedure baseline measurement, which showed an average IPSS of 22.1 (95% CI 20.4-23.9). Technical success was seen in 90.1% of patients in the study. Short-term (n=21), mid-term (n=24), and long-term (n=11) follow-up of these patients showed average IPSS scores of 10.2 (95% CI 7.3-13.1), 9.7 (95% CI 6.7-12.7), and 6.1 (95% CI 4.2-8.0). The results show a statistically significant ($p = 0.000$) and dramatic drop in IPSS of 13.5 points in the short term. The trend post-embolization, although not statistically significant ($p = 0.321$) shows that IPSS scores remain decreased over-time. Prostate size decreased from pre-PAE procedure (n=35) to post-PAE procedure follow up (n=27) from an average of 138.7 cc to 89.9 cc ($p = 0.000$).

CONCLUSION

s The short term, statistically significant drop in IPSS after PAE appears to be sustained in the medium and long term study period in our study, with all available data. Although these results suggest a sustained long term clinical success of the procedure, large multi-center studies are needed.

CLINICAL RELEVANCE/APPLICATION

PAE has emerged as a minimally invasive technique to treat BPH that involves a reduced hospital stay and less adverse effects compared to current gold standard approaches, all while maintaining significant symptom reduction over long term follow-up.

In-vitro Characterization of Drug Eluting Superabsorbent Polymer Microspheres: Absorption and Eluting Capacity of Contrast Material, Antibiotics and/or Analgesics

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - IR DPS

Participants
Akiko Narita, MD, PhD, Nagakute, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Superabsorbent polymer microspheres (SAP-MS) have a property of absorbing fluids to swell. Therefore, drug-loaded SAP-MS will become visible, antibacterial and/or analgesic. The purpose of this study was to examine the characteristics of drug-loaded SAP-MS.

METHODS AND MATERIALS

SAP-MS were suspended in the drug solution (a) antibiotics (Cefazolin) (b) analgesics (Lidocaine) (c) contrast material (Iopamidol) and Cefazolin (d) Iopamidol and Lidocaine (e) Iopamidol, Cefazolin and Lidocaine. 1) Change of the diameter of each drug-loaded SAP-MS was observed by a stereomicroscope for three hours. 2) Absorption capacity of each drug-loaded SAP-MS were assessed by measuring the concentration of drug solution using high performance liquid chromatography (HPLC) sequentially. 3) Filtered each drug-loaded SAP-MS were mixed with 100ml of saline and drug eluting capacity of each drug-loaded SAP-MS were evaluated using HPLC over time.

RESULTS

1) Diameter of drug-loaded SAP-MS increased for about 15 minutes and came to an equilibrium. Finally, the diameter was (a) 3.9 times (b) 5.0 times (c) 2.2 times (d) 5.5 times (e) 3.6 times larger than its original size. 2) The concentration of drug solution did not change and the amount of drug solution decreased. 3) Each drug was released into 10 minutes and came to an equilibrium. The concentration of each drug in the mixture was increased by (a) Cefazolin: 1.82 mg/ml (b) Lidocaine: 0.06 mg/ml (c) Iopamidol: 1.34 mg/ml, Cefazolin: 0.17 mg/ml (d) Iopamidol: 4.51 mg/ml, Lidocaine: 0.11 mg/ml (e) Iopamidol: 2.70 mg/ml, Cefazolin: 1.10 mg/ml, Lidocaine: 0.03 mg/ml.

CONCLUSION

s SAP-MS can absorb each drug as much as it swells. And drug-loaded SAP-MS release contrast material, antibiotics and analgesics.

CLINICAL RELEVANCE/APPLICATION

Visible, antibiotic and/or analgesic microspheres will contribute to safe and useful embolization, in addition, relief of pain and prevention infection like abscess.

Bariatric Arterial Embolization with Radiopaque Hydrogel Microspheres Suppresses Weight Gain and Fundal Ghrelin Levels in Swine

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - IR DPS

Participants
Yingli Fu, Baltimore, MD (*Presenter*) Nothing to Disclose

PURPOSE

Octreotide is a somatostatin analogue with beneficial effect on ghrelin suppression and weight loss. The purpose of this study is to evaluate the effect of octreotide-eluting, lipiodol-impregnated, alginate microspheres (OLMs) on the safety and efficacy of bariatric arterial embolization (BAE) in swine.

METHODS AND MATERIALS

X-ray-visible OLMs were produced from lipiodol-impregnated alginate (2% w/v) solution containing 10 mg/ml octreotide using an electrostatic droplet generator. BAE was performed in 6 healthy, growing swine (mean weight: 22.2 kg) by selective infusion of X-ray-visible OLMs (n = 3) or saline (n = 3) into the right gastric artery (RGA) and the left gastroepiploic artery (LGEA) under X-ray guidance. Weight was obtained in all animals at baseline and weekly up to 8 weeks post embolization. Cone-beam CT (CBCT) images of the stomachs were acquired immediately after embolization and at 8 weeks prior to sacrifice to assess the embolization coverage of the fundus, and the visibility and distribution of OLMs. All animals were euthanized for gross and histological examination of stomach mucosal integrity at 8 weeks. Ghrelin-expressing cells (GECs) in the stomach were assessed immunohistochemically and analyzed using the Mann-Whitney U test.

RESULTS

OLMs were monodispersed with diameter of 185 ± 6 μm. BAE with OLMs was successfully performed in all animals. The OLMs can be visualized both on fluoroscopy and CBCT images during the embolization procedure. The post-procedural percentage of weight gain was lower in BAE-treated animals as compared to controls (BAE vs. control: 39.4% ± 12.9 vs. 61.0% ± 3.2 at 8 weeks). The GECs were significantly decreased in the gastric fundus of OLM- embolized animals compared to control animals (BAE vs. control: 14.9 ± 3.6 vs. 24.3 ± 5.4, $p < 0.0001$). Superficial healed mucosal ulcers were observed in one OLM-embolized animal along the stomach fundus and body.

CONCLUSION

s BAE with octreotide-eluting, lipiodol/alginate microspheres can be safely performed in all animals and significantly suppress the percentage of weight gain and fundal ghrelin levels.

CLINICAL RELEVANCE/APPLICATION

BAE with octreotide-eluting, lipiodol/alginate microspheres may be useful for treating obesity.

New TRUS Techniques and Imaging Features of PI-RADS 4 or 5: Influence on Tumor Targeting

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - IR DPS

Participants
Byung Kwan Park, MD, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

To determine if the new transrectal ultrasound (TRUS) techniques and imaging features contribute to targeting Prostate Imaging and Reporting and Data System (PI-RADS) 4 or 5.

METHODS AND MATERIALS

Between December 2018 and February 2020, 115 men underwent cognitive biopsy by radiologist A, who was familiar with the new TRUS findings and biopsy techniques. During the same period, 179 men underwent magnetic resonance imaging-TRUS image fusion or cognitive biopsy by radiologist B, who was unfamiliar with the new biopsy techniques. Prior to biopsy, both radiologists knew MRI findings such as the location, size, and shape of PI-RADS 4 or 5. We recorded how many target biopsies were performed without systematic biopsy and how many of these detected higher Gleason score (GS) than those detected by systematic biopsy. The numbers of biopsy cores were also obtained. Fisher Exact or Mann-Whitney test was used for statistical analysis.

RESULTS

For PI-RADS 4, target biopsy alone was performed in 0% (0/84) by radiologist A and 0.8% (1/127) by radiologist B ($p>0.9999$). Target biopsy yielded higher GSs in 57.7% (30/52) by radiologist A and 29.5% (23/78) by radiologist B ($p = 0.0019$). For PI-RADS 5, target biopsy alone was performed in 29.0% (9/31) by radiologist A and 1.9% (1/52) by radiologist B ($p = 0.0004$). Target biopsy yielded higher GSs in 50.0% (14/28) by radiologist A and 18.2% (8/44) by radiologist B ($p = 0.0079$). Radiologist A sampled fewer biopsy cores than radiologist B ($p = 0.0008$ and 0.0023 for PI-RADS 4 and 5), respectively.

CONCLUSION

s PI-RADS 4 or 5 can be more precisely targeted if the new TRUS biopsy techniques are applied.

CLINICAL RELEVANCE/APPLICATION

The new TRUS biopsy techniques help to not only target PI-RADS 4 or 5 lesions more precisely but also to reduce the number of biopsy cores needed. Moreover, systematic biopsy can be omitted in PI-RADS 5 patients who do not stop taking aspirin because of cardiovascular disease.

S3B-SPMK-1 Impact of Non-steroidal Anti-inflammatory Drugs (NSAIDs) on Synovitis and The Progression of Osteoarthritis: Data From The Osteoarthritis Initiative (OAI)

Participants
Johanna Luitjens, MD, San Fransisco, CA (*Presenter*) Consultant, Smart Reporting

PURPOSE

Synovitis and associated inflammation have been shown to play a major role in promoting progression of osteoarthritis (OA). Non-steroidal anti-inflammatory drugs (NSAIDs) are commonly used to treat pain in OA patients and could also influence the progression of the disease through their anti-inflammatory effect. To investigate these mechanisms, the goals of this study were (1) to analyze the association between the use of NSAIDs and synovitis and (2) to assess how treatment with NSAIDs impacts structural outcomes over four years.

METHODS AND MATERIALS

Participants from the Osteoarthritis Initiative (OAI) cohort with moderate to severe OA (Kellgren-Lawrence (K/L) grades 2-4) and sustained NSAID treatment for =1 year between baseline and 4-year follow-up were included and compared with non-NSAID treated participants (controls). All participants underwent a 3T MRI of the knee at baseline and after 4 years. Images were semi-quantitatively scored for MR biomarkers of synovial inflammation (effusion-synovitis, size and signal intensity of infrapatellar fat pad (IFP), synovial proliferation score (SPS)). Cartilage thickness and T2-relaxation time measurements served as non-invasive biomarkers for evaluating OA progression. The associations between baseline and findings after 4 years were investigated with linear regression models (including adjustment for sex, BMI, age, pain, K/L grade).

RESULTS

A total of 721 participants matched the inclusion criteria (129 with and 592 participants without regular usage of NSAID). At baseline, significantly higher signal intensity in the IFP was observed in NSAID users as compared to controls (adjusted difference in score, 95% CI, p) (0.26; [-0.5, -0.129], 0.039). Additionally in the longitudinal analysis, there was a significantly higher increase in signal intensity of IFP (0.46; [0.2, 0.72], < 0.001) and higher increase in effusion-synovitis (0.27, [0.06, 0.47], 0.01) in NSAIDs users compared to controls. The size of IFP and SPS did not show a significant difference between groups at baseline and no significant change over time. NSAID users showed more degenerative changes regarding T2-relaxation time and cartilage thickness over time, but this did not reach statistical significance.

CONCLUSION

s NSAID users demonstrated higher signal intensity in IFP and more effusion/ synovitis than controls, suggesting that longtime NSAID usage is associated with more synovitis.

CLINICAL RELEVANCE/APPLICATION

In this study, no structural long-term benefit of NSAID use in patients with OA could be found. Furthermore, users showed more synovitis at baseline and change over 4 years, which may lead to an increase in pain and a decrease in joint function.

S3B-SPMK-2 Contrast-enhanced 3D UTE MRI to Assess Active Inflammation of Sacroiliitis in Spondyloarthropathy: The Diagnostic Performance Compared with Contrast-enhanced fat-suppressed T1 Weighted Spin Echo Sequence

Participants
Yeo Ju Kim, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the diagnostic performance of contrast-enhanced 3D ultrashort echo time MRI (CE-3DUTE) for active inflammation of sacroiliitis in spondyloarthropathy compared with contrast-enhanced T1 weighted spin-echo sequence with fat suppression (CE-T1).

METHODS AND MATERIALS

A total of 50 patients (mean age: 40.6 years old, age range: 20-79, 30 men, 20 women), composed of 30 patients with axial spondyloarthropathy (ASPA group), 7 patients with inflammatory back pain, and 13 patients with mechanical back pain were enrolled in this retrospective study. All patients performed oblique coronal CE-3DUTE and CE-T1 for sacroiliac joint, respectively. Active inflammation of the sacroiliac joint in MRI such as osteitis, synovitis, capsulitis, and enthesitis was semi-quantitatively scored by two musculoskeletal radiologists independently and compared between CE-3DUTE and CE-T1 using a one-way ANOVA test. Clinical inflammation activity such as the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI), AS Disease Activity

Score (ASDAS), erythrocyte sedimentation rate (ESR), C-reactive protein (CRP) level were also documented and correlated with imaging inflammatory scores using bivariate correlation analysis.

RESULTS

ASPA group showed higher scores of osteitis, synovitis, and enthesitis in both CE-3DUTE and CE-T1 than other groups (P<0.05). Among clinical inflammatory activity index, ESR was correlated with osteitis, synovitis, enthesitis in both CE-3DUTE and CE-T1, and with capsulitis in CE-3DUTE with statistical significance (P<0.05). CRP was correlated with osteitis in CE-3D UTE and CE-T1, synovitis in CE-3D UTE, and enthesitis in CE-T1 (P<0.05).

CONCLUSION

s CE-3D UTE might differentiate ASPA from other non-specific inflammatory back pain and mechanical back pain and may reflect inflammatory activity as a complement to CE-T1.

CLINICAL RELEVANCE/APPLICATION

UTE has been expected to better reflect the degree of inflammation in tissues with the majority of short T2 components such as ligaments and tendons, which show no signal in conventional MRI, but there have been few clinical studies in the meantime. Our study suggests that UTE may be useful in the diagnosis of spondyloarthropathy as well as many inflammatory diseases involving tissue with the majority of short T2 components and reflect the inflammatory activity.

S3B-SPMK-3 Radiographic OA Progression Following Meniscus Surgery

Participants
Azad Darbandi, BS, MS, Chicago, IL (*Presenter*) Nothing to Disclose

PURPOSE

Osteoarthritis (OA) is one of the most common joint disorders affecting over fifty-eight million individuals in the United States with an estimated annual cost of $185 billion. Known risk factors include obesity, joint trauma, and overuse. Radiographic scoring and analysis are utilized to assess the progression on OA in patients and help assist with clinical management. To date, the effects of meniscus surgery on osteoarthritis have not been well studied. To help define the risk of meniscus surgery on osteoarthritis progression, we conducted a case-control study comparing radiographic markers of OA progression in patients with and without meniscus surgery by utilizing data from the Osteoarthritis Initiative.

METHODS AND MATERIALS

Patients were identified based on the presence of imaging data and outcomes at baseline and at a 48-month period. Following exclusion criteria, 83 patients with meniscus surgery were matched against 83 controls. Patients were matched based on various confounding factors including age, sex, BMI, comorbidities, intraarticular injections, and semi-quantitative imaging outcomes at baseline. ANCOVA testing was done using imaging outcomes as dependent variables and confounding factors as covariates. Imaging outcomes included joint space narrowing, Kellgren Lawrence (KL) grade, osteophyte formation in tibia/femur medial/lateral compartment, and sclerosis in tibia/femur medial/lateral compartment.

RESULTS

At 48M, a significant difference was found in medial compartment joint space narrowing (p<.001) and osteophyte presentation in the femur medial compartment (p=.005) between patients who received meniscus surgery and patients who did not. Sclerosis of the femur medial compartment (p=.02) and sclerosis of the tibia lateral compartment (p = .02) was found significant as well. KL Grade was 2.04±1.08 in patients who received meniscal surgery and 1.22±.96 in control patients, with a significant difference between the two groups (p<.001). Patients who had meniscus surgery scored higher in each significant radiological marker.

CONCLUSION

s A significant increase in radiographic osteoarthritis progression was seen in patients receiving meniscus surgery compared to control patients. Patients with meniscus surgery had an increase in various radiographic markers including sclerosis, formation of osteophytes, and joint space narrowing. The risks of osteoarthritis following meniscus surgery should be discussed with patients and accounted for throughout clinical management.

CLINICAL RELEVANCE/APPLICATION

Given the increased radiographic progression of osteoarthritis following meniscus surgery, providers should weigh the advantages and disadvantages of the intervention with their patients.

Impact of Non-steroidal Anti-inflammatory Drugs (NSAIDs) on Synovitis and The Progression of Osteoarthritis: Data From The Osteoarthritis Initiative (OAI)

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - MK DPS

Participants
Johanna Luitjens, MD, San Fransisco, CA (*Presenter*) Consultant, Smart Reporting

PURPOSE

Synovitis and associated inflammation have been shown to play a major role in promoting progression of osteoarthritis (OA). Non-steroidal anti-inflammatory drugs (NSAIDs) are commonly used to treat pain in OA patients and could also influence the progression of the disease through their anti-inflammatory effect. To investigate these mechanisms, the goals of this study were (1) to analyze the association between the use of NSAIDs and synovitis and (2) to assess how treatment with NSAIDs impacts structural outcomes over four years.

METHODS AND MATERIALS

Participants from the Osteoarthritis Initiative (OAI) cohort with moderate to severe OA (Kellgren-Lawrence (K/L) grades 2-4) and sustained NSAID treatment for =1 year between baseline and 4-year follow-up were included and compared with non-NSAID treated participants (controls). All participants underwent a 3T MRI of the knee at baseline and after 4 years. Images were semi-quantitatively scored for MR biomarkers of synovial inflammation (effusion-synovitis, size and signal intensity of infrapatellar fat pad (IFP), synovial proliferation score (SPS)). Cartilage thickness and T2-relaxation time measurements served as non-invasive biomarkers for evaluating OA progression. The associations between baseline and findings after 4 years were investigated with linear regression models (including adjustment for sex, BMI, age, pain, K/L grade).

RESULTS

A total of 721 participants matched the inclusion criteria (129 with and 592 participants without regular usage of NSAID). At baseline, significantly higher signal intensity in the IFP was observed in NSAID users as compared to controls (adjusted difference in score, 95% CI, p) (0.26; [-0.5, -0.129], 0.039). Additionally in the longitudinal analysis, there was a significantly higher increase in signal intensity of IFP (0.46; [0.2, 0.72], < 0.001) and higher increase in effusion-synovitis (0.27, [0.06, 0.47], 0.01) in NSAIDs users compared to controls. The size of IFP and SPS did not show a significant difference between groups at baseline and no significant change over time. NSAID users showed more degenerative changes regarding T2-relaxation time and cartilage thickness over time, but this did not reach statistical significance.

CONCLUSION

s NSAID users demonstrated higher signal intensity in IFP and more effusion/ synovitis than controls, suggesting that longtime NSAID usage is associated with more synovitis.

CLINICAL RELEVANCE/APPLICATION

In this study, no structural long-term benefit of NSAID use in patients with OA could be found. Furthermore, users showed more synovitis at baseline and change over 4 years, which may lead to an increase in pain and a decrease in joint function.

Contrast-enhanced 3D UTE MRI to Assess Active Inflammation of Sacroiliitis in Spondyloarthropathy: The Diagnostic Performance Compared with Contrast-enhanced fat-suppressed T1 Weighted Spin Echo Sequence

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - MK DPS

Participants
Yeo Ju Kim, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the diagnostic performance of contrast-enhanced 3D ultrashort echo time MRI (CE-3DUTE) for active inflammation of sacroiliitis in spondyloarthropathy compared with contrast-enhanced T1 weighted spin-echo sequence with fat suppression (CE-T1).

METHODS AND MATERIALS

A total of 50 patients (mean age: 40.6 years old, age range: 20-79, 30 men, 20 women), composed of 30 patients with axial spondyloarthropathy (ASPA group), 7 patients with inflammatory back pain, and 13 patients with mechanical back pain were enrolled in this retrospective study. All patients performed oblique coronal CE-3DUTE and CE-T1 for sacroiliac joint, respectively. Active inflammation of the sacroiliac joint in MRI such as osteitis, synovitis, capsulitis, and enthesitis was semi-quantitatively scored by two musculoskeletal radiologists independently and compared between CE-3DUTE and CE-T1 using a one-way ANOVA test. Clinical inflammation activity such as the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI), AS Disease Activity Score (ASDAS), erythrocyte sedimentation rate (ESR), C-reactive protein (CRP) level were also documented and correlated with imaging inflammatory scores using bivariate correlation analysis.

RESULTS

ASPA group showed higher scores of osteitis, synovitis, and enthesitis in both CE-3DUTE and CE-T1 than other groups ($P<0.05$). Among clinical inflammatory activity index, ESR was correlated with osteitis, synovitis, enthesitis in both CE-3DUTE and CE-T1, and with capsulitis in CE-3DUTE with statistical significance ($P<0.05$). CRP was correlated with osteitis in CE-3D UTE and CE-T1, synovitis in CE-3D UTE, and enthesitis in CE-T1 ($P<0.05$).

CONCLUSION

s CE-3D UTE might differentiate ASPA from other non-specific inflammatory back pain and mechanical back pain and may reflect inflammatory activity as a complement to CE-T1.

CLINICAL RELEVANCE/APPLICATION

UTE has been expected to better reflect the degree of inflammation in tissues with the majority of short T2 components such as ligaments and tendons, which show no signal in conventional MRI, but there have been few clinical studies in the meantime. Our study suggests that UTE may be useful in the diagnosis of spondyloarthropathy as well as many inflammatory diseases involving tissue with the majority of short T2 components and reflect the inflammatory activity.

Radiographic OA Progression Following Meniscus Surgery

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - MK DPS

Participants
Azad Darbandi, BS, MS, Chicago, IL (*Presenter*) Nothing to Disclose

PURPOSE

Osteoarthritis (OA) is one of the most common joint disorders affecting over fifty-eight million individuals in the United States with an estimated annual cost of $185 billion. Known risk factors include obesity, joint trauma, and overuse. Radiographic scoring and analysis are utilized to assess the progression on OA in patients and help assist with clinical management. To date, the effects of meniscus surgery on osteoarthritis have not been well studied. To help define the risk of meniscus surgery on osteoarthritis progression, we conducted a case-control study comparing radiographic markers of OA progression in patients with and without meniscus surgery by utilizing data from the Osteoarthritis Initiative.

METHODS AND MATERIALS

Patients were identified based on the presence of imaging data and outcomes at baseline and at a 48-month period. Following exclusion criteria, 83 patients with meniscus surgery were matched against 83 controls. Patients were matched based on various confounding factors including age, sex, BMI, comorbidities, intraarticular injections, and semi-quantitative imaging outcomes at baseline. ANCOVA testing was done using imaging outcomes as dependent variables and confounding factors as covariates. Imaging outcomes included joint space narrowing, Kellgren Lawrence (KL) grade, osteophyte formation in tibia/femur medial/lateral compartment, and sclerosis in tibia/femur medial/lateral compartment.

RESULTS

At 48M, a significant difference was found in medial compartment joint space narrowing ($p<.001$) and osteophyte presentation in the femur medial compartment ($p=.005$) between patients who received meniscus surgery and patients who did not. Sclerosis of the femur medial compartment ($p=.02$) and sclerosis of the tibia lateral compartment ($p = .02$) was found significant as well. KL Grade was 2.04±1.08 in patients who received meniscal surgery and 1.22±.96 in control patients, with a significant difference between the two groups ($p<.001$). Patients who had meniscus surgery scored higher in each significant radiological marker.

CONCLUSION

s A significant increase in radiographic osteoarthritis progression was seen in patients receiving meniscus surgery compared to control patients. Patients with meniscus surgery had an increase in various radiographic markers including sclerosis, formation of osteophytes, and joint space narrowing. The risks of osteoarthritis following meniscus surgery should be discussed with patients and accounted for throughout clinical management.

CLINICAL RELEVANCE/APPLICATION

Given the increased radiographic progression of osteoarthritis following meniscus surgery, providers should weigh the advantages and disadvantages of the intervention with their patients.

S3B-SPNMMI-1 99mTc-pyrophosphate Scintigraphy and Clinical Findings Related to Early-Onset Patients With Wild-Type Transthyretin Cardiomyopathy

Participants
Kouji Ogasawara, Kumamoto, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Wild-type transthyretin cardiomyopathy (ATTRwt-CM) is an increasingly recognized cause of heart failure especially in elderly patients, but there are a small number of early-onset ATTRwt-CM patients. We aimed to evaluate the status of amyloid deposition and clinical risk factors related to the early-onset ATTRwt-CM patients using 99mTc-pyrophosphate (PYP) scintigraphy with SPECT/CT examination.

METHODS AND MATERIALS

Our study included 111 patients who were clinically diagnosed with ATTRwt-CM and underwent PYP scintigraphy including SPECT/CT. Of all patients, 36 cases under 75 years were classified as early-onset group (Group 1), and 75 cases over 75 years were designated as late-onset group (Group 2). Heart-to-contralateral ratio (H/CL) was calculated from a planar image, and the uptake ratio of PYP in the septum (Se), posterior (Po), anterior (An), lateral (La), and apex (Ap) walls to the cavity pool (C) on SPECT/CT was calculated as Se/C. Po/C, An/C, La/C, and Ap/C, respectively. Clinical risk factors for heart disease included hypertension (HT), dyslipidemia (DL), diabetes mellitus (DM), chronic kidney disease (CKD), and smoking history. Univariate analysis and multiple logistic regression analysis were performed to evaluate the relationship between the scintigraphy and clinical findings and the patient’s onset.

RESULTS

All indices of PYP scintigraphy were significantly higher for Group 1 than Group 2 (p lt; 0.01). The proportion of male gender was significantly higher for Group 1 (94%) than Group 2 (79%) (p = 0.01). Compared to Group 2, Group 1 had significantly higher DM prevalence (53% Group 1 vs 24% Group 2; p = 0.04) and smoking history (73% Group 1 vs 44% Group 2; p lt; 0.01). Multiple logistic regression analysis showed that independent, significant factors were An/C (p lt; 0.01), DM (p lt; 0.01), and smoking history (p = 0.05).

CONCLUSION

s Myocardial accumulation of PYP was significantly higher in the early-onset patients with ATTRwt-CM than in the late-onset, suggesting that the rate of amyloid deposition may affect the age of onset. Also, the early-onset patients had a higher proportion of DM prevalence and smoking history, which may be factors accelerating amyloid deposition.

CLINICAL RELEVANCE/APPLICATION

Early-onset ATTRwt-CM patients have different scintigraphy and clinical findings compared to late-onset patients. Further investigation is needed as to whether treatment strategies should be considered according to the patient's onset.

S3B-SPNMMI-2 Multi-pool Model-based CEST Imaging Compared to IVIM and 11C-MET Uptake on PET/CT in Patients with Gliomas

Participants
Yasukage Takami, Mikicho, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Although magnetization transfer ratio asymmetry (MTRasym) analysis is often used as a chemical exchange saturation transfer (CEST), it is semiquantitative and entails some pitfalls. Recently, we developed the new parameters on CEST imaging by the multi-pool model (MPM). The MPM analysis can produce quantitative results and it may allow for a more detailed assessment of the tumors. The purpose of this study was to evaluate the clinical significance of the new parameters on CEST imaging by assessing the correlation among parameters on CEST imaging by MPM, intravoxel incoherent motion (IVIM) and and 11C-methionine (MET) uptake on PET/CT in gliomas.

METHODS AND MATERIALS

The preoperative MRI and 11C-MET PET/CT examinations of a total of 30 lesions from 17 patients with gliomas were examined. The magnetization transfer ratio asymmetry (MTRasym) value at 3.5 ppm downfield from the water signal was obtained by calculating the difference in signal intensity (SI) at ±3.5 ppm on both sides of the water center frequency in the Z-spectrum. MPM assumes the magnetization transfer (MT) between free water pool, APT pool and binding water MT pool. "APT density" x "APT transfer rate" x ("Free water T1" or "T2") was visualized as APT_T1 or APT_T2, respectively. The MT image is obtained via MPM fitting. Firstly, the maximum values of the parameters (MTRasym, APT_T1, APT_T2, T2/T1 ratio, and MT) on CEST imaging were measured respectively by regions of interest (ROI) analysis. Secondly, ROIs of IVIM and 11C-MET PET/CT were placed in similar anatomical locations by visual assessment. ROIs were carefully placed in the solid component of a tumor and the best effort was given to avoid cystic components of the tumor. 11C-MET uptake was semiquantitatively assessed using tumor-to-contralateral normal brain tissue (T/N) ratio.

RESULTS

There were significant positive correlations between APT_T1 and MET T/N ratio (? = 0.86, p < 0.01), APT_T2 and MET T/N ratio (? = 0.42, p < 0.05), T2/T1 and ADC (? = 0.36, p = 0.05), T2/T1 and D (? = 0.41, p < 0.05), and MTRasym and MET T/N ratio (? = 0.51, p < 0.01). There existed significant negative correlations between APT_T1 and ADC (? = -0.64, p < 0.01), APT_T1 and D (? = -0.67, p < 0.01), APT_T2 and D* (? = -0.46, p = 0.01), and T2/T1 and MET T/N ratio (? = -0.37, p < 0.05).

CONCLUSION

s These preliminary results suggest that parameters on CEST imaging by multi pool model seems to correlate with IVIM and 11C-MET uptake on PET/CT in patients with gliomas. Combining Multi-pool model-based CEST imaging, IVIM and 11C-MET PET/CT may improve the diagnostic ability of gliomas.

CLINICAL RELEVANCE/APPLICATION

Combining Multi-pool model-based CEST imaging, IVIM and 11C-MET PET/CT may improve the diagnostic ability of gliomas.

S3B-SPNMMI-3 Low-dose EDB Fibronectin Gd-DOTA Specific Probe for Pancreatic Cancer Targeting Magnetic-optical Dual-modality Imaging

Participants
Wenjia Zhang, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

Pancreatic ductal adenocarcinoma (PDAC) is a lethal malignancy worldwide. PDAC is a hypovascular tumor surrounded by dense stroma, which is recognized as a vital factor of tumor progression. Multimodal molecular imaging of onco-proteins is a promising method for accurate, early detection of the disease. Extradomain-B fibronectin (EDB-FN), a high-expression onco-protein in the tumor extracellular matrix, can realize targeted and effective molecular imaging. Here, we prepared a novel Gd-based contrast agent of EDB-Cy7 to perform fluorescence molecular imaging (FMI) and molecular MRI, in order to realize accurate, early and safe detection of PDAC.

METHODS AND MATERIALS

The EDB-FN targeting peptide and near infrared dye Cy7 were conjugated to the Gd-DOTA (EDB-Gd-Cy7) for the PDAC-targeting multimodality imaging. Five-week-old BALB/c nude mice were implanted with human pancreatic stellate cells (PSC) and human PDAC cell lines (Bxpc-3) to establish the subcutaneous and orthotopic PDAC models. Mice were intravenously injected with EDB-Gd-Cy7 or Gd-DOTA at the Gd concentration of 0.05 mmol/kg, which is merely a half of clinical dose. T1 mapping MRI and FMI were performed. The TBR (Tumor background ratio) of fluorescence intensity and the ratio of T1 value reduction (T1d%) were compared quantitatively. Histological and immunofluorescence analyses were used as references for ex vivo validation.

RESULTS

The concentration of EDB-Gd-Cy7 showed a correlation with fluorescence intensity and T1 relaxation time in vitro. For in vivo MRI, the T1d% showed the most significant difference at 30 minutes post-injection in subcutaneous and orthotopic PDAC xenograft models. For in vivo FMI, at 30 minutes post-injection, the TBR of fluorescence intensity showed the most significant difference in subcutaneous models, while the TBR of fluorescence intensity showed no significant differences between two groups in orthotopic models. Immunofluorescence confirmed the targeting of EDB-Gd-Cy7 to EDB-FN in both PDAC models.

CONCLUSION

s Our dual-modal imaging findings indicate that FMI and molecular MRI could complement its advantages and translation of oncoprotein targeted dual-modal imaging with low-dose EDB-Gd-Cy7 to humans, which might provide a promising imaging technique to detect PDAC precisely. Moreover, these findings suggest that EDB-FN targeting MRI might have clinical application to evaluate the tumor extracellular matrix and chemo-therapy efficacy in the future.

CLINICAL RELEVANCE/APPLICATION

Molecular MRI with the EDB-targeted probe provided robust detection of PDAC in two animal models and may enable non-invasive detection, precise staging and monitoring post-treatment fibrotic changes of PDAC compared to standard Gd-DOTA contrast agents.

99mTc-pyrophosphate Scintigraphy and Clinical Findings Related to Early-Onset Patients With Wild-Type Transthyretin Cardiomyopathy

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - NMMI DPS

Participants
Kouji Ogasawara, Kumamoto, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Wild-type transthyretin cardiomyopathy (ATTRwt-CM) is an increasingly recognized cause of heart failure especially in elderly patients, but there are a small number of early-onset ATTRwt-CM patients. We aimed to evaluate the status of amyloid deposition and clinical risk factors related to the early-onset ATTRwt-CM patients using 99mTc-pyrophosphate (PYP) scintigraphy with SPECT/CT examination.

METHODS AND MATERIALS

Our study included 111 patients who were clinically diagnosed with ATTRwt-CM and underwent PYP scintigraphy including SPECT/CT. Of all patients, 36 cases under 75 years were classified as early-onset group (Group 1), and 75 cases over 75 years were designated as late-onset group (Group 2). Heart-to-contralateral ratio (H/CL) was calculated from a planar image, and the uptake ratio of PYP in the septum (Se), posterior (Po), anterior (An), lateral (La), and apex (Ap) walls to the cavity pool (C) on SPECT/CT was calculated as Se/C. Po/C, An/C, La/C, and Ap/C, respectively. Clinical risk factors for heart disease included hypertension (HT), dyslipidemia (DL), diabetes mellitus (DM), chronic kidney disease (CKD), and smoking history. Univariate analysis and multiple logistic regression analysis were performed to evaluate the relationship between the scintigraphy and clinical findings and the patient’s onset.

RESULTS

All indices of PYP scintigraphy were significantly higher for Group 1 than Group 2 (p lt; 0.01). The proportion of male gender was significantly higher for Group 1 (94%) than Group 2 (79%) (p = 0.01). Compared to Group 2, Group 1 had significantly higher DM prevalence (53% Group 1 vs 24% Group 2; p = 0.04) and smoking history (73% Group 1 vs 44% Group 2; p lt; 0.01). Multiple logistic regression analysis showed that independent, significant factors were An/C (p lt; 0.01), DM (p lt; 0.01), and smoking history (p = 0.05).

CONCLUSION

s Myocardial accumulation of PYP was significantly higher in the early-onset patients with ATTRwt-CM than in the late-onset, suggesting that the rate of amyloid deposition may affect the age of onset. Also, the early-onset patients had a higher proportion of DM prevalence and smoking history, which may be factors accelerating amyloid deposition.

CLINICAL RELEVANCE/APPLICATION

Early-onset ATTRwt-CM patients have different scintigraphy and clinical findings compared to late-onset patients. Further investigation is needed as to whether treatment strategies should be considered according to the patient's onset.

S3B-SPNPM-1 Artificial Intelligence Support in MR-Imaging of Renal Masses: A Primary Economic Evaluation

Participants
Felix Gassert, MD, MBA, Munich, Germany (*Presenter*) Consultant, SmartReporting GmbH

PURPOSE

Unclear renal lesions often appear as incidental findings during various imaging procedures as they are common, especially in people over the age of 50. Correct differentiation between malignant and benign incidentally found renal lesions has critical implications for patient management. As shown in previous studies, modern artificial intelligence-based algorithms are on-par with or even exceed radiologists' performance in the differentiation of those lesions. Therefore, the aim of this study was to evaluate the cost-effectiveness of an AI-based system in the context of the evaluation of incidental renal masses based on MR images and define maximal possible costs for AI.

METHODS AND MATERIALS

For estimation of quality-adjusted life years (QALYs) and lifetime costs, a decision model was created, including the options MRI with and without applying an AI algorithm. For obtaining model input parameters, review of recent literature was performed. Willingness to pay (WTP) was set to $100,000/QALY. Costs of $0 were assumed in the base-case scenario and adapted accordingly in the sensitivity analysis. Model uncertainty and possible costs of the AI system were assessed using deterministic sensitivity analysis of diagnostic parameters and costs. Probabilistic sensitivity was determined using Monte Carlo modeling.

RESULTS

In the base-case scenario, total costs were at $8054 for MRI and at $7939 for the additional use of an AI-based algorithm, whereas the model yielded a cumulative effectiveness of 8.77 QALYs for both the use of MRI with and without the algorithm. Therefore, the incremental cost-effectiveness ratio was negative, and the use of AI was the dominant strategy from a cost-effectiveness point of view. Deterministic and probabilistic sensitivity analysis showed high robustness of the model with the incremental cost-effectiveness ratio remaining belowthe WTP for a wide range of variability of the input parameters. If increasing costs for the algorithm, the threshold of $0 / QALY was exceeded at $115, and the defined WTP was exceeded at $667.

CONCLUSION

s The use of AI-supported evaluation is feasible in classifying unclear renal masses using MRI from a cost-effectiveness point of view. Costs as high as $667 for the algorithm can be accepted with high robustness of the model.

CLINICAL RELEVANCE/APPLICATION

The presented results have medical and economic impact on diagnostic workup of incidental renal masses and could help improve patient care by accelerating the translation of AI into clinical routine by proofing its cost-effectiveness.

Lijuan Zhu, (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this study was to investigate the effect of 70KV combined with DLIR and ASiR-V on the quality of CCTA images in overweight patients.

METHODS AND MATERIALS

A total of 48 overweight patients (24 kg/m2=BMI<28.5kg/m2) who underwent low-voltage CCTA with Revolution Apex CT in our hospital from September 2021 to January 2022 were selected, reconstruted with FBP, 40% weight, 80% weight ASiR-V and low-level (DLIR-L), medium-level (DLIR-M) and high-level respectively (DLIR-H) DLIR. The image noise of the aortic root and proximal main coronary artery of each group of images was recorded, and the SNR and CNR were calculated for subjective and objective images. Quality Evaluation. Subjective image quality was rated on a 5-point scale by two diagnostic radiologists with more than 5 years of experience.

RESULTS

1) The noise of FBP, ASiR-40%, ASiR-80%, DLIR-L, DLIR-M and DLIR-H decreased with the increase of reconstruction level (all P<0.05), and SNR and CNR gradually increased. For DLIR-H, it had an average increase of 13.81% and 79.23% compared with ASiR-80%. 2) For DLIR group, the scores of two observers, physician A and physician B, showed that the reconstruction weight increased with the increase of the reconstruction weight. Both observers believed that the best diagnostic effect was DLIR-H, which was better than DLIR-L increased by 20.32%, and the consistent Kappa value between the two observers was 0.857; for the ASiR-V, the two observers' scoring results showed that with the increase of the reconstruction weight, ASiR-80% On the contrary, the subjective image quality of ASiR-40% decreased by 4.47%, but the subjective image scores of both were higher than that of FBP, ASiR-40% increased by 43.28%, and ASiR-80% increased by 38.81% (P <0.05), and the consistent Kappa values between the two observers were greater than 0.8.

CONCLUSION

s As the weight of the ASiR-V reconstruction algorithm increases, the objective image evaluation improves. However, the excessive weight (ASiR-80%) changes the noise texture of the image, resulting in a decrease in the subjective score and affecting the diagnosis of the disease. Compared with the ASiR-V reconstruction algorithm, the DLIR algorithm can significantly reduce the noise of the CCTA image, improve the SNR and CNR of the image, and improve the subjective and objective image quality, without affecting the diagnosis of the disease. Overall, the DLIR algorithm has a high clinical application value.

CLINICAL RELEVANCE/APPLICATION

By comparing the effects of ASiR-V and DLIR on conventional CCTA scan images of overweight patients under the condition of low tube voltage. The choice of reconstruction algorithms for patient CCTA scans offers more possibilities.

Artificial Intelligence Support in MR-Imaging of Renal Masses: A Primary Economic Evaluation

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - NPM DPS

Participants
Felix Gassert, MD, MBA, Munich, Germany (*Presenter*) Consultant, SmartReporting GmbH

PURPOSE

Unclear renal lesions often appear as incidental findings during various imaging procedures as they are common, especially in people over the age of 50. Correct differentiation between malignant and benign incidentally found renal lesions has critical implications for patient management. As shown in previous studies, modern artificial intelligence-based algorithms are on-par with or even exceed radiologists' performance in the differentiation of those lesions. Therefore, the aim of this study was to evaluate the cost-effectiveness of an AI-based system in the context of the evaluation of incidental renal masses based on MR images and define maximal possible costs for AI.

METHODS AND MATERIALS

For estimation of quality-adjusted life years (QALYs) and lifetime costs, a decision model was created, including the options MRI with and without applying an AI algorithm. For obtaining model input parameters, review of recent literature was performed. Willingness to pay (WTP) was set to $100,000/QALY. Costs of $0 were assumed in the base-case scenario and adapted accordingly in the sensitivity analysis. Model uncertainty and possible costs of the AI system were assessed using deterministic sensitivity analysis of diagnostic parameters and costs. Probabilistic sensitivity was determined using Monte Carlo modeling.

RESULTS

In the base-case scenario, total costs were at $8054 for MRI and at $7939 for the additional use of an AI-based algorithm, whereas the model yielded a cumulative effectiveness of 8.77 QALYs for both the use of MRI with and without the algorithm. Therefore, the incremental cost-effectiveness ratio was negative, and the use of AI was the dominant strategy from a cost-effectiveness point of view. Deterministic and probabilistic sensitivity analysis showed high robustness of the model with the incremental cost-effectiveness ratio remaining belowthe WTP for a wide range of variability of the input parameters. If increasing costs for the algorithm, the threshold of $0 / QALY was exceeded at $115, and the defined WTP was exceeded at $667.

CONCLUSION

s The use of AI-supported evaluation is feasible in classifying unclear renal masses using MRI from a cost-effectiveness point of view. Costs as high as $667 for the algorithm can be accepted with high robustness of the model.

CLINICAL RELEVANCE/APPLICATION

The presented results have medical and economic impact on diagnostic workup of incidental renal masses and could help improve patient care by accelerating the translation of AI into clinical routine by proofing its cost-effectiveness.

To Explore the Effect of 70KVp Tube Voltage Coronary CTA Combined With Different Image Reconstruction Algorithms on the Image Quality of Overweight Patients

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - NPM DPS

Participants
Lijuan Zhu, (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this study was to investigate the effect of 70KV combined with DLIR and ASiR-V on the quality of CCTA images in overweight patients.

METHODS AND MATERIALS

A total of 48 overweight patients (24 kg/m2=BMI<28.5kg/m2) who underwent low-voltage CCTA with Revolution Apex CT in our hospital from September 2021 to January 2022 were selected, reconstruted with FBP, 40% weight, 80% weight ASiR-V and low-level (DLIR-L), medium-level (DLIR-M) and high-level respectively (DLIR-H) DLIR. The image noise of the aortic root and proximal main coronary artery of each group of images was recorded, and the SNR and CNR were calculated for subjective and objective images. Quality Evaluation. Subjective image quality was rated on a 5-point scale by two diagnostic radiologists with more than 5 years of experience.

RESULTS

1) The noise of FBP, ASiR-40%, ASiR-80%, DLIR-L, DLIR-M and DLIR-H decreased with the increase of reconstruction level (all P<0.05), and SNR and CNR gradually increased. For DLIR-H, it had an average increase of 13.81% and 79.23% compared with ASiR-80%. 2) For DLIR group, the scores of two observers, physician A and physician B, showed that the reconstruction weight increased with the increase of the reconstruction weight. S3B-SPNR-1 Volume and Permeability of White Matter Hyperintensity on Cognition: A DCE Imaging study in A Prospective Elderly Cohort

Participants
Hyeongwoo Kim, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

We aimed to evaluate the relationship between volume, permeability, and the effect of white matter pathology on cognition in elderly patients with mild to moderate WMH from a prospective elderly cohort.

METHODS AND MATERIALS

In this IRB-approved retrospective analysis of the prospective study, written informed consent was obtained from all participants. We selected 193 elderly participants of the age range (55-80 years) with minimal-to-moderate WMH from a prospective DCE MRI cohort (n=259) with normal and impaired cognition between August 2017 and June 2021. Periventricular WMH (PWMH), deep WMH (DWMH), and normal-appearing white matter (NAWM) were automatically segmented using a 3D T1-weighted sequence. Volume transfer constant [Ktrans] as BBB permeability was determined using DCE MRI. The effects of Ktrans of WMH and NAWM were evaluated using multivariable linear regression adjusted for demographic and volume measures.

RESULTS

and volume measures. 193 participants (age, 70.1±6.8 years; 128 women) include 44 with CDR=0, 119 with CDR=0.5, and 30 with CDR=1.0. The degree of WMH was minimal (n=87) and moderate (n=106).Higher Ktrans was observed in PWMH (0.598 ±0.509 x10-3 min-1) compared to DWMH (0.496 ± 0.478 x10-3min-1) and NAWM (0.476 ± 0.398 x10-3min-1) ($p<0.001$). The strong negative correlation between Ktrans and the volume was noted in PWMH (rho=-0.357, $p<0.001$) and DWMH (rho = -0.200, $p=0.005$), but not in NAWM (rho = 0.053, $p=0.460$).After adjusting for age, sex, APOE4, education, cortex volume, PWMH volume (B =-0.0008, SE = 0.0002, beta = -0.363, $p <0.001$) and history of cardiovascular disease (B = 0.0066., SE = 0.0028, beta = 0.229, $p <0.021$) were predictive factors for Ktrans of PWMH ($R2=0.191$, $F(2, 86) = 10.153$, $p<0.001$). After adjusting for covariates, only history of cardiovascular disease was the predictor for Ktrans of NAWM ($R2=0.036$, $F(1,153) =5.740$, $p<0.018$).After adjusting covariates (age, sex, and APOE4 status), hippocampal volume ($p<0.001$), and PWMH volume (along with education level were independent predictors of worse cognition (CDR-SB = 3), whereas cortex volume and Ktrans of PWMH were not.

CONCLUSION

s We found higher permeability of PWMH compared to DWMH and NAWM and a negative relationship between its permeability and volume. The volume of PWMH is the predictor of worse cognition in elderly individuals. Further, our finding suggests that WMH permeability and WMH volume change may be independent events.

CLINICAL RELEVANCE/APPLICATION

Our findings suggest the different underlying pathophysiology of PWMH and DWMH. In addition, the volume of PWMH predicts worse cognition in elderly individuals.

S3B-SPNR-10 Assessment of White Matter Lesion Volume and Disability in Neuromyelitis Optica Spectrum Disorder

Participants
Jitlada Kusol, MD, Bangkok Noi, Thailand (*Presenter*) Nothing to Disclose

PURPOSE

Neuromyelitis optica spectrum disorder (NMOSD) is an aquaporin-4 (AQP4) antibody-mediated disease, affecting the white matter (WM). However, how burden of WM correlates to outcome is yet to be studied. The purposes of this study were to measure white matter lesion volume (WMLV) at locations with high AQP4 expression and to study its association to disability and disease progression.

METHODS AND MATERIALS

Retrospective review of 32 NMOSD patients who underwent two consecutive brain MRI scans with = 1-year interval were performed. Patients were categorized into low EDSS group (EDSS=3, n =15) and high EDSS group (EDSS=3.5, n=17). Disease progression (sustained increase in EDSS) was also significant parameter. WMLV were measured and categorized into five locations (diencephalic, dorsal brainstem, callosal/periventricular, hemispheric WM and corticospinal tract). Changes in WMLV in

aforementioned locations were also defined.

RESULTS

WMLV was significantly larger in the high EDSS group at the callosal/periventricular, hemispheric WM and corticospinal tract ($p<0.001$, 0.041 and 0.025, respectively). In addition, the high EDSS group showed the lower change in the WMLV at hemispheric WM over the follow-up period ($p=0.044$). Patients with disease progression (6.3%) had higher WMLV at callosal/periventricular area than those without progression ($p=0.024$).

CONCLUSION

s Greater WMLV at callosal/periventricular, hemispheric WM and corticospinal tract related to the higher disability in NMOSD patients. In addition, higher WMLV at callosal/periventricular region may predict the development of disease progression. Our findings reflect that higher WMLV may correlate to worse clinical outcome.

CLINICAL RELEVANCE/APPLICATION

Higher WMLV in NMOSD patients may correlate to worse clinical outcome, especially at callosal/periventricular, hemispheric WM and corticospinal tract.

S3B-SPNR-11 Altered Vascular Permeability in Autoimmune Encephalitis: Region-based Evaluation with Dynamic Contrast-enhanced MRI and Automatic Whole Brain Segmentation

Participants
Sohyun Ji, MD, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the change in permeability of brain-blood barrier (BBB) in patients with autoimmune encephalitis, as compared with the healthy control group, by using dynamic contrast enhanced MRI (DCE-MRI) and to explore its predictive value for the treatment response in the patients.

METHODS AND MATERIALS

In this retrospective study, a total of 38 patients with probable or possible autoimmune encephalitis and 15 healthy controls underwent DCE-MRI between April 2020 and May 2021. Automatic volumetric segmentation was performed on pre-/postcontrast T1-weighted images by using FreeSurfer, and encephalitis-associated brain region masks were extracted by using the software NordicICE. Ktrans maps, derived from DCE-MRI using Patlak model, were coregistered with the region-of-interest masks to calculate their mean values at the total volume of interest. The Wilcoxon rank sum test and Friedman test were used to compare Ktrans. Receiver operating characteristic curve analysis was used to assess the diagnostic performance.

RESULTS

All brain regions showed significantly increased Ktrans in the patients, as compared with the controls ($P < .05$). The right cerebral cortex (1.232 vs. 0.0003 min-1) and right nucleus accumbens (0.371 vs. 0.0002 min-1) had the largest mean difference of Ktrans between the patients and controls, followed by the right parahippocampus and right occipital lobe. The same trends were observed in each autoimmune encephalitis subtype (anti-LGI1, anti-NMDAR, and antibody-negative). No significant differences in Ktrans were found between the baseline and follow-up. Poor treatment response group had significantly higher baseline Ktrans in all brain regions ($P < .05$), as compared with good treatment response group, except for the right nucleus accumbens ($P = 0.33$) and right cerebral cortex ($P = 0.08$). At the cutoff value of 0.002 min-1, sensitivity and specificity for the prediction of treatment response were 86% and 100%, respectively for the left cerebellar cortex.

CONCLUSION

s The BBB permeability was persistently increased in all brain regions in autoimmune encephalitis patients, as compared with controls, and baseline Ktrans were higher in patients with poor treatment outcome.

CLINICAL RELEVANCE/APPLICATION

Autoimmune encephalitis patients showed increased BBB permeability in all brain regions, and the increased permeability of BBB was associated with treatment response.

S3B-SPNR-13 A Review of The Appropriateness of Magnetic Resonance Imaging for Optic Neuritis in A Tertiary Referral Center in The West of Ireland

Participants
Richard Farnan, BMBCh, BSc, (*Presenter*) Nothing to Disclose

PURPOSE

Optic neuritis is a clinical condition which involves inflammation of the optic nerves. It is often seen concurrently with central nervous system (CNS) demyelination and there is well known link with multiple sclerosis. [1] The purpose of this study was to evaluate the appropriateness of magnetic resonance imaging of the CNS in patients with confirmed optic neuritis.

METHODS AND MATERIALS

The study retrospectively reviewed MRI requests for patients with optic neuritis over a five-year period at University Hospital, Galway. Our institution is a tertiary referral center with neurology expertise in the west of Ireland. The study established which CNS imaging was requested by neurologists. Additionally, the final radiology reports were reviewed to establish if the imaging technique diagnosed any relevant positive findings.

RESULTS

MRI brain and Orbits was the most commonly ordered investigation with neurologists requesting this study in 89 patients. Of these, 40 patients (44.9%) showed patterns consistent with optic neuritis. MRI orbits (alone) was the second most commonly requested imaging. 45 MRI patients underwent MRI orbits with relevant changes reported in 16 (35.6%) patients. MRI C-spine was performed on 47 patients with 12 (25.5%) showing significant changes. MRI T-spine was the least common investigation ordered with 10

patients undergoing such. From these, only 1 patient (10%) showed significant change on imaging.

CONCLUSION

s The purpose of this study was to establish how much imaging of the CNS is justified in patients with optic neuritis. MRI brain and orbits were the most prevalent imaging ordered. Their role in investigating patients with optic neuritis is largely justified with changes such as plaque accumulation and demyelination patterns noted in a significant portion of patients. Of note, only 10% of patients with optic neuritis had positive findings on MRI T-spine. This raises the question of whether MRI T-spine should be included in imaging work up for optic neuritis. Strengths of this study include relatively large sample size (n= 191), 5 year timeframe and significance of the hospital site as a tertiary referral center in the west of Ireland.

CLINICAL RELEVANCE/APPLICATION

In conclusion, our study shows that MR imaging of brain and Orbits is justified when investigating patients with optic neuritis. Imaging the C-spine is justified in some circumstances. Our study shows that due to the low yield, MRI Thoracic spine is not justified in most cases. Requesting MRI T-Spine in most cases leads to unnecessary investigation and associated delay in patient flow and associated costs. We recommend that protocols should be in place to ensure MRI T-spine is only requested in very specific cases, upon discussion with senior neurologists.

S3B-SPNR-14 Enlarged Choroid Plexus Related with Whole Brain Atrophy in Multiple Sclerosis

Participants
Xiao Chen, MS,MS, Chongqing, China (*Presenter*) Nothing to Disclose

PURPOSE

This study aims to investigate the alteration of choroid plexus volume and whole brain morphology in patients with MS and neuromyelitis optica spectrum diseases (NMOSD).

METHODS AND MATERIALS

Fifty-one patients with MS, 42 patients with NMOSD and 56 healthy controls (HC) were recruited, of which 25 patients with MS and 20 patients with NMOSD were followed up. T2 FLAIR, 3DT1 image data and related clinical data were collected. The morphological changes of choroid plexus and whole brain tissue (ventricular system volume, sulcus cortex thickness, gyrus cortex thickness and deep gray matter volume) were compared between three groups and the correlation between choroid plexus volume and brain atrophy were further investigated.

RESULTS

Compared with the HC group, the volume of choroid plexus was increased in the MS group ($P<0.001$), but not in the NMOSD group. The MS group showed the whole-brain atrophy (increased ventricle system volume, reduced cortex thickness and deep gray matter volume) and the distribution of cortical atrophy in the sulcus area (61%, 41/67) was greater than that in the gyrus area (43%, 29/67). The NMOSD group showed mild brain atrophy related with increased third ventricle volume and decreased deep gray matter volume. In MS group ($P<0.05$, $r=-0.292$~-0.538) and NMOSD group ($P<0.05$, $r=-0.325$~-0.572), there were widespread correlations between choroid plexus volume and cerebral cortex thickness.In MS, compared with the baseline, the right nucleus accumbens and total deep gray matter brain volume were decreased ($P<0.001$), and bilateral lateral ventricle volume were increased ($P<0.001$) in follow-up. There was no significant alteration between baseline and follow-up in the NMOSD group.

CONCLUSION

s MS patients show enlarged choroid plexus related with whole brain atrophy, while the NMOSD patients show local brain atrophy. In the short-term follow-up, the brain atrophy in MS patients was gradually aggravated, and there was no obvious alteration in NMOSD patients.

CLINICAL RELEVANCE/APPLICATION

A combined MRI and PET study showed that the increased choroid plexus tissue was significantly positively correlated with the expression of inflammatory factors, indicating that the mechanism based on the choroid plexus blood-cerebrospinal fluid barrier may play an important role in MS. The choroid plexus blood-cerebrospinal fluid barrier comprises a single layer of choroid plexus epithelial cells, which separates blood-borne substances from cerebrospinal fluid. Therefore, the choroid plexus blood-cerebrospinal fluid barrier may also play an important role in maintaining the stability of the brain environment.

S3B-SPNR-15 Safety and Effectiveness of First-line Endovascular Management of Low-Grade Brain Arteriovenous Malformations: A Single Center Experience in 145 Patients

Participants
Maichael MEKHAIL, (*Presenter*) Nothing to Disclose

PURPOSE

Spetzler-Martin grade (SMG) I-II (low-grade) brain arteriovenous malformations (BAVMs) are often considered safe for microsurgical resection. However, the role of endovascular treatment (EVT) remains to be clarified in this indication, especially for unruptured BAVMs. The purpose of our study was to assess the safety and effectiveness of endovascular treatment as the first-line therapy for low-grade BAVMs.

METHODS AND MATERIALS

From our local database, we retrospectively retrieved patients with low-grade BAVMs, either ruptured or unruptured, treated by embolization as first-line therapy in our department between January 2005 and January 2020. The primary endpoint was the total obliteration rate of BAVMs, and secondary endpoints were hemorrhagic complications, final clinical outcome, assessed through shift of the modified Rankin Scale, and mortality rate secondary to BAVM embolization.

RESULTS

One hundred-forty-five patients meeting inclusion criteria and treated by EVT as first-line therapy were included in the study (82 ruptured and 63 unruptured BAVMs). Overall, complete exclusion of BAVMs was achieved in 110 patients (75.9%); 58 patients (70.7%) among ruptured BAVMs and 52 (82.5%) among unruptured ones, including 37.9% BAVMs excluded by EVT alone (35.5%

among ruptured BAVMs and 44.4% among unruptured ones) and 38% by combined treatment (EVT and surgery or EVT and SRS). There was no BAVM volume cut-off predictive for total obliteration by embolization alone. Early minor hemorrhagic complications were reported in 14 patients (9.6%) and early major hemorrhagic complications were reported in 5 patients (3.4%). No late hemorrhagic complications (0%) occurred; mortality rate was 0.7% (1/145 patients). Improved /unchanged mRS was reported in 137 patients (94.5%).

CONCLUSION

s Endovascular treatment, alone or associated with others exclusion techniques, might be safe and effective for complete exclusion of low-grade brain arteriovenous malformations regardless of their volumes.

CLINICAL RELEVANCE/APPLICATION

KEY WORDS Brain arteriovenous malformations, Endovascular treatment, Surgery, Pressure cooker technique.

S3B-SPNR-16 Variations in Temperature Changes with SAR, B1+rms and Pulse Sequence: A Need for Caution?

Participants
David Gultekin, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

The applications of high field magnetic resonance imaging (MRI) are limited partly by considerations of radiofrequency (RF) safety and the design of RF systems. A current dilemma in moderate to high field MRI (3T to 9.4T) is how to optimize image quality and productivity while maintaining safety. Often one may be improved at the expense of other factors. There is growing interest in assessing the utility of temperature (T) and time (t) diagrams (T-t), specific absorption rate (SAR) and RF field (B1+rms) to monitor RF absorption and thermal hazards in tissues especially in the presence of conductive implants.

METHODS AND MATERIALS

A phantom consisting of a conductive metallic wire in a tissue equivalent gel is used in this study. Any conductive wire such as a lead used for deep brain stimulation (DBS) with four electrodes or a half wavelength (l/2) copper (Cu) or titanium (Ti) wires can be used as probes for monitoring the effects of RF using fiber optic temperature probes. Standard imaging sequences (functional, morphological, diffusion and perfusion) were implemented on a 3T Siemens Prisma MRI with a TEM RF transmit body coil interfaced with a 43.2 kW peak power transmitter amplifier and a 64-channel head and neck coil (64-H/N) for receiving the RF signals.

RESULTS

The T-t diagrams can be used to assess different protocols for the scenario of slow imaging, allowing for cooling time between sequences, and of fast imaging, without allowing for cooling times. T-t diagrams were acquired for pairs of sequences with the same SAR and B1+rms but different RF exposure times (NA), different SAR, B1+rms and exposure time, and different SAR, B1+rms but the same exposure time. The functional, morphological, diffusion and perfusion MRI sequences show the utility of the each of T-t diagrams, B1+rms and SAR. The integration of T-t diagrams for the slow and fast imaging segments of the same fMRI series shows the conservation of thermal dose in two scenarios.

CONCLUSION

s We show that T-t diagrams provide additional important information about thermal effects of RF heating that SAR and B1+rms alone cannot provide. By keeping SAR and B1+rms the same but increasing NA increases exposure time resulting in a substantially higher temperature rise with time. A practical method involving temperature and time diagrams can be used to evaluate, compare and optimize various imaging protocols to ensure patient safety.

CLINICAL RELEVANCE/APPLICATION

This method can further be developed to scan patients with implants safely.

S3B-SPNR-17 Dual-layer Detector Cone-beam CT Angiography Improves Intracranial Vessel Conspicuity and Reduces Artifacts

Participants
Fredrik Stahl, MD, (*Presenter*) Fredrik Ståhl has received reimbursements for conference travel expenses from Philips in 2022

PURPOSE

To evaluate whether a dual-layer detector cone-beam CT prototype improves image quality in stroke patients, compared to reference standard single layer detector cone-beam CT angiography.

METHODS AND MATERIALS

A prospective single center clinical trial (NCT04571099) enrolled consecutive patients, 50 years or older with ischemic or hemorrhagic stroke. Patients were subsequently imaged with the prototype system following an intravenous contrast media injection. Single layer (Front layer, FL) and 70 keV virtual monoenergetic images (VMI) derived from both detector layers were reconstructed and evaluated in a single-sequence two-period crossover design by two blinded neuroradiologists. Sixteen intracranial arterial segments were evaluated for vessel conspicuity and artifact presence on 5-point Likert scales (5: highest vessel conspicuity or fewest artifacts). The Wilcoxon matched-pairs signed-rank test was performed to determine significance ($p<0.05$), with Bonferroni correction for multiple tests.

RESULTS

28 patients were enrolled. The median conspicuity of the sixteen FL and VMI arterial vessel segments for each patient was 3.5 (IQR 2-4) and 4 (IQR 3-5), $p<0.001$. The median artifact ratings for FL and VMI were 3 (IQR 2-4) and 4 (IQR 3-5), $p<0.001$. For individual segments the VMI showed superior conspicuity for the Basilar, SCA, M4- and P1- segment ($p<0.001$), as well as the P2- and M3- segment ($p<0.01$). The P1-segment ($p<0.001$) and Basilar, SCA, M1-, M3-, M4-, P2-, A1- and A2-segment ($p<0.01$) had a significantly lower degree of artifacts in VMI compared to FL.

CONCLUSION

s Dual-layer detector cone-beam CT virtual monoenergetic images improves intracranial vessel conspicuity and reduces artifacts

s Dual-layer detector cone-beam CT virtual monoenergetic images improves intracranial vessel conspicuity and reduces artifacts compared to reference standard single layer detector cone-beam CT angiography.

CLINICAL RELEVANCE/APPLICATION

Cone-beam CT angiography is increasingly used in the primary diagnostic work-up of suspected ischemic stroke, and could be an alternative to CT angiography to shorten door to thrombectomy time. Our findings indicate that dual-layer detector cone-beam CT angiography improves intracranial image quality over standard single-layer cone-beam CT angiography.

S3B-SPNR-18 Efficacy and Safety of Endovascular Trans-venous Embolization of Cerebrospinal Fluid-venous Fistulas Associated with Spontaneous Intracranial Hypotension

Participants
Donna Parizadeh, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To independently evaluate the efficacy and safety of endovascular transvenous embolization for treatment of patients with spontaneous intracranial hypotension (SIH) secondary to CSF-venous fistulas (CVF).

METHODS AND MATERIALS

We performed a retrospective review of a prospectively maintained database of patients with 1) clinical diagnosis of SIH and 2) definitive diagnosis of CVF on either lateral decubitus digital subtraction myelogram or CT myelogram who underwent 3) transvenous embolization for treatment of CVF at our institute between Dec. 2020 to Apr. 2022. To evaluate efficacy of the procedure, we assessed pre- and 3-month post-embolization clinical and imaging outcomes including Headache Impact Test (HIT-6) and Patient Global Impression of Change (PGIC) scores, and the Bern SIH score on brain MRI. Procedural and post-procedural complications were recorded. Post-embolization change in measures was assessed with Wilcoxon Signed rank test.

RESULTS

A total of 19 patients, median (IQR) age 60 (49-65) years, 74% female, underwent transvenous embolization. At 3-month follow-up, 18/19 (95%) of patients reported having either much or very much improved symptoms on PGIC. Follow-up HIT-6 and imaging were available for 18 and 15 patients, respectively. Among these patients, headache improved significantly from a median (IQR) HIT-6 score of 68 (58-72) pre-embolization to 36 (36-38) post-embolization ($p = 0.001$). Bern SIH score improved significantly from median (IQR) of 8 (6-8) pre-embolization to 2 (1-3) post-embolization ($p = 0.001$). One (5%) patient did not have improvement of clinical or imaging findings consistent with a treatment failure. There were no neurovascular complications. Side effects were localized back pain (84%) and rebound headache (74%) which resolved within one month with medical treatment in all cases.

CONCLUSION

s Transvenous embolization is a highly efficacious and safe treatment for CVF in SIH patients.

CLINICAL RELEVANCE/APPLICATION

Transvenous embolization is emerging as a novel highly efficacious, safe, and minimally invasive treatment for patients with spontaneous intracranial hypotension secondary to CSF-venous fistula.

S3B-SPNR-19 Clinical and Imaging Outcomes of Percutaneous Sclerotherapy for Venous Malformations Affecting the Eye and Orbit

Participants
Tushar Garg, MD, Baltimore, MD (*Presenter*) Conference Travel, Siemens Healthineers

PURPOSE

Sclerotherapy treatment can be used for patients with venous malformations (VMs) affecting the eye and orbit region. This study evaluates the safety and outcomes of these interventions.

METHODS AND MATERIALS

All patients who received sclerotherapy for VMs involving the eye and orbit between 12/2005 to 6/2021 were reviewed. The clinical and imaging findings of these patients were assessed. Clinical symptoms response was classified as resolved, improved and stable, or worsened. Differences between pre-and post-procedure MRI of the largest lesion diameter in one plane were used to calculate changes in VM size, similar to the response evaluation criteria in solid tumors: complete response (100% reduction), partial response (30% reduction), stable disease (=30% reduction or =20% enlargement), progressive disease (=20% VM size increase) worse. SIR classification criteria were used to classify adverse events. Clinical response, lesion size changes, and complication rates were evaluated. Fisher's Exact Test- was used for statistical analysis.

RESULTS

13 patients (53.8% F) underwent a total of 32 embolization procedures with an average follow up period of 1344.5 days. The most common presenting symptoms were enlargement (6,46.2%) and functional deficit (6, 46.2%). Other common complications included pain (5; 38.5%), mass (4; 30.8%), cosmetic deformity (3; 23.1%), discoloration (3; 23.1%), bleeding/ discharge (1; 7.7%) or other (1, 7.7%). Patients had an average of 2.46 (med: 2) procedures with a technical success rate of 100% (32/32). Embolization did not significantly decrease VM size on imaging ($p=0.4762$). 11 patients (11/13; 84.6%) had both pre- and post- MRI imaging measurements. Of these, zero patients saw complete response, 2 patients (18.2%) experienced partial response, 6 patients (54.5%) experienced no change in VM size, and 3 patients (27.3%) saw increased VM size. There was only one (3.1%) incident of early (30 days) post-procedural complications (delayed extubation) among a total of 32 procedures. The most common sclerosants used were bleomycin foam (8, 25.0%) and sotradecol (8, 25%). This was followed by ethanol (4, 12.5%), n-BCA (4, 12.5%), onyx (2, 6.3%) and coils (1, 3.1%). Some procedures used more than one agent. Sclerotherapy significantly improved clinical symptoms with 7.7% (1/13) resolved, 30.8% (4/13) improved, and 61.5% (8/13) stable or worsened ($p = 0.0391$).

CONCLUSION

s This study shows that sclerotherapy of venous malformations within the eye and orbit is a safe and effective treatment.

CLINICAL RELEVANCE/APPLICATION

The results of this study showed that sclerotherapy can be used for the management of VMs involving the eye and orbit without the need for more invasive surgical management.

S3B-SPNR-20 Percutaneous Sclerotherapy for Superficial Venous Malformations Involving the Tongue: Clinical and Imaging Outcomes

Participants
Anna Gong, Baltimore, MD (*Presenter*) Nothing to Disclose

PURPOSE

To assess the safety and effectiveness of percutaneous sclerotherapy (PS) of venous malformations (VMs) involving the tongue.

METHODS AND MATERIALS

Between 7/2004 and 8/2021, we reviewed all patients who received PS for VMs of the tongue. Clinical response, lesion size changes, and complication rates were evaluated using clinical and imaging results. The type of sclerosant was used to sub-stratify analysis. For statistical analysis, Fisher's Exact Tests were applied. The severity of clinical symptoms was graded as resolved, improved, and stable/worsened. The difference between pre and post procedure MRI of the largest lesion diameter in one plane was used to calculate VM size change, similar to the response evaluation criteria in solid tumors: complete response (CR, 100% reduction), partial response (PR, 30% reduction), stable disease (SD, =30% reduction or =20% enlargement), progressive disease (PD, =20% VM enlargement) worse. Adverse events were scored using SIR classification criteria.

RESULTS

A total of 58 embolization procedures were performed in 26 patients (80.8% F), with a mean follow-up duration of 975 days. Pain (14, 24.1 %), enlargement (12, 20.7%), difficulty with mastication (7, 12.1%), difficulty with speaking (7, 12.1%), and difficulty swallowing (7, 12.1 %) were the most prevalent presenting complaints. Patients underwent a median of 3 procedures (range:1-6) with a 100% technical success rate. Bleomycin foam (51, 64.5%) was the most commonly deployed sclerosant, followed by ethanol (26, 32.9%), and sotradecol foam (14, 17.7%), with some procedures using multiple agents. Sclerotherapy significantly improved clinical symptoms with 15.4% resolved (4, 15.4%), 53.8% improved (14, 53.8), and (8,30.8%) stable or worsened ($p < 0.0001$). On imaging, embolization demonstrated significant reduction in lesion size ($p=0.0184$). Of the 17 (65.4%) patients who had both pre and post MR measurements, 0 patients had a complete response, 6 patients (35.3%) showed a PR, 11 patients (64.7%) showed no change in VM size, and 0 patients showed increased VM size. Early (30 day) post-procedural complications occurred after 3 of 58 procedures (5.2 %), the majority of which were skin burns.

CONCLUSION

s Percutaneous sclerotherapy significantly decreases lesion size and improves clinical symptoms of VMs involving the tongue.

CLINICAL RELEVANCE/APPLICATION

Percutaneous, image-guide sclerotherapy is a safe and effective treatment for low-flow, venous malformations involving tongue.

S3B-SPNR-3 Alterations of Cerebral Perfusion and Functional Connectivity in Children with Idiopathic Generalized Epilepsy

Participants
Guiqin Chen, (*Presenter*) Nothing to Disclose

PURPOSE

Previous studies have demonstrated that adults with idiopathic generalized epilepsy (IGE) have functional abnormalities,however, the neuropathological pathogenesis differs between adults and children. This study aimed to explore the alterations of cerebral blood flow (CBF) and functional connectivity (FC) simultaneously to comprehensively understand the neuropathological mechanisms of IGE in children.

METHODS AND MATERIALS

Arterial spin labeling (ASL) and blood oxygenation level-dependent magnetic resonance imaging data were acquired for 28 patients with IGE and 35 matched healthy controls (Table 1). Using ASL perfusion, we identified several regions of altered CBF in patients with IGE. Seed-based whole-brain FC analysis was then performed on regions with significant CBF changes. Multiple comparisons were corrected using a voxel-wise Gaussian random field method ($P < 0.05$, two tailed). The mean CBF and FC of each cluster with significant group differences were extracted and correlated with the clinical variables in the IGE group using Pearson's correlation analysis.

RESULTS

Compared to controls, patients with IGE showed abnormalities in CBF, mainly located in the right middle temporal gyrus, right middle occipital gyrus (MOG), right superior frontal gyrus (SFG), and left inferior frontal gyrus, triangular part (IFGtriang) (Table 2, Figure 1). Based on these four regions, we constituted the whole-brain FC and observed that the FC between the left IFGtriang and calcarine fissure (CAL) was decreased, (Figure 2A) and the FC between the right MOG and bilateral CAL was decreased (Figure 2B). Correlation analyses indicated that hyperperfusion in the right SFG was correlated with IGE age of onset($r=-3.81$, $P=0.045$) (Figure 3A), and decreased connectivity in the left CAL was correlated with the IGE patient's duration($r=-4.20$, $P=0.026$) (Figure 3B).

CONCLUSION

s The study findings suggest simultaneous alterations in both CBF and FC in the left IFGtriang and right MOG in children with IGE by combining ASL and rs-fMRI,and the abnormal brain area is associated with duration.

CLINICAL RELEVANCE/APPLICATION

The combination of CBF and FC not only describe and track the progress of the disease, provide imaging basis for early diagnosis of IGE, but also can provide complementary information and comprehensive insights into the pathophysiology of IGE from the perspective of neuronal and vascular integration.

S3B-SPNR-4 Bitmap 3D Printing of Multimodal Imaging for Epilepsy Surgery

Participants
Nicholas Jacobson, (*Presenter*) Nothing to Disclose

PURPOSE

Surgical Planning for epilepsy requires the sequential review of multiple volumetric and vector-based datasets. This data is viewed sequentially on a 2D screen, requiring significant visuospatial memory to composite and spatially reconstruct. The presurgical data review process has thus become increasingly inefficient and does not provide a holistic visualization of the data. This worrisome trajectory ignores the biggest promise of the information revolution: increased communication, connectivity, and interoperability. This cognitive load can be reduced by combing multimodal volumetric images with a 3D printed model. We present a method for creating a presurgical planning model that combines T1 MRI, CT SEEG data, tractography, and fMRI from pediatric epilepsy patients. The purpose is to reduce the cognitive load on surgeons and facilitate focused communication between the entire epilepsy team.

METHODS AND MATERIALS

16 bit image data, CT/MRI/fMRI, is mapped to color and opacity material mixing ratios corresponding to DICOM intensity values. 256 bit vector field data, Tractography/SEEG activation, is composted onto the image data in 3D voxel space. The composted multimodal 3D model is sliced for 3D printing in a voxel-based modeling program. The bitmap slices are printed at the spatial resolution of the images in a multi-material polyjet 3D printer. The model is reviewed during surgical conferences and used during a procedure in a clinical study (n=15).

RESULTS

Our method embeds vector-based features, representing dynamic physiology, within image-based models that represent gradients in biological tissue. The results leverage color-encoded data, displaying composited MRI, CT SEEG probes and activation, DWI tractography, and fMRI information. The models were used in discussion during case conferences and surgery. Preliminary survey results indicate increased spatial understanding and confidence in the surgical approach.

CONCLUSION

s We show that a variety of computationally derived physiologic datasets found in medical imaging can be directly 3D printed for neurosurgical epilepsy interventions. The relationships between data visualization, computer science, digital fabrication, and medicine are fostering an information revolution with the potential for increased communication, connectivity, and interoperability of data, bringing form and function together to improve health.

CLINICAL RELEVANCE/APPLICATION

The multimodal models unify and express more of the ever-increasing amount of data in surgical planning. The models are developing a platform that can be extended to study disease states that require information from multiple modalities of images.

S3B-SPNR-5 Clinical Significance of Hippocampal Asymmetry as a Sole Imaging Finding in Patients with Seizure

Participants
Hasan Azeem Khan, MD, Galveston, WV (*Presenter*) Nothing to Disclose

PURPOSE

Hippocampal volume loss on MRI (Magnetic Resonance Imaging) is described as potential source or sequelae of seizure. Since the introduction of post processing automated volumetric techniques, there has been a reliable and objective method to assess hippocampus volume. Hippocampal asymmetry in the context of normal volume of individual hippocampi is an uncommon finding observed on volumetric studies of brain MRI performed for evaluation of seizure. The clinical significance and correlation of hippocampal asymmetry with seizures and EEG findings are lacking. We set out to create a study that evaluates the relationship between asymmetric otherwise normal hippocampi and seizures.

METHODS AND MATERIALS

We gathered data on 49 patients from 1257 brain MRIs performed for evaluation of seizure over the past 3 years. The total 49 patients are divided into two groups. A group of 25 patients with hippocampal asymmetry diagnosed on MRI using the Neuroquant protocol and a comparison group of 24 patients with symmetrical hippocampi. This included data of left/right hippocampal volume, asymmetry index reviewed and evaluated by a fellowship-trained neuroradiologist. EEG, clinical presentation and demographic characteristics were collected from the electronic medical record.

RESULTS

A total of 49 patients who presented with seizures were included in the study. All patients had normal hippocampal volumes on NeuroQuant volumetric analysis. 10 patients had epileptiform EEG findings and 39 patients had no epileptiform changes on EEG. 25 patients (51%) had hippocampal asymmetry, considered positive for volumetric analysis, while 24 (49%) were symmetric. Of the 25 patients with asymmetry, 6 patients (12%) had epileptiform findings on EEG, considered positive for EEG changes. Of the 24 patients with symmetric hippocampal volumes, 4 (8%) had positive EEG. Overall, in this population the likelihood of hippocampal asymmetry was 51% and the likelihood of epileptiform EEG findings was 20%. A McNemar's test for correlated proportions yielded a p-value of 0.003.

CONCLUSION

s Our study suggests that there may be an association between hippocampal asymmetry and EEG changes in the setting of otherwise normal-appearing hippocampi of normal volume. This could be considered an additional parameter in the assessment of patients with seizures.

CLINICAL RELEVANCE/APPLICATION

This finding should prompt follow-up imaging to assess the trajectory of the volume loss, which might have implications on patients' management and prognosis.

S3B-SPNR-6 Seed-to-Voxel Analysis of Resting-State fMRI Can Detect Functional Alterations in Seizure Onset and Spread Regions in Patients with Non-Lesional Temporal Lobe Epilepsy

Participants
India Shelley, BA, Philadelphia, PA (*Presenter*) Nothing to Disclose

PURPOSE

Temporal lobe epilepsy (TLE) can have severe clinical signs and symptoms. Abnormal neural seizure networks from underlying pathology may facilitate seizure spread and be involved in the manifestation of symptoms in TLE. Currently, stereotactic electroencephalography (sEEG) can detect correlations between zones of seizure onset (OZ) and early (ESZ) and late (LSZ) spread. We examined whether patient resting-state fMRI (rsfMRI) scans can detect similar correlations between the OZ, ESZ, and LSZ. We aimed to see whether noninvasive imaging techniques can uncover patterns of seizure spread to potentially demarcate areas for intervention.

METHODS AND MATERIALS

This is a retrospective study of 8 patients with refractory, non-lesional TLE (ages 25-53) and 10 controls (ages 22-35). The TLE patients were MRI- on routine diagnostics and subsequently received sEEG. The OZ, ESZ, and LSZ were calculated by generating regions around sEEG contacts that recorded seizure activity. The LSZ was only available for 3 patients. These regions and functional images were registered to MNI space using MIRTK. For each subject, we used dual regression to detect amplitude synchronization of the OZ with the rest of the brain and calculated the ratio of correlated voxels to the spread zone. The same process was done using the OZ, ESZ, and LSZ of each TLE patient for each control. TLE patients were compared to controls individually using a Wilcoxon test and as a group using a Student's t-test, alpha = 0.05. The average BOLD signal over the time series was calculated in the onset and spread regions and compared using z-score analysis and a Student's t-test, alpha = 0.05.

RESULTS

5/8 TLE patients showed decreased correlations from the OZ to the ESZ compared to controls. Only 1 TLE patient showed an increased correlation. 2/3 TLE patients showed decreased correlations between the OZ and LSZ. Group analysis showed TLE patients had lower overall connectivity with the ESZ compared to controls. TLE patients had higher average BOLD signal in the OZ and ESZ but not LSZ.

CONCLUSION

s TLE patients show decreased functional connectivity from the OZ to both ESZ and LSZ. TLE patients showed higher neuronal activity in the OZ and ESZ. These results indicate TLE patients show high levels of pathologic seizure activity but dysfunctional connections in seizure-related areas. Seed-to-voxel analysis of rsfMRI can detect functional network disruption that may expose pathophysiology underlying seizure propagation.

CLINICAL RELEVANCE/APPLICATION

fMRI analysis is a promising noninvasive method to detect correlated brain regions that may be involved in seizure propagation. It can explore underlying pathology and understanding of the disease.

S3B-SPNR-7 Automated Subfield Volumetric Analysis of Amygdala, Hippocampus, and Thalamic Nuclei in Mesial Temporal Lobe Epilepsy

Participants
India Shelley, BA, Philadelphia, PA (*Presenter*) Nothing to Disclose

PURPOSE

Identifying relationships between clinical features and quantitative characteristics of the amygdala-hippocampal and thalamic subregions in mesial temporal lobe epilepsy (mTLE) may offer insights into pathophysiology and the basis for imaging prognostic markers of treatment outcome.

METHODS AND MATERIALS

27 mTLE subjects with mesial temporal sclerosis (MTS) were scanned for conventional 3D T1w MPRAGE image and T2w scans. With respect to 12 months post-surgical seizure outcomes, 15 subjects reported seizure free and 12 had seizures. We performed quantitative automated segmentation and cortical parcellation using Freesurfer. Automatic labeling and volume estimation of hippocampal subfields, amygdala, and thalamic subnuclei were performed. Volume ratio (VR) for each label was computed and compared using linear regression analysis with significant FDR corrected p-value of <0.05. Additionally, we used age, sex, existence of tonic-clonic, age of seizure onset, and seizure class as confounding variables.

RESULTS

Amygdala: In the amygdala, the medial nucleus was the most significantly reduced in patients who were not seizure free when compared to patients who remained seizure free. Hippocampus: Comparison of volumes ipsilateral and contralateral with seizure outcomes showed volume loss was most noted in mesial hippocampal regions such as CA4 and hippocampal fissure. Volume loss was also most reduced in the presubiculum body in patients who were not seizure free at follow-up. Thalamus: VPL and PuL were the most significantly reduced thalamic nuclei in non-seizure free patients.In all statistically significant areas, volume reduction has been observed in the non-seizure free group.

CONCLUSION

s We demonstrated varying degrees of volume loss in the hippocampus, thalamus, and amygdala subregions of MTS, especially between patients who remained seizure-free and those who did not. These results can be used to further understand mTLE pathophysiology.

CLINICAL RELEVANCE/APPLICATION

In the future, we hope these results can be used to deepen the understanding of mTLE pathophysiology, leading to improved patient outcomes and treatments.

S3B-SPNR-8 Comparison of Functionally Versus Structurally-defined Nodes for Evaluation of DTI Connectome Edge Density (ED) in Infants with Autism Spectrum Disorder (ASD)

Participants
Clara Weber, New Haven, CT (*Presenter*) Nothing to Disclose

PURPOSE

In our previous study, conventional DTI metrics and connectome ED based on structurally-defined nodes found significant ASD-related changes among adolescents and adults, but not pediatric cohorts. Here, we analyzed infants at risk of ASD and adults, to evaluate connectome ED based on tractography between functionally defined nodes that showed correlation with from ASD severity in a separate cohort.

METHODS AND MATERIALS

We retrieved DTI from n=155 infants (Longitudinal MRI study of infants at Risk for Autism; median age at scan 7 months, ASD assessment at 24m) and n = 96 adults (Atypical Late Neurodevelopment in Autism, median age 230m) from the National Database of Autism Research. Lake et al. (Biol Psychiatry 2019;86(4):315-26) have previously identified cerebral regions (nodes) that showed significant positive, and respectively negative, functional correlation with symptom severity as measured by ADOS (Autism Diagnostic Observation Schedule) scores based on rs-fMRI from n=260 children. We subset these regions in two sensitivity levels and subsequently specified them as seed points in probabilistic tractography to generate ED maps. For statistical analysis, mean ED values within the JHU White Matter (WM) Labels atlas tracts were extracted.

RESULTS

ED within major WM tracts shows pervasive correlation with ASD diagnosis (Figure 1) in both infants and adults. While present both for ED generated based on positively and negatively correlated cortical regions, positively correlated regions showed more widespread ASD-related changes. Comparing correlation coefficients between different sensitivity levels revealed that ED based on more sensitive nodes shows stronger correlation to ASD diagnosis than ED constructed from less sensitive nodes.

CONCLUSION

s While tractography ED based on structural nodes could only find ASD-related differences in adults' cohort (but not infants), we showed that constructing ED based on functionally defined nodes could identify ASD-related changes in both infants' and adults' cohorts.

CLINICAL RELEVANCE/APPLICATION

As alterations could only be detected in adolescent and adult cohorts in anatomy-based ED, our results imply benefits of combining functional and diffusion-weighted imaging for construction of connectome ED, especially in pediatric populations.

S3B-SPNR-9 Temporal Encephaloceles and Drug Resistant Epilepsy: Is There Radiological Correlation with The Epileptogenic Focus?

Participants
Aleix Jareno Badenas, MD, Sant Vicenc de Castellet, Spain (*Presenter*) Nothing to Disclose

PURPOSE

Encephaloceles are protrusions of cerebral tissue through a skull defect. They are a possible cause of epilepsy, although their actual epileptogenic potential has not been assessed yet. Lately, with the improvement of MRI imaging, the identification of encephaloceles in patients with drug resistant epilepsy (DRE) has increased. The purposes of this study are: To correlate the location of encephaloceles with the epileptogenic focus in patients with DRE. To evaluate their characteristics and to correlate them with their epileptogenicity.

METHODS AND MATERIALS

We performed a retrospective analysis of the MRI and neurofunctional studies of patients of our epilepsy unit with DRE and an MRI diagnosis of encephalocele. We evaluated the correlation between the encephalocele's location and the epileptogenic focus, as well as their characteristics (number, location, size and presence of gliosis). The location and characteristics of the encephaloceles were evaluated in the 3T MRI studies with a specific epilepsy protocol. The epileptogenic focus was evaluated in our epilepsy unit after the evaluation of different neurofunctional techniques (video-EEG, PET/SPECT and SEEG).

RESULTS

We had a study population of 11 patients (7 women and 4 men) with a mean age of 24.6 years. Six (55%) patients had correlation between the epileptogenic focus and the location of the encephalocele, whilst in the other 5 (45%) they were not matching. 67% of the patients with correlation showed gliosis and a mean encephaloceles volume of 0.25cc, while 40% of patients without correlation presented gliosis and a mean volume of 0.33cc.

CONCLUSION

s Our results show that encephaloceles have to be considered as potentially epileptogenic lesions in patients with DRE. Gliosis may be an indicator of higher epileptogenicity. In our group of patients, the smaller encephaloceles were more epileptogenic, which is inconsistent with previous literature.

CLINICAL RELEVANCE/APPLICATION

Our study shows that encephaloceles have epileptogenic potential and that some characteristics, such as the gliosis, may help to assess their epileptogenic potential.

S3B-SPNR-1

Volume and Permeability of White Matter Hyperintensity on Cognition: A DCE Imaging study in A Prospective Elderly Cohort

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Hyeongwoo Kim, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

We aimed to evaluate the relationship between volume, permeability, and the effect of white matter pathology on cognition in elderly patients with mild to moderate WMH from a prospective elderly cohort.

METHODS AND MATERIALS

In this IRB-approved retrospective analysis of the prospective study, written informed consent was obtained from all participants. We selected 193 elderly participants of the age range (55-80 years) with minimal-to-moderate WMH from a prospective DCE MRI cohort (n=259) with normal and impaired cognition between August 2017 and June 2021. Periventricular WMH (PWMH), deep WMH (DWMH), and normal-appearing white matter (NAWM) were automatically segmented using a 3D T1-weighted sequence. Volume transfer constant [Ktrans] as BBB permeability was determined using DCE MRI. The effects of Ktrans of WMH and NAWM were evaluated using multivariable linear regression adjusted for demographic and volume measures.

RESULTS

and volume measures. 193 participants (age, 70.1±6.8 years; 128 women) include 44 with CDR=0, 119 with CDR=0.5, and 30 with CDR=1.0. The degree of WMH was minimal (n=87) and moderate (n=106).Higher Ktrans was observed in PWMH (0.598 ±0.509 x10-3 min-1) compared to DWMH (0.496 ± 0.478 x10-3min-1) and NAWM (0.476 ± 0.398 x10-3min-1) ($p<0.001$). The strong negative correlation between Ktrans and the volume was noted in PWMH (rho=-0.357, $p<0.001$) and DWMH (rho = -0.200, $p=0.005$), but not in NAWM (rho = 0.053, $p=0.460$).After adjusting for age, sex, APOE4, education, cortex volume, PWMH volume (B =-0.0008, SE = 0.0002, beta = -0.363, $p <0.001$) and history of cardiovascular disease (B = 0.0066., SE = 0.0028, beta = 0.229, $p <0.021$) were predictive factors for Ktrans of PWMH ($R2=0.191$, $F(2, 86) = 10.153$, $p<0.001$). After adjusting for covariates, only history of cardiovascular disease was the predictor for Ktrans of NAWM ($R2=0.036$, $F(1,153) =5.740$, $p<0.018$).After adjusting covariates (age, sex, and APOE4 status), hippocampal volume ($p<0.001$), and PWMH volume (along with education level were independent predictors of worse cognition (CDR-SB = 3), whereas cortex volume and Ktrans of PWMH were not.

CONCLUSION

s We found higher permeability of PWMH compared to DWMH and NAWM and a negative relationship between its permeability and volume. The volume of PWMH is the predictor of worse cognition in elderly individuals. Further, our finding suggests that WMH permeability and WMH volume change may be independent events.

CLINICAL RELEVANCE/APPLICATION

Our findings suggest the different underlying pathophysiology of PWMH and DWMH. In addition, the volume of PWMH predicts worse cognition in elderly individuals.

S3B-SPNR-10

Assessment of White Matter Lesion Volume and Disability in Neuromyelitis Optica Spectrum Disorder

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Jitlada Kusol, MD, Bangkok Noi, Thailand (*Presenter*) Nothing to Disclose

PURPOSE

Neuromyelitis optica spectrum disorder (NMOSD) is an aquaporin-4 (AQP4) antibody-mediated disease, affecting the white matter (WM). However, how burden of WM correlates to outcome is yet to be studied. The purposes of this study were to measure white matter lesion volume (WMLV) at locations with high AQP4 expression and to study its association to disability and disease progression.

METHODS AND MATERIALS

Retrospective review of 32 NMOSD patients who underwent two consecutive brain MRI scans with = 1-year interval were performed. Patients were categorized into low EDSS group (EDSS=3, n =15) and high EDSS group (EDSS=3.5, n=17). Disease progression (sustained increase in EDSS) was also significant parameter. WMLV were measured and categorized into five locations (diencephalic, dorsal brainstem, callosal/periventricular, hemispheric WM and corticospinal tract). Changes in WMLV in aforementioned locations were also defined.

RESULTS

WMLV was significantly larger in the high EDSS group at the callosal/periventricular, hemispheric WM and corticospinal tract ($p<0.001$, 0.041 and 0.025, respectively). In addition, the high EDSS group showed the lower change in the WMLV at hemispheric WM over the follow-up period ($p=0.044$). Patients with disease progression (6.3%) had higher WMLV at callosal/periventricular area than those without progression ($p=0.024$).

CONCLUSION

s Greater WMLV at callosal/periventricular, hemispheric WM and corticospinal tract related to the higher disability in NMOSD patients. In addition, higher WMLV at callosal/periventricular region may predict the development of disease progression. Our findings reflect that higher WMLV may correlate to worse clinical outcome.

CLINICAL RELEVANCE/APPLICATION

Higher WMLV in NMOSD patients may correlate to worse clinical outcome, especially at callosal/periventricular, hemispheric WM and corticospinal tract.

S3B-SPNR-11

Altered Vascular Permeability in Autoimmune Encephalitis: Region-based Evaluation with Dynamic Contrast-enhanced MRI and Automatic Whole Brain Segmentation

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Sohyun Ji, MD, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the change in permeability of brain-blood barrier (BBB) in patients with autoimmune encephalitis, as compared with the healthy control group, by using dynamic contrast enhanced MRI (DCE-MRI) and to explore its predictive value for the treatment response in the patients.

METHODS AND MATERIALS

In this retrospective study, a total of 38 patients with probable or possible autoimmune encephalitis and 15 healthy controls underwent DCE-MRI between April 2020 and May 2021. Automatic volumetric segmentation was performed on pre-/postcontrast T1-weighted images by using FreeSurfer, and encephalitis-associated brain region masks were extracted by using the software NordicICE. Ktrans maps, derived from DCE-MRI using Patlak model, were coregistered with the region-of-interest masks to calculate their mean values at the total volume of interest. The Wilcoxon rank sum test and Friedman test were used to compare Ktrans. Receiver operating characteristic curve analysis was used to assess the diagnostic performance.

RESULTS

All brain regions showed significantly increased Ktrans in the patients, as compared with the controls ($P < .05$). The right cerebral cortex (1.232 vs. 0.0003 min-1) and right nucleus accumbens (0.371 vs. 0.0002 min-1) had the largest mean difference of Ktrans between the patients and controls, followed by the right parahippocampus and right occipital lobe. The same trends were observed in each autoimmune encephalitis subtype (anti-LGI1, anti-NMDAR, and antibody-negative). No significant differences in Ktrans were found between the baseline and follow-up. Poor treatment response group had significantly higher baseline Ktrans in all brain regions ($P < .05$), as compared with good treatment response group, except for the right nucleus accumbens ($P = 0.33$) and right cerebral cortex ($P = 0.08$). At the cutoff value of 0.002 min-1, sensitivity and specificity for the prediction of treatment response were 86% and 100%, respectively for the left cerebellar cortex.

CONCLUSION

s The BBB permeability was persistently increased in all brain regions in autoimmune encephalitis patients, as compared with controls, and baseline Ktrans were higher in patients with poor treatment outcome.

CLINICAL RELEVANCE/APPLICATION

Autoimmune encephalitis patients showed increased BBB permeability in all brain regions, and the increased permeability of BBB was associated with treatment response.

A Review of The Appropriateness of Magnetic Resonance Imaging for Optic Neuritis in A Tertiary Referral Center in The West of Ireland

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Richard Farnan, BMBCh, BSc, (*Presenter*) Nothing to Disclose

PURPOSE

Optic neuritis is a clinical condition which involves inflammation of the optic nerves. It is often seen concurrently with central nervous system (CNS) demyelination and there is well known link with multiple sclerosis. [1] The purpose of this study was to evaluate the appropriateness of magnetic resonance imaging of the CNS in patients with confirmed optic neuritis.

METHODS AND MATERIALS

The study retrospectively reviewed MRI requests for patients with optic neuritis over a five-year period at University Hospital, Galway. Our institution is a tertiary referral center with neurology expertise in the west of Ireland. The study established which CNS imaging was requested by neurologists. Additionally, the final radiology reports were reviewed to establish if the imaging technique diagnosed any relevant positive findings.

RESULTS

MRI brain and Orbits was the most commonly ordered investigation with neurologists requesting this study in 89 patients. Of these, 40 patients (44.9%) showed patterns consistent with optic neuritis. MRI orbits (alone) was the second most commonly requested imaging. 45 MRI patients underwent MRI orbits with relevant changes reported in 16 (35.6%) patients. MRI C-spine was performed on 47 patients with 12 (25.5%) showing significant changes. MRI T-spine was the least common investigation ordered with 10 patients undergoing such. From these, only 1 patient (10%) showed significant change on imaging.

CONCLUSION

s The purpose of this study was to establish how much imaging of the CNS is justified in patients with optic neuritis. MRI brain and orbits were the most prevalent imaging ordered. Their role in investigating patients with optic neuritis is largely justified with changes such as plaque accumulation and demyelination patterns noted in a significant portion of patients. Of note, only 10% of patients with optic neuritis had positive findings on MRI T-spine. This raises the question of whether MRI T-spine should be included in imaging work up for optic neuritis. Strengths of this study include relatively large sample size (n= 191), 5 year timeframe and significance of the hospital site as a tertiary referral center in the west of Ireland.

CLINICAL RELEVANCE/APPLICATION

In conclusion, our study shows that MR imaging of brain and Orbits is justified when investigating patients with optic neuritis. Imaging the C-spine is justified in some circumstances. Our study shows that due to the low yield, MRI Thoracic spine is not justified in most cases. Requesting MRI T-Spine in most cases leads to unnecessary investigation and associated delay in patient flow and associated costs. We recommend that protocols should be in place to ensure MRI T-spine is only requested in very specific cases, upon discussion with senior neurologists.

Enlarged Choroid Plexus Related with Whole Brain Atrophy in Multiple Sclerosis

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Xiao Chen, MS,MS, Chongqing, China (*Presenter*) Nothing to Disclose

PURPOSE

This study aims to investigate the alteration of choroid plexus volume and whole brain morphology in patients with MS and neuromyelitis optica spectrum diseases (NMOSD).

METHODS AND MATERIALS

Fifty-one patients with MS, 42 patients with NMOSD and 56 healthy controls (HC) were recruited, of which 25 patients with MS and 20 patients with NMOSD were followed up. T2 FLAIR, 3DT1 image data and related clinical data were collected. The morphological changes of choroid plexus and whole brain tissue (ventricular system volume, sulcus cortex thickness, gyrus cortex thickness and deep gray matter volume) were compared between three groups and the correlation between choroid plexus volume and brain atrophy were further investigated.

RESULTS

Compared with the HC group, the volume of choroid plexus was increased in the MS group ($P<0.001$), but not in the NMOSD group. The MS group showed the whole-brain atrophy (increased ventricle system volume, reduced cortex thickness and deep gray matter volume) and the distribution of cortical atrophy in the sulcus area (61%, 41/67) was greater than that in the gyrus area (43%, 29/67). The NMOSD group showed mild brain atrophy related with increased third ventricle volume and decreased deep gray matter volume. In MS group ($P<0.05$, $r=-0.292\sim-0.538$) and NMOSD group ($P<0.05$, $r=-0.325\sim-0.572$), there were widespread correlations between choroid plexus volume and cerebral cortex thickness.In MS, compared with the baseline, the right nucleus accumbens and total deep gray matter brain volume were decreased ($P<0.001$), and bilateral lateral ventricle volume were increased ($P<0.001$) in follow-up. There was no significant alteration between baseline and follow-up in the NMOSD group.

CONCLUSION

s MS patients show enlarged choroid plexus related with whole brain atrophy, while the NMOSD patients show local brain atrophy. In the short-term follow-up, the brain atrophy in MS patients was gradually aggravated, and there was no obvious alteration in NMOSD patients.

CLINICAL RELEVANCE/APPLICATION

A combined MRI and PET study showed that the increased choroid plexus tissue was significantly positively correlated with the expression of inflammatory factors, indicating that the mechanism based on the choroid plexus blood-cerebrospinal fluid barrier may play an important role in MS. The choroid plexus blood-cerebrospinal fluid barrier comprises a single layer of choroid plexus epithelial cells, which separates blood-borne substances from cerebrospinal fluid. Therefore, the choroid plexus blood-cerebrospinal fluid barrier may also play an important role in maintaining the stability of the brain environment.

Safety and Effectiveness of First-line Endovascular Management of Low-Grade Brain Arteriovenous Malformations: A Single Center Experience in 145 Patients

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Maichael MEKHAIL, (*Presenter*) Nothing to Disclose

PURPOSE

Spetzler-Martin grade (SMG) I-II (low-grade) brain arteriovenous malformations (BAVMs) are often considered safe for microsurgical resection. However, the role of endovascular treatment (EVT) remains to be clarified in this indication, especially for unruptured BAVMs. The purpose of our study was to assess the safety and effectiveness of endovascular treatment as the first-line therapy for low-grade BAVMs.

METHODS AND MATERIALS

From our local database, we retrospectively retrieved patients with low-grade BAVMs, either ruptured or unruptured, treated by embolization as first-line therapy in our department between January 2005 and January 2020. The primary endpoint was the total obliteration rate of BAVMs, and secondary endpoints were hemorrhagic complications, final clinical outcome, assessed through shift of the modified Rankin Scale, and mortality rate secondary to BAVM embolization.

RESULTS

One hundred-forty-five patients meeting inclusion criteria and treated by EVT as first-line therapy were included in the study (82 ruptured and 63 unruptured BAVMs). Overall, complete exclusion of BAVMs was achieved in 110 patients (75.9%); 58 patients (70.7%) among ruptured BAVMs and 52 (82.5%) among unruptured ones, including 37.9% BAVMs excluded by EVT alone (35.5% among ruptured BAVMs and 44.4% among unruptured ones) and 38% by combined treatment (EVT and surgery or EVT and SRS). There was no BAVM volume cut-off predictive for total obliteration by embolization alone. Early minor hemorrhagic complications were reported in 14 patients (9.6%) and early major hemorrhagic complications were reported in 5 patients (3.4%). No late hemorrhagic complications (0%) occurred; mortality rate was 0.7% (1/145 patients). Improved /unchanged mRS was reported in 137 patients (94.5%).

CONCLUSION

s Endovascular treatment, alone or associated with others exclusion techniques, might be safe and effective for complete exclusion of low-grade brain arteriovenous malformations regardless of their volumes.

CLINICAL RELEVANCE/APPLICATION

KEY WORDS Brain arteriovenous malformations, Endovascular treatment, Surgery, Pressure cooker technique.

Variations in Temperature Changes with SAR, B1+rms and Pulse Sequence: A Need for Caution?

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
David Gultekin, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

The applications of high field magnetic resonance imaging (MRI) are limited partly by considerations of radiofrequency (RF) safety and the design of RF systems. A current dilemma in moderate to high field MRI (3T to 9.4T) is how to optimize image quality and productivity while maintaining safety. Often one may be improved at the expense of other factors. There is growing interest in assessing the utility of temperature (T) and time (t) diagrams (T-t), specific absorption rate (SAR) and RF field (B1+rms) to monitor RF absorption and thermal hazards in tissues especially in the presence of conductive implants.

METHODS AND MATERIALS

A phantom consisting of a conductive metallic wire in a tissue equivalent gel is used in this study. Any conductive wire such as a lead used for deep brain stimulation (DBS) with four electrodes or a half wavelength (l/2) copper (Cu) or titanium (Ti) wires can be used as probes for monitoring the effects of RF using fiber optic temperature probes. Standard imaging sequences (functional, morphological, diffusion and perfusion) were implemented on a 3T Siemens Prisma MRI with a TEM RF transmit body coil interfaced with a 43.2 kW peak power transmitter amplifier and a 64-channel head and neck coil (64-H/N) for receiving the RF signals.

RESULTS

The T-t diagrams can be used to assess different protocols for the scenario of slow imaging, allowing for cooling time between sequences, and of fast imaging, without allowing for cooling times. T-t diagrams were acquired for pairs of sequences with the same SAR and B1+rms but different RF exposure times (NA), different SAR, B1+rms and exposure time, and different SAR, B1+rms but the same exposure time. The functional, morphological, diffusion and perfusion MRI sequences show the utility of the each of T-t diagrams, B1+rms and SAR. The integration of T-t diagrams for the slow and fast imaging segments of the same fMRI series shows the conservation of thermal dose in two scenarios.

CONCLUSION

s We show that T-t diagrams provide additional important information about thermal effects of RF heating that SAR and B1+rms alone cannot provide. By keeping SAR and B1+rms the same but increasing NA increases exposure time resulting in a substantially higher temperature rise with time. A practical method involving temperature and time diagrams can be used to evaluate, compare and optimize various imaging protocols to ensure patient safety.

CLINICAL RELEVANCE/APPLICATION

This method can further be developed to scan patients with implants safely.

Dual-layer Detector Cone-beam CT Angiography Improves Intracranial Vessel Conspicuity and Reduces Artifacts

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Fredrik Stahl, MD, (*Presenter*) Fredrik Ståhl has received reimbursements for conference travel expenses from Philips in 2022

PURPOSE

To evaluate whether a dual-layer detector cone-beam CT prototype improves image quality in stroke patients, compared to reference standard single layer detector cone-beam CT angiography.

METHODS AND MATERIALS

A prospective single center clinical trial (NCT04571099) enrolled consecutive patients, 50 years or older with ischemic or hemorrhagic stroke. Patients were subsequently imaged with the prototype system following an intravenous contrast media injection. Single layer (Front layer, FL) and 70 keV virtual monoenergetic images (VMI) derived from both detector layers were reconstructed and evaluated in a single-sequence two-period crossover design by two blinded neuroradiologists. Sixteen intracranial arterial segments were evaluated for vessel conspicuity and artifact presence on 5-point Likert scales (5: highest vessel conspicuity or fewest artifacts). The Wilcoxon matched-pairs signed-rank test was performed to determine significance ($p<0.05$), with Bonferroni correction for multiple tests.

RESULTS

28 patients were enrolled. The median conspicuity of the sixteen FL and VMI arterial vessel segments for each patient was 3.5 (IQR 2-4) and 4 (IQR 3-5), $p<0.001$. The median artifact ratings for FL and VMI were 3 (IQR 2-4) and 4 (IQR 3-5), $p<0.001$. For individual segments the VMI showed superior conspicuity for the Basilar, SCA, M4- and P1- segment ($p<0.001$), as well as the P2- and M3- segment ($p<0.01$). The P1-segment ($p<0.001$) and Basilar, SCA, M1-, M3-, M4-, P2-, A1- and A2-segment ($p<0.01$) had a significantly lower degree of artifacts in VMI compared to FL.

CONCLUSION

s Dual-layer detector cone-beam CT virtual monoenergetic images improves intracranial vessel conspicuity and reduces artifacts compared to reference standard single layer detector cone-beam CT angiography.

CLINICAL RELEVANCE/APPLICATION

Cone-beam CT angiography is increasingly used in the primary diagnostic work-up of suspected ischemic stroke, and could be an alternative to CT angiography to shorten door to thrombectomy time. Our findings indicate that dual-layer detector cone-beam CT angiography improves intracranial image quality over standard single-layer cone-beam CT angiography.

S3B-SPNR-18

Efficacy and Safety of Endovascular Trans-venous Embolization of Cerebrospinal Fluid-venous Fistulas Associated with Spontaneous Intracranial Hypotension

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Donna Parizadeh, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To independently evaluate the efficacy and safety of endovascular transvenous embolization for treatment of patients with spontaneous intracranial hypotension (SIH) secondary to CSF-venous fistulas (CVF).

METHODS AND MATERIALS

We performed a retrospective review of a prospectively maintained database of patients with 1) clinical diagnosis of SIH and 2) definitive diagnosis of CVF on either lateral decubitus digital subtraction myelogram or CT myelogram who underwent 3) transvenous embolization for treatment of CVF at our institute between Dec. 2020 to Apr. 2022. To evaluate efficacy of the procedure, we assessed pre- and 3-month post-embolization clinical and imaging outcomes including Headache Impact Test (HIT-6) and Patient Global Impression of Change (PGIC) scores, and the Bern SIH score on brain MRI. Procedural and post-procedural complications were recorded. Post-embolization change in measures was assessed with Wilcoxon Signed rank test.

RESULTS

A total of 19 patients, median (IQR) age 60 (49-65) years, 74% female, underwent transvenous embolization. At 3-month follow-up, 18/19 (95%) of patients reported having either much or very much improved symptoms on PGIC. Follow-up HIT-6 and imaging were available for 18 and 15 patients, respectively. Among these patients, headache improved significantly from a median (IQR) HIT-6 score of 68 (58-72) pre-embolization to 36 (36-38) post-embolization ($p = 0.001$). Bern SIH score improved significantly from median (IQR) of 8 (6-8) pre-embolization to 2 (1-3) post-embolization ($p = 0.001$). One (5%) patient did not have improvement of clinical or imaging findings consistent with a treatment failure. There were no neurovascular complications. Side effects were localized back pain (84%) and rebound headache (74%) which resolved within one month with medical treatment in all cases.

CONCLUSION

s Transvenous embolization is a highly efficacious and safe treatment for CVF in SIH patients.

CLINICAL RELEVANCE/APPLICATION

Transvenous embolization is emerging as a novel highly efficacious, safe, and minimally invasive treatment for patients with spontaneous intracranial hypotension secondary to CSF-venous fistula.

Clinical and Imaging Outcomes of Percutaneous Sclerotherapy for Venous Malformations Affecting the Eye and Orbit

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Tushar Garg, MD, Baltimore, MD (*Presenter*) Conference Travel, Siemens Healthineers

PURPOSE

Sclerotherapy treatment can be used for patients with venous malformations (VMs) affecting the eye and orbit region. This study evaluates the safety and outcomes of these interventions.

METHODS AND MATERIALS

All patients who received sclerotherapy for VMs involving the eye and orbit between 12/2005 to 6/2021 were reviewed. The clinical and imaging findings of these patients were assessed. Clinical symptoms response was classified as resolved, improved and stable, or worsened. Differences between pre-and post-procedure MRI of the largest lesion diameter in one plane were used to calculate changes in VM size, similar to the response evaluation criteria in solid tumors: complete response (100% reduction), partial response (30% reduction), stable disease (=30% reduction or =20% enlargement), progressive disease (=20% VM size increase) worse. SIR classification criteria were used to classify adverse events. Clinical response, lesion size changes, and complication rates were evaluated. Fisher's Exact Test- was used for statistical analysis.

RESULTS

13 patients (53.8% F) underwent a total of 32 embolization procedures with an average follow up period of 1344.5 days. The most common presenting symptoms were enlargement (6,46.2%) and functional deficit (6, 46.2%). Other common complications included pain (5; 38.5%), mass (4; 30.8%), cosmetic deformity (3; 23.1%), discoloration (3; 23.1%), bleeding/ discharge (1; 7.7%) or other (1, 7.7%). Patients had an average of 2.46 (med: 2) procedures with a technical success rate of 100% (32/32). Embolization did not significantly decrease VM size on imaging (p=0.4762). 11 patients (11/13; 84.6%) had both pre- and post- MRI imaging measurements. Of these, zero patients saw complete response, 2 patients (18.2%) experienced partial response, 6 patients (54.5%) experienced no change in VM size, and 3 patients (27.3%) saw increased VM size. There was only one (3.1%) incident of early (30 days) post-procedural complications (delayed extubation) among a total of 32 procedures. The most common sclerosants used were bleomycin foam (8, 25.0%) and sotradecol (8, 25%). This was followed by ethanol (4, 12.5%), n-BCA (4, 12.5%), onyx (2, 6.3%) and coils (1, 3.1%). Some procedures used more than one agent. Sclerotherapy significantly improved clinical symptoms with 7.7% (1/13) resolved, 30.8% (4/13) improved, and 61.5% (8/13) stable or worsened (p = 0.0391).

CONCLUSION

s This study shows that sclerotherapy of venous malformations within the eye and orbit is a safe and effective treatment.

CLINICAL RELEVANCE/APPLICATION

The results of this study showed that sclerotherapy can be used for the management of VMs involving the eye and orbit without the need for more invasive surgical management.

S3B-SPNR-20

Percutaneous Sclerotherapy for Superficial Venous Malformations Involving the Tongue: Clinical and Imaging Outcomes

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Anna Gong, Baltimore, MD (*Presenter*) Nothing to Disclose

PURPOSE

To assess the safety and effectiveness of percutaneous sclerotherapy (PS) of venous malformations (VMs) involving the tongue.

METHODS AND MATERIALS

Between 7/2004 and 8/2021, we reviewed all patients who received PS for VMs of the tongue. Clinical response, lesion size changes, and complication rates were evaluated using clinical and imaging results. The type of sclerosant was used to sub-stratify analysis. For statistical analysis, Fisher's Exact Tests were applied. The severity of clinical symptoms was graded as resolved, improved, and stable/worsened. The difference between pre and post procedure MRI of the largest lesion diameter in one plane was used to calculate VM size change, similar to the response evaluation criteria in solid tumors: complete response (CR, 100% reduction), partial response (PR, 30% reduction), stable disease (SD, =30% reduction or =20% enlargement), progressive disease (PD, =20% VM enlargement) worse. Adverse events were scored using SIR classification criteria.

RESULTS

A total of 58 embolization procedures were performed in 26 patients (80.8% F), with a mean follow-up duration of 975 days. Pain (14, 24.1 %), enlargement (12, 20.7%), difficulty with mastication (7, 12.1%), difficulty with speaking (7, 12.1%), and difficulty swallowing (7, 12.1 %) were the most prevalent presenting complaints. Patients underwent a median of 3 procedures (range:1-6) with a 100% technical success rate. Bleomycin foam (51, 64.5%) was the most commonly deployed sclerosant, followed by ethanol (26, 32.9%), and sotradecol foam (14, 17.7%), with some procedures using multiple agents. Sclerotherapy significantly improved clinical symptoms with 15.4% resolved (4, 15.4%), 53.8% improved (14, 53.8), and (8,30.8%) stable or worsened ($p < 0.0001$). On imaging, embolization demonstrated significant reduction in lesion size ($p=0.0184$). Of the 17 (65.4%) patients who had both pre and post MR measurements, 0 patients had a complete response, 6 patients (35.3%) showed a PR, 11 patients (64.7%) showed no change in VM size, and 0 patients showed increased VM size. Early (30 day) post-procedural complications occurred after 3 of 58 procedures (5.2 %), the majority of which were skin burns.

CONCLUSION

s Percutaneous sclerotherapy significantly decreases lesion size and improves clinical symptoms of VMs involving the tongue.

CLINICAL RELEVANCE/APPLICATION

Percutaneous, image-guide sclerotherapy is a safe and effective treatment for low-flow, venous malformations involving tongue.

S3B-SPNR-3

Alterations of Cerebral Perfusion and Functional Connectivity in Children with Idiopathic Generalized Epilepsy

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Guiqin Chen, (*Presenter*) Nothing to Disclose

PURPOSE

Previous studies have demonstrated that adults with idiopathic generalized epilepsy (IGE) have functional abnormalities,however, the neuropathological pathogenesis differs between adults and children. This study aimed to explore the alterations of cerebral blood flow (CBF) and functional connectivity (FC) simultaneously to comprehensively understand the neuropathological mechanisms of IGE in children.

METHODS AND MATERIALS

Arterial spin labeling (ASL) and blood oxygenation level-dependent magnetic resonance imaging data were acquired for 28 patients with IGE and 35 matched healthy controls (Table 1). Using ASL perfusion, we identified several regions of altered CBF in patients with IGE. Seed-based whole-brain FC analysis was then performed on regions with significant CBF changes. Multiple comparisons were corrected using a voxel-wise Gaussian random field method ($P < 0.05$, two tailed). The mean CBF and FC of each cluster with significant group differences were extracted and correlated with the clinical variables in the IGE group using Pearson's correlation analysis.

RESULTS

Compared to controls, patients with IGE showed abnormalities in CBF, mainly located in the right middle temporal gyrus, right middle occipital gyrus (MOG), right superior frontal gyrus (SFG), and left inferior frontal gyrus, triangular part (IFGtriang) (Table 2, Figure 1). Based on these four regions, we constituted the whole-brain FC and observed that the FC between the left IFGtriang and calcarine fissure (CAL) was decreased, (Figure 2A) and the FC between the right MOG and bilateral CAL was decreased (Figure 2B). Correlation analyses indicated that hyperperfusion in the right SFG was correlated with IGE age of onset($r=-3.81$, $P=0.045$) (Figure 3A), and decreased connectivity in the left CAL was correlated with the IGE patient's duration($r=-4.20$, $P=0.026$) (Figure 3B).

CONCLUSION

s The study findings suggest simultaneous alterations in both CBF and FC in the left IFGtriang and right MOG in children with IGE by combining ASL and rs-fMRI,and the abnormal brain area is associated with duration.

CLINICAL RELEVANCE/APPLICATION

The combination of CBF and FC not only describe and track the progress of the disease, provide imaging basis for early diagnosis of IGE, but also can provide complementary information and comprehensive insights into the pathophysiology of IGE from the perspective of neuronal and vascular integration.

Bitmap 3D Printing of Multimodal Imaging for Epilepsy Surgery

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Nicholas Jacobson, (*Presenter*) Nothing to Disclose

PURPOSE

Surgical Planning for epilepsy requires the sequential review of multiple volumetric and vector-based datasets. This data is viewed sequentially on a 2D screen, requiring significant visuospatial memory to composite and spatially reconstruct. The presurgical data review process has thus become increasingly inefficient and does not provide a holistic visualization of the data. This worrisome trajectory ignores the biggest promise of the information revolution: increased communication, connectivity, and interoperability. This cognitive load can be reduced by combing multimodal volumetric images with a 3D printed model. We present a method for creating a presurgical planning model that combines T1 MRI, CT SEEG data, tractography, and fMRI from pediatric epilepsy patients. The purpose is to reduce the cognitive load on surgeons and facilitate focused communication between the entire epilepsy team.

METHODS AND MATERIALS

16 bit image data, CT/MRI/fMRI, is mapped to color and opacity material mixing ratios corresponding to DICOM intensity values. 256 bit vector field data, Tractography/SEEG activation, is composted onto the image data in 3D voxel space. The composted multimodal 3D model is sliced for 3D printing in a voxel-based modeling program. The bitmap slices are printed at the spatial resolution of the images in a multi-material polyjet 3D printer. The model is reviewed during surgical conferences and used during a procedure in a clinical study (n=15).

RESULTS

Our method embeds vector-based features, representing dynamic physiology, within image-based models that represent gradients in biological tissue. The results leverage color-encoded data, displaying composited MRI, CT SEEG probes and activation, DWI tractography, and fMRI information. The models were used in discussion during case conferences and surgery. Preliminary survey results indicate increased spatial understanding and confidence in the surgical approach.

CONCLUSION

s We show that a variety of computationally derived physiologic datasets found in medical imaging can be directly 3D printed for neurosurgical epilepsy interventions. The relationships between data visualization, computer science, digital fabrication, and medicine are fostering an information revolution with the potential for increased communication, connectivity, and interoperability of data, bringing form and function together to improve health.

CLINICAL RELEVANCE/APPLICATION

The multimodal models unify and express more of the ever-increasing amount of data in surgical planning. The models are developing a platform that can be extended to study disease states that require information from multiple modalities of images.

S3B-SPNR-5

Clinical Significance of Hippocampal Asymmetry as a Sole Imaging Finding in Patients with Seizure

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Hasan Azeem Khan, MD, Galveston, WV (*Presenter*) Nothing to Disclose

PURPOSE

Hippocampal volume loss on MRI (Magnetic Resonance Imaging) is described as potential source or sequelae of seizure. Since the introduction of post processing automated volumetric techniques, there has been a reliable and objective method to assess hippocampus volume. Hippocampal asymmetry in the context of normal volume of individual hippocampi is an uncommon finding observed on volumetric studies of brain MRI performed for evaluation of seizure. The clinical significance and correlation of hippocampal asymmetry with seizures and EEG findings are lacking. We set out to create a study that evaluates the relationship between asymmetric otherwise normal hippocampi and seizures.

METHODS AND MATERIALS

We gathered data on 49 patients from 1257 brain MRIs performed for evaluation of seizure over the past 3 years. The total 49 patients are divided into two groups. A group of 25 patients with hippocampal asymmetry diagnosed on MRI using the Neuroquant protocol and a comparison group of 24 patients with symmetrical hippocampi. This included data of left/right hippocampal volume, asymmetry index reviewed and evaluated by a fellowship-trained neuroradiologist. EEG, clinical presentation and demographic characteristics were collected from the electronic medical record.

RESULTS

A total of 49 patients who presented with seizures were included in the study. All patients had normal hippocampal volumes on NeuroQuant volumetric analysis. 10 patients had epileptiform EEG findings and 39 patients had no epileptiform changes on EEG. 25 patients (51%) had hippocampal asymmetry, considered positive for volumetric analysis, while 24 (49%) were symmetric. Of the 25 patients with asymmetry, 6 patients (12%) had epileptiform findings on EEG, considered positive for EEG changes. Of the 24 patients with symmetric hippocampal volumes, 4 (8%) had positive EEG. Overall, in this population the likelihood of hippocampal asymmetry was 51% and the likelihood of epileptiform EEG findings was 20%. A McNemar's test for correlated proportions yielded a p-value of 0.003.

CONCLUSION

s Our study suggests that there may be an association between hippocampal asymmetry and EEG changes in the setting of otherwise normal-appearing hippocampi of normal volume. This could be considered an additional parameter in the assessment of patients with seizures.

CLINICAL RELEVANCE/APPLICATION

This finding should prompt follow-up imaging to assess the trajectory of the volume loss, which might have implications on patients' management and prognosis.

Seed-to-Voxel Analysis of Resting-State fMRI Can Detect Functional Alterations in Seizure Onset and Spread Regions in Patients with Non-Lesional Temporal Lobe Epilepsy

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
India Shelley, BA, Philadelphia, PA (*Presenter*) Nothing to Disclose

PURPOSE

Temporal lobe epilepsy (TLE) can have severe clinical signs and symptoms. Abnormal neural seizure networks from underlying pathology may facilitate seizure spread and be involved in the manifestation of symptoms in TLE. Currently, stereotactic electroencephalography (sEEG) can detect correlations between zones of seizure onset (OZ) and early (ESZ) and late (LSZ) spread. We examined whether patient resting-state fMRI (rsfMRI) scans can detect similar correlations between the OZ, ESZ, and LSZ. We aimed to see whether noninvasive imaging techniques can uncover patterns of seizure spread to potentially demarcate areas for intervention.

METHODS AND MATERIALS

This is a retrospective study of 8 patients with refractory, non-lesional TLE (ages 25-53) and 10 controls (ages 22-35). The TLE patients were MRI- on routine diagnostics and subsequently received sEEG. The OZ, ESZ, and LSZ were calculated by generating regions around sEEG contacts that recorded seizure activity. The LSZ was only available for 3 patients. These regions and functional images were registered to MNI space using MIRTK. For each subject, we used dual regression to detect amplitude synchronization of the OZ with the rest of the brain and calculated the ratio of correlated voxels to the spread zone. The same process was done using the OZ, ESZ, and LSZ of each TLE patient for each control. TLE patients were compared to controls individually using a Wilcoxon test and as a group using a Student’s t-test, alpha = 0.05. The average BOLD signal over the time series was calculated in the onset and spread regions and compared using z-score analysis and a Student’s t-test, alpha = 0.05.

RESULTS

5/8 TLE patients showed decreased correlations from the OZ to the ESZ compared to controls. Only 1 TLE patient showed an increased correlation. 2/3 TLE patients showed decreased correlations between the OZ and LSZ. Group analysis showed TLE patients had lower overall connectivity with the ESZ compared to controls. TLE patients had higher average BOLD signal in the OZ and ESZ but not LSZ.

CONCLUSION

s TLE patients show decreased functional connectivity from the OZ to both ESZ and LSZ. TLE patients showed higher neuronal activity in the OZ and ESZ. These results indicate TLE patients show high levels of pathologic seizure activity but dysfunctional connections in seizure-related areas. Seed-to-voxel analysis of rsfMRI can detect functional network disruption that may expose pathophysiology underlying seizure propagation.

CLINICAL RELEVANCE/APPLICATION

fMRI analysis is a promising noninvasive method to detect correlated brain regions that may be involved in seizure propagation. It can explore underlying pathology and understanding of the disease.

Automated Subfield Volumetric Analysis of Amygdala, Hippocampus, and Thalamic Nuclei in Mesial Temporal Lobe Epilepsy

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
India Shelley, BA, Philadelphia, PA (*Presenter*) Nothing to Disclose

PURPOSE

Identifying relationships between clinical features and quantitative characteristics of the amygdala-hippocampal and thalamic subregions in mesial temporal lobe epilepsy (mTLE) may offer insights into pathophysiology and the basis for imaging prognostic markers of treatment outcome.

METHODS AND MATERIALS

27 mTLE subjects with mesial temporal sclerosis (MTS) were scanned for conventional 3D T1w MPRAGE image and T2w scans. With respect to 12 months post-surgical seizure outcomes, 15 subjects reported seizure free and 12 had seizures. We performed quantitative automated segmentation and cortical parcellation using Freesurfer. Automatic labeling and volume estimation of hippocampal subfields, amygdala, and thalamic subnuclei were performed. Volume ratio (VR) for each label was computed and compared using linear regression analysis with significant FDR corrected p-value of <0.05. Additionally, we used age, sex, existence of tonic-clonic, age of seizure onset, and seizure class as confounding variables.

RESULTS

Amygdala: In the amygdala, the medial nucleus was the most significantly reduced in patients who were not seizure free when compared to patients who remained seizure free. Hippocampus: Comparison of volumes ipsilateral and contralateral with seizure outcomes showed volume loss was most noted in mesial hippocampal regions such as CA4 and hippocampal fissure. Volume loss was also most reduced in the presubiculum body in patients who were not seizure free at follow-up. Thalamus: VPL and PuL were the most significantly reduced thalamic nuclei in non-seizure free patients.In all statistically significant areas, volume reduction has been observed in the non-seizure free group.

CONCLUSION

s We demonstrated varying degrees of volume loss in the hippocampus, thalamus, and amygdala subregions of MTS, especially between patients who remained seizure-free and those who did not. These results can be used to further understand mTLE pathophysiology.

CLINICAL RELEVANCE/APPLICATION

In the future, we hope these results can be used to deepen the understanding of mTLE pathophysiology, leading to improved patient outcomes and treatments.

S3B-SPNR-8

Comparison of Functionally Versus Structurally-defined Nodes for Evaluation of DTI Connectome Edge Density (ED) in Infants with Autism Spectrum Disorder (ASD)

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Clara Weber, New Haven, CT (*Presenter*) Nothing to Disclose

PURPOSE

In our previous study, conventional DTI metrics and connectome ED based on structurally-defined nodes found significant ASD-related changes among adolescents and adults, but not pediatric cohorts. Here, we analyzed infants at risk of ASD and adults, to evaluate connectome ED based on tractography between functionally defined nodes that showed correlation with from ASD severity in a separate cohort.

METHODS AND MATERIALS

We retrieved DTI from n=155 infants (Longitudinal MRI study of infants at Risk for Autism; median age at scan 7 months, ASD assessment at 24m) and n = 96 adults (Atypical Late Neurodevelopment in Autism, median age 230m) from the National Database of Autism Research. Lake et al. (Biol Psychiatry 2019;86(4):315-26) have previously identified cerebral regions (nodes) that showed significant positive, and respectively negative, functional correlation with symptom severity as measured by ADOS (Autism Diagnostic Observation Schedule) scores based on rs-fMRI from n=260 children. We subset these regions in two sensitivity levels and subsequently specified them as seed points in probabilistic tractography to generate ED maps. For statistical analysis, mean ED values within the JHU White Matter (WM) Labels atlas tracts were extracted.

RESULTS

ED within major WM tracts shows pervasive correlation with ASD diagnosis (Figure 1) in both infants and adults. While present both for ED generated based on positively and negatively correlated cortical regions, positively correlated regions showed more widespread ASD-related changes. Comparing correlation coefficients between different sensitivity levels revealed that ED based on more sensitive nodes shows stronger correlation to ASD diagnosis than ED constructed from less sensitive nodes.

CONCLUSION

s While tractography ED based on structural nodes could only find ASD-related differences in adults' cohort (but not infants), we showed that constructing ED based on functionally defined nodes could identify ASD-related changes in both infants' and adults' cohorts.

CLINICAL RELEVANCE/APPLICATION

As alterations could only be detected in adolescent and adult cohorts in anatomy-based ED, our results imply benefits of combining functional and diffusion-weighted imaging for construction of connectome ED, especially in pediatric populations.

Temporal Encephaloceles and Drug Resistant Epilepsy: Is There Radiological Correlation with The Epileptogenic Focus?

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Aleix Jareno Badenas, MD, Sant Vicenc de Castellet, Spain (*Presenter*) Nothing to Disclose

PURPOSE

Encephaloceles are protrusions of cerebral tissue through a skull defect. They are a possible cause of epilepsy, although their actual epileptogenic potential has not been assessed yet. Lately, with the improvement of MRI imaging, the identification of encephaloceles in patients with drug resistant epilepsy (DRE) has increased. The purposes of this study are: To correlate the location of encephaloceles with the epileptogenic focus in patients with DRE. To evaluate their characteristics and to correlate them with their epileptogenicity.

METHODS AND MATERIALS

We performed a retrospective analysis of the MRI and neurofunctional studies of patients of our epilepsy unit with DRE and an MRI diagnosis of encephalocele. We evaluated the correlation between the encephalocele's location and the epileptogenic focus, as well as their characteristics (number, location, size and presence of gliosis). The location and characteristics of the encephaloceles were evaluated in the 3T MRI studies with a specific epilepsy protocol. The epileptogenic focus was evaluated in our epilepsy unit after the evaluation of different neurofunctional techniques (video-EEG, PET/SPECT and SEEG).

RESULTS

We had a study population of 11 patients (7 women and 4 men) with a mean age of 24.6 years. Six (55%) patients had correlation between the epileptogenic focus and the location of the encephalocele, whilst in the other 5 (45%) they were not matching. 67% of the patients with correlation showed gliosis and a mean encephaloceles volume of 0.25cc, while 40% of patients without correlation presented gliosis and a mean volume of 0.33cc.

CONCLUSION

s Our results show that encephaloceles have to be considered as potentially epileptogenic lesions in patients with DRE. Gliosis may be an indicator of higher epileptogenicity. In our group of patients, the smaller encephaloceles were more epileptogenic, which is inconsistent with previous literature.

CLINICAL RELEVANCE/APPLICATION

Our study shows that encephaloceles have epileptogenic potential and that some characteristics, such as the gliosis, may help to assess their epileptogenic potential.

S3B-SPOB-1 A Multi-Parametric Quantitative Assessment of Fetuses With Growth Restriction Using Advanced MRI Methods

Participants
Dafna Ben Bashat, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

To assess fetal - placental structural and functional parameters using multi-parametric MRI methods and their association with gestational age (GA) and with fetal growth restriction (FGR) caused by placental insufficiency.

METHODS AND MATERIALS

Subjects 76 fetuses (31-38 weeks); 60 appropriate for gestational age (AGA), and 16 FGR caused by placental insufficiency. MRI data: acquired on 3T MRI systems (Siemens, Prisma/Skyra), including high-resolution fetal brain and body T2-weighted MRI for structural assessment of the fetus and placenta; and Pseudo continuous arterial spin labeling (pCASL) and intra-voxel incoherent motion (IVIM) for placental perfusion assessment. Image analysis: Total fetal body, brain and placenta volumes were extracted using deep learning segmentation methods. The distance of the umbilical cord insertion from the center (CI) was quantified manually. Placental perfusion parameters were calculated from pCASL and IVIM. Radiomics analysis was performed on all structural and functional parameters. Statistical analysis: Correlations with gestational age (GA) were measured in the AGA group, and differences between AGA and FGR were assessed using ANCOVA controlling for GA. Statistical significance was set to $p<0.05$.

RESULTS

Significant correlations with GA were detected within the AGA group for total body volume; brain volume; and placental flow (f) extracted from IVIM. FGR fetuses had smaller total body and brain volumes compared to AGA, as well as larger CI, i.e, more marginal cord insertion. No significant differences between groups were detected for mean values of placental perfusion parameters, however, few radiomics features relating to shape and heterogeneity differentiated between groups.

CONCLUSION

s This study provides MRI quantitative structural and perfusion assessment of 3rd trimester fetuses and demonstrates differences between AGA and FGR fetuses.

CLINICAL RELEVANCE/APPLICATION

This study demonstrated an MRI multi-parametric approach, providing reference values for several structural and functional parameters at late GA, and may be used to improve differentiation between AGA and FGR fetuses.

S3B-SPOB-2 Rhombencephalosynapsis: A Underdiagnosed Condition Behind Severe Ventriculomegaly

Awards
Trainee Research Prize - Fellow

Participants
Isabella Bertuol Kinoshita, MD, Sao Paulo, Brazil (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate and emphasize the association of rhombencephalosynapsis and severe ventriculomegaly in fetal magnetic resonance imaging (MRI).

METHODS AND MATERIALS

Fetal MR examinations performed due to ventriculomegaly in a single academic hospital were retrospectively reviewed. Fetuses with severe hydrocephalus in sonographic evaluation (ventricular atrium size of at least 15,1 mm plus brain parenchymal thinning) were included. Neural tube defects and unilateral or non-obstructive ventriculomegaly were exclusion criteria. MRI was performed after 24 week's gestational age, when the vermis and cerebellar folia are clearly visible. Four millimeters sections (without intervals) MR images were obtained with a field-of-view (FOV) of 30 or less. A Skyra 3T or Espree 1.5T unit (Siemens Healthineers, Erlangen, Germany) with 8 channel body array coils was employed. MR pulse sequences included: HASTE (TR 1000; TE 117), TrueFISP (TR 4,3; TE 2,15) and T1-W Gradient Echo (TR 136; TE 4). A detailed evaluation of the cerebellum and posterior fossa was conducted. The findings were described by two experienced pediatric neuroradiologists using pre-established rhombencephalosynapsis grading

criteria.

RESULTS

Of 201 fetuses referred to MR due to severe ventriculomegaly, 111 were included. In 24,3% of the cases, an association of aqueductal stenosis and rhombencephalosynapsis was seen. Aqueductal stenosis alone was identified in 27,9%. Other associated conditions were: posterior fossa anomalies (17,1%); holoprosencephaly (18,8%) and diencephalic-mesencephalic junction anomalies (2,7%). Extrinsic aqueductal obstruction was seen in 5 cases, due to interhemispheric cyst (2,7%) and diencephalic-mesencephalic tumors (1,8%). In all fetuses, the following were also depicted: transverse cerebellar diameter inferior to the 3rd percentile for the gestational age; fusion of the dentate nucleus and continuous cerebellar folia in at least one axial and one coronal slice.

CONCLUSION

s Rhombencephalosynapsis is found in a high percentage of fetuses with aqueductal stenosis and hydrocephalus.

CLINICAL RELEVANCE/APPLICATION

Few reports describe the diagnosis of rhombencephalosynapsis associated with aqueductal stenosis in fetal MRI. The study shed light on the imaging findings and provided tools for accurate diagnosis.

S3B-SPPD-1 Quantification of Liver Fat Using Ultrasound-Guided Attenuation Parameter for Assessment of Steatosis with Reference to MRI-PDFF in Pediatric Non-Alcoholic Fatty Liver Disease

Participants
Jake Weeks, La Jolla, CA (*Presenter*) Nothing to Disclose

PURPOSE

The rising incidence of NAFLD demands the development of widely available, non-invasive screening techniques for evaluating liver steatosis. Prior studies have shown that the attenuation coefficient, as measured by Ultrasound-Guided Attenuation Parameter (UGAP), demonstrates a strong correlation with MRI-PDFF in adults. However, no study has evaluated its correlation with MRI-PDFF in children, and its performance in this group remains a gap in knowledge. This prospective pilot study examines the correlation of UGAP to MRI-PDFF in children with known or suspected NAFLD.

METHODS AND MATERIALS

Eighteen children with biopsy-proven NAFLD or suspected NAFLD, ages 10-16, were prospectively enrolled in an ongoing pilot research study to investigate quantitative ultrasound (US) and MRI biomarkers of liver disease. Each research visit included two ultrasound exams using a GE LOGIQ E10 system (GE Healthcare, Waukesha WI) and, on the same day, two MR exams on a GE Discovery MR750 3.0T scanner. In each ultrasound exam, least 6 valid UGAP values were acquired in a homogeneous area of liver parenchyma in the right lobe; the median and interquartile range (IQR) values were recorded. If the IQR/median < 0.30, the exam was considered reliable. MRI-PDFF was measured in the liver using IDEAL-IQ. Median UGAP values were correlated to PDFF values, using all available data. The confidence interval and significance of the correlation coefficient were computed using initial and repeat exams by a non-parametric bootstrap with per-patient resampling to adjust for within-patient dependence.

RESULTS

All UGAP exams met reliability criteria. 3 children could not tolerate MRI. The median of the 6 UGAP measurements and mean PDFF for 25 pairs of US and MRI exams were tested for correlation. Median per-child UGAP values ranged from 0.49 to 0.88 dB/cm/MHz (mean, 0.72). Mean per-child PDFF values ranged from 1.4% to 34.2% (mean, 17.6%). Median UGAP values and mean PDFF values were correlated for all 25 pairs of available data: the Pearson correlation coefficient was $r = 0.72$ ($p < 0.001$; 95% CI: 0.34, 0.88).

CONCLUSION

s UGAP and MRI-PDFF are significantly correlated in this preliminary pilot study in children with known or suspected NAFLD. This correlation is of similar strength to that found in prior studies in adults, but the sample size is small and the confidence interval is wide. Future studies with larger cohorts will be necessary to validate these findings.

CLINICAL RELEVANCE/APPLICATION

In this pilot study, UGAP showed promising correlation with MRI-PDFF in evaluating hepatic steatosis in children.

S3B-SPPH-1 Diagnostic Accuracy of Artificial Intelligence for Pediatric Pulmonary Nodule Detection in Computed Tomography of the Chest: Comparison at Standard and Simulated Lower Radiation Doses

Participants
Rida Salman, MD, Houston, TX (*Presenter*) Nothing to Disclose

PURPOSE

To determine the diagnostic accuracy of an adult pulmonary nodule detection AI algorithm in pediatric patients imaged with CT chest, at standard and simulated lower radiation doses.

METHODS AND MATERIALS

We performed a retrospective chart review of all patients between 12-18 years-old who underwent a chest CT with or without contrast, on the Siemens SOMATOM Force from 12/20/2021 to 4/12/2022. Simulated lower doses at 75%, 50% and 25% were reconstructed at 3 mm slice thickness and with lung kernel Bl64d using ReconCT (Siemens Healthineers, Forchheim, Germany) and imported to an existing AI software, Syngo CT Lung Computer Aided Design (CAD) (Siemens Healthineers, Forchheim, Germany). Two Board certified radiologists reviewed the CTs and their consensus read was considered the gold standard. A pediatric radiology fellow compared the Lung CAD results at each dose level to the gold standard on a nodule by nodule basis. Data analysis was done using descriptive statistics; the sensitivity (Sn), specificity (Sp), positive predictive value (PPV), and false positive rate (FPR) of lung nodule detection at different doses was reported.

RESULTS

30 patients were included. 164 nodules were identified by the two radiologists. At 100%, 75%, 50%, 25%, Lung CAD detected 60,62,58,62 nodules; 28,28,29,26 were true positive (Sn=17%,17%,18%,16%), 30,32,27,34 were false positive (PPV=52%,53%,48%,57%) and 2 were missed by radiologists in 2 patients (2/30, 7%), respectively. Lung CAD and radiologists agreed on 4,5,5,3 patients who did not have any nodule (true negative), respectively. The 30,32,27,34 false nodules were identified by Lung CAD in 15,14,13,16 patients; 4,3,3,5 of whom did not have any nodule by gold standard read (Sp=4/19=21%,26%,28%,16% and FPR=15/19=79%,74%,72%,84%), respectively.

CONCLUSION

s The adult Lung CAD shows low sensitivity and specificity with high false positive rate at all simulated lower doses. However, the dose may be reduced by 50% without further compromise to the Lung CAD performance. Slice thickness of the reconstructed volumes could be a likely cause for the less than optimal performance and further evaluation with thinner slices and other kernels is planned as a future study.

CLINICAL RELEVANCE/APPLICATION

Evaluation of adult Lung CAD performance for pulmonary nodules detection in children at lower simulated doses might guide ongoing research focusing on algorithm improvements in children.

S3B-SPPH-2 Accurate Liver Tumor Detection on Noncontrast CT Scans via Annotation-Efficient Semi-Supervised Learning

Participants
Jack Wang, (*Presenter*) Nothing to Disclose

PURPOSE

Noncontrast CT routinely performed for different clinicalindications is good for opportunistic screening of liver cancer at noadditional cost or radiation exposure. We aim to develop a deep learning toolto assist radiologists in detecting hepatocellular carcinoma (HCC) and otherliver tumors.

METHODS AND MATERIALS

We collected multiphase liver CT images from 909 patientswith HCC, 307 patients with nonHCC (cholangiocarcinoma, metastasis,hemangioma), and 280 patients with normal liver. All HCC and nonHCC wereconfirmed by pathology. To obtain mask-level annotations, we applied nnUNet andsemi-supervised learning on five public abdomen CT datasets (BTCV and four MSDsub-datasets) to train an initial multi-class (liver, liver tumor, hepaticvessels, gallbladder, stomach, spleen) semantic segmentation model on venousphase CT images. It was then applied to the venous phase of our data togenerate initial multi-class masks. The HCC masks

were reviewed and correctedby an experienced liver imaging specialist using a customized multiphase CTlabeling tool with referring to medical reports. The masks were then registeredto the noncontrast phase CT by DEEDS, to obtain annotations. We randomly splitour data into training, validation, and testing sets according to a radio of64%, 16%, and 20%. A nnUNet was trained to segment the HCC, nonHCC, and otherclasses. A patient was classified as HCC, nonHCC, or normal based on thesegmented tumor volumes, with the optimal cutoff determined on the validationset.

RESULTS

The testing set included 190 HCCs, 62 nonHCCs, and 51 normals.Our model achieved an AUC = 0.977. With the optimal cutoff volume (HCC+nonHCC)of 1.5 cm3, the patient-level sensitivity is 94.5%, and specificity is 98.5%.Defining successful tumor detection as the overlapping betweenauto-segmentation and ground-truth > 0 voxels, the sensitivity is 91.2%.When considering the segmented tumor type with a larger volume as thepatient-level tumor type, the classification accuracy of HCC vs. nonHCC is85.3% vs. 46.8%.

CONCLUSION

s The annotation-efficient semi-supervised learning methodenabled automated liver tumor detection from noncontrast CT scans with highsensitivity and specificity.

CLINICAL RELEVANCE/APPLICATION

The developed model can help reduce missing rate with lowfalse-positive rate in noncontrast CT scans. It can also be used as anopportunistic screening tool for liver cancer.

S3B-SPPH-3 Development of a Moiré Free Two Dimensional Anti-scatter to Improve Image Quality in Cone-Beam Computed Tomography System

Participants
Jongkuk Kim, (*Presenter*) Nothing to Disclose

PURPOSE

Conventional anti-scatter grid (ASG) has been rarely used in a cone-beam computed tomography (CBCT) system because it does not provide a sufficient effect on the scatter reduction and also can cause Moiré artifact. We have developed a two-dimensional anti-scatter grid (2D ASG) designed with Moiré free as a scatter reduction solution in CBCT system. We show how the 2D ASG is fabricated using sawing process method and demonstrate Moiré free image and the improvement of image quality compared with conventional ASGs.

METHODS AND MATERIALS

In order to fabricate a Moiré free 2D ASG, a graphite plate was used as an interspace body and it was sawed by a diamond-coated blade to make septa focused on x-ray source. Line density of the 2D ASG was designed to match with a pixel pitch of a VIVIX-D 1212G flat panel detector (FPD) in our CBCT testbed. Projection images were acquired at 100 kV of tube voltage and 4 mA for Catphan700 phantom to analyze Moiré image qualitatively and they were reconstructed using Feldkamp-Davis-Kress (FDK) algorithm to evaluate the effect of 2D ASG compared to a conventional ASG. Quantitative analysis for ASGs was performed using uniformity index to measure cupping effect and contrast noise ratio (CNR) with respect to No-ASG.

RESULTS

No Moiré artifact was shown in the projection image of the 2D ASG compared with an image of a conventional ASG, and the spatial frequency domain image also shows there are no frequency peaks that indicate Moiré artifact. The cupping artifact was reduced by about 42 % for the 2D ASG and about 28 % for the conventional ASG. CNR values for the two types of ASG were increased by 40% and 25 % respectively.

CONCLUSION

s The improvement of image quality for the 2D ASG was demonstrated by both measurement results of cupping and CNR compared to the conventional ASG. Also, the 2D ASG does not have to take a further step to remove Moiré artifact. Thus, the Moiré free 2D ASG can be a solution for scatter rejection in CBCT.

CLINICAL RELEVANCE/APPLICATION

The Moiré free 2D ASG can be easily applied to improve image quality by reducing scatter radiation in clinical CBCT systems, such as image-guided radiation therapy.

S3B-SPPH-4 Effective Doses Associated With Weight-Bearing Imaging of the Hip and Extremities on a New Dedicated Cone-Beam CT Scanner

Participants
Jaydev K. Dave, PhD, Philadelphia, PA (*Presenter*) Research Grant, Koninklijke Philips NV;Equipment support, Lantheus Medical Imaging;Equipment support, General Electric Company;Research Consultant, Curvebeam LLC;Consultant, Rayscan, Inc.

PURPOSE

The purpose of this project was two-fold; first, to measure organ and effective doses associated with weight-bearing CT imaging of the hip with a new dedicated cone-beam CT (CBCT) scanner (HiRise, CurveBeam) and compare with hip imaging performed on a conventional multidetector CT (MDCT; iCT 256, Philips Healthcare) and second, to compare effective doses associated with hand/wrist imaging and weight-bearing imaging of knees and foot/ankle between HiRise CBCT and other CBCT scanner (LineUp, Curvebeam) designed for extremity imaging.

METHODS AND MATERIALS

Sectional and customized anthropomorphic phantoms of the adult hip (ATOM 701-G, CIRS), and hand/wrist (Model-XA231P), knee (Model-XA245L), and foot/ankle (Model-XA241R; The Phantom Laboratory) were used. Organ dose measurements were performed with OSL dosimeters (screened nanoDots, Landauer) readout by a calibrated microStar reader (Landauer). Adult hip phantom was scanned on the HiRise and iCT scanners, and other phantoms were scanned on the HiRise and LineUp scanners for dose comparisons using routine and manufacturer-recommended protocols. CBCT scans were repeated to assess reproducibility and

rotational variability.

RESULTS

For hip imaging, average tissue-absorbed doses were significantly higher with MDCT (11.7±5.1 mGy) relative to CBCT (3.6±2.1 mGy; p<0.001), yielding effective dose values of 3.5 mSv and 0.9 mSv, respectively. No differences were noted in dose measurements while assessing reproducibility (p=0.89) and rotational dependency (p=0.26). The effective doses for imaging of the hand/wrist, knees and foot/ankle were significantly higher (p=0.001) for the HiRise system (1.6-6.8 µSv) relative to the LineUp system (0.3-3.2 µSv).

CONCLUSION

s Effective doses for hip imaging with CBCT could be substantially lower than with MDCT. The reported effective dose values for weight-bearing imaging of the hip (0.9 mSv) and extremities (max 6.8 µSv) are low. Therefore, clinical appropriateness/applicability should be considered for imaging using dedicated CBCT scanners.

CLINICAL RELEVANCE/APPLICATION

Weight-bearing imaging of the hip and extremities permits diagnosis and surgical management by assessing misalignment and concomitant deformities.

S3B-SPPH-5 Photon Counting Detector: The First Human Images

Participants
Ibrahim Bechwati, Danvers, MA (*Presenter*) Employee, Samsung Electronics Co, Ltd

PURPOSE

The main purpose is to demonstrate the clinical imaging capabilities of the new Photon Counting Detector (PCD) fitted on the OmniTom scanner built by Neurologica Corporation.

METHODS AND MATERIALS

The OmniTom scanner fitted with PCD array becomes the second scanner to get FDA 510K approval. The scanner gets approved for full diagnostic imaging. The OmniTom is a battery operated 16 slice head mobile scanner. It supports axial and helical scanning modes. The PCD array is made of individual cells of 0.19x0.23 mm2. The Cadmium Telluride (CdTe) cells are binned to match the EID scanner detector size. The array provides three overlapping energy bands generating three images. A full spectrum image, a medium energy image and a high energy image. The first PCD image generated by the full spectrum is equivalent to the current CT images of the EID array. Two OmniTom scanners equipped with a PCD and an EID detector array were used to compare the image quality. Three different volunteers were scanned using a low dose scan of 40 mGy. Two volunteers were scanned on both scanners. Images from three 10mm sections were compared. The scanned sections are taken at the sinus level, the orbital region, and the top of the skull. The third volunteer underwent a complete head scan using only the OmniTom PCD. The scan covers the entire brain starting from above the upper jaw.

RESULTS

The scans clearly show that PCD detectors can generate diagnostically acceptable images. The images were reviewed by two independent radiologists who both agreed that the images from the PCD OmniTom are diagnostically equivalent to the EID scanner.

CONCLUSION

s The comparative studies show the similarity between the PCD and the EID detectors. The full head scan demonstrates the ability of the PCD in doing complete clinical scan as needed.

CLINICAL RELEVANCE/APPLICATION

Although this study is focused on demonstrating equivalent image quality to the conventional CT, the PCD scanner shows better low contrast distinction between the white and grey matter in the brain images. The PCD images also show less beam hardening artifact as seen in the nasal and orbital images.

S3B-SPPH-6 Spectral Physical Density Quantifications for Non-invasive, Real-Time Spectral CT Thermometry

Participants
Leening Liu, Philadelphia, PA (*Presenter*) Nothing to Disclose

PURPOSE

Hepatocellular carcinoma (HCC) is typically treated with thermal ablation under the guidance of computed tomography (CT). Though it is the best performing procedure, the rate of local recurrence is high. Real-time temperature feedback may provide the means to ensure complete ablation while preventing damage to surrounding healthy tissue and critical structures. We assess the feasibility of non-invasive spectral CT thermometry by the principle of thermal volumetric expansion that relates temperature and physical density.

METHODS AND MATERIALS

To evaluate the relationship between physical density and temperature, a fiber optic temperature sensor was placed within a specifically designed tissue mimicking phantom that emulates the attenuation and thermal properties of liver. The phantom was subjected to a range of temperatures through heating and cooling while simultaneously being scanned with a dual-layer spectral CT at varying radiation doses (5 - 56.8 mGy). Clinically available spectral results were then utilized to generate physical density maps. Physical density was measured in regions of interest corresponding to the temperature sensor every 5 °C for each dose. A linear fit based on thermal volumetric expansion was applied to assess the relationship, and temperature sensitivity was calculated for different reconstruction parameters to inform future protocol optimization.

RESULTS

Physical density reflected thermal volumetric expansion with a slope of 0.000491 mL/g/°C and a R value of 0.9942, demonstrating a strong positively correlated relationship. Temperature sensitivity improved with larger slice thickness, a smooth iterative

reconstruction kernel, and higher iterative reconstruction level. With radiation dose, it varied from 6.0 to 1.6 °C/g/mL between 5 and 56.8 mGy.

CONCLUSION

s Spectral physical density quantifications of the tissue mimicking phantom affirmed a strong relationship with temperature that corresponded to thermal volumetric expansion. With this relationship, changes in physical density can be utilized to determine changes in temperature to provide non-invasive, real-time thermometry in thermal ablation with a temperature sensitivity of 1.6 °C/g/mL.

CLINICAL RELEVANCE/APPLICATION

Thermal ablation procedures, using spectral CT thermometry with physical density measurements, may be effectively carried out for reducing local tumor recurrences by providing non-invasive, real-time feedback.

S3B-SPPH-7 The Performance of Using CT Value Distribution in Dual-Energy Spectral CT Images to Predict Osteoporosis

Participants
Tongtong DU, Xian, China (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the performance of using CT value distribution in dual-energy spectral CT (DEsCT) images to predict osteoporosis.

METHODS AND MATERIALS

This study was IRB approved and consented by patients. A total of 156 consecutive patients (81 females and 80 males; mean age: 57.43±5.95 years, range 50-83 years) for chest CT screening were prospectively enrolled. All patients underwent chest DEsCT and Dual energy X-ray absorptiometry (DXA). Patients were divided into 2 groups using the T-score for the 1st lumbar vertebra on DXA: non-osteoporosis with T>-2.5 (n=101) and Osteoporosis with T=-2.5 (n=55). The chest DEsCT was performed on a 256-row Revolution CT (GE Healthcare) using 80-140kVp switching, 200mA and 0.5s/r. All images were reconstructed with 1.25mm thickness and analyzed using the GSI Viewer software on an AW4.7 workstation. CT values of the 1st lumbar vertebra were measured on the 120kVp-like images. According to CT histogram, the CT values were divided into 4 levels: A, <100HU; B, 100-199HU; C, 200-299 HU; D, =300HU. The distribution percentage in each level was compered between osteoporosis and non-osteoporosis groups. The cutoff of CT value distribution percentage for differentiating osteoporosis from non-osteoporosis was obtained by drawing a receiver operating characteristic (ROC) curve. The sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) were calculated. All statistical analyses were performed using the IBM SPSS statistical software (version 22.0), and two-tailed $p<0.05$ was considered statistically significant.

RESULTS

The CT value distribution percentages in all four levels in osteoporosis group were significant different from those in non-osteoporosis group (all $p<0.05$). Specifically, the percentage in level A showed the best diagnostic performance for osteoporosis, and provided the area-under-the-curve (AUC), sensitivity, specificity, PPV and NPV of 0.805, 0.818, 0.745, 0.654 and 0.748, respectively with a cutoff of 18.74%.

CONCLUSION

s The distribution percentage of CT value based on spectral histogram could predict osteoporosis and have a good diagnostic performance.

CLINICAL RELEVANCE/APPLICATION

CT value distribution percentage based on DEsCT could provide more information about osteoporosis.

S3B-SPPH-9 Technical Performance Study of the First Mobile Photon-Counting Detector CT

Participants
Junyoung Park, Suwon-Si, Korea, Republic Of (*Presenter*) Employee, Samsung Electronics Co, Ltd

PURPOSE

The purpose of this study is to evaluate the unique applications of photon-counting detectors (PCD) CT. The first is ability to “on demand” changes the scanner spatial resolution. The second is the ability to do “simultaneous” multi-energy scanning for material decomposition.

METHODS AND MATERIALS

In this study, the FDA 510(k) cleared mobile PCD-CT (OmniTom Elite) was used. The diagnostic performance of the scanner was proven using three clinical scans. The spatial resolution of the PCD-CT scanner was tested using the high contrast module of ACR accreditation phantom. The spatial resolutions of a large detector pitch of 0.71-mm (14 lp/cm) and a smaller pitch of 0.35-mm (28 lp/cm) for PCD-CT were tested. For multi-energy CT feasibility, Gammex phantom containing solid iodine and calcium inserts was scanned with three energy thresholds using PCD-CT. For material decomposition capability of PCD-CT, the iodine, calcium, and water maps were generated. Virtual mono-energetic images (VMI) from 40 keV to 120 keV were synthesized and the linear attenuation coefficients (LAC) of all the inserts of Gammex phantom were compared against manufacturer reference values.

RESULTS

The small pitch acquisition mode shows the highest resolution pattern of 11 lp/cm while only the resolution pattern of 7 lp/cm is seen when the same kernel (Posterior Fossa-kernel) is used in large pitch acquisition mode. For the quantitative multi-energy CT performance, the measured LAC in VMI of inserts of Gammex phantom matched the manufacturer reference values with mean percent error of 0.986%. In addition, the decomposition results with PCD-CT show that the iodine, calcium, and water can be well separated and quantified.

CONCLUSION

s We have shown that the PCD detector CT can accommodate a multiple resolution acquisition mode without physically changing

s We have shown that the PCD detector CT can accommodate a multiple resolution acquisition mode without physically changing the detector CT. The first clinical mobile PCD-CT can provide superior spatial resolution than large pitch acquisition mode which is equivalent with conventional mobile CT. Additionally, the results from quantitative multi-energy CT performance demonstrated that the PCD-CT was able to provide reliable simultaneous multi-energy images for material decomposition with single exposure.

CLINICAL RELEVANCE/APPLICATION

The validated unique characteristics of PCD-CT are highly desirable in clinical scanning. The ability to switch between different acquisition modes expands the clinical use of the scanner, e.g., high resolution temporal bone scans and lower resolution abdominal imaging. The capability of simultaneous multi-energy imaging leads to a precise registration that is needed to ensure the success of various multi-energy applications, including generation of material decomposition maps, VMI and virtual non-contrast images.

Diagnostic Accuracy of Artificial Intelligence for Pediatric Pulmonary Nodule Detection in Computed Tomography of the Chest: Comparison at Standard and Simulated Lower Radiation Doses

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Rida Salman, MD, Houston, TX (*Presenter*) Nothing to Disclose

PURPOSE

To determine the diagnostic accuracy of an adult pulmonary nodule detection AI algorithm in pediatric patients imaged with CT chest, at standard and simulated lower radiation doses.

METHODS AND MATERIALS

We performed a retrospective chart review of all patients between 12-18 years-old who underwent a chest CT with or without contrast, on the Siemens SOMATOM Force from 12/20/2021 to 4/12/2022. Simulated lower doses at 75%, 50% and 25% were reconstructed at 3 mm slice thickness and with lung kernel Bl64d using ReconCT (Siemens Healthineers, Forchheim, Germany) and imported to an existing AI software, Syngo CT Lung Computer Aided Design (CAD) (Siemens Healthineers, Forchheim, Germany). Two Board certified radiologists reviewed the CTs and their consensus read was considered the gold standard. A pediatric radiology fellow compared the Lung CAD results at each dose level to the gold standard on a nodule by nodule basis. Data analysis was done using descriptive statistics; the sensitivity (Sn), specificity (Sp), positive predictive value (PPV), and false positive rate (FPR) of lung nodule detection at different doses was reported.

RESULTS

30 patients were included. 164 nodules were identified by the two radiologists. At 100%, 75%, 50%, 25%, Lung CAD detected 60,62,58,62 nodules; 28,28,29,26 were true positive (Sn=17%,17%,18%,16%), 30,32,27,34 were false positive (PPV=52%,53%,48%,57%) and 2 were missed by radiologists in 2 patients (2/30, 7%), respectively. Lung CAD and radiologists agreed on 4,5,5,3 patients who did not have any nodule (true negative), respectively. The 30,32,27,34 false nodules were identified by Lung CAD in 15,14,13,16 patients; 4,3,3,5 of whom did not have any nodule by gold standard read (Sp=4/19=21%,26%,28%,16% and FPR=15/19=79%,74%,72%,84%), respectively.

CONCLUSION

s The adult Lung CAD shows low sensitivity and specificity with high false positive rate at all simulated lower doses. However, the dose may be reduced by 50% without further compromise to the Lung CAD performance. Slice thickness of the reconstructed volumes could be a likely cause for the less than optimal performance and further evaluation with thinner slices and other kernels is planned as a future study.

CLINICAL RELEVANCE/APPLICATION

Evaluation of adult Lung CAD performance for pulmonary nodules detection in children at lower simulated doses might guide ongoing research focusing on algorithm improvements in children.

S3B-SPPH-2

Accurate Liver Tumor Detection on Noncontrast CT Scans via Annotation-Efficient Semi-Supervised Learning

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Jack Wang, (*Presenter*) Nothing to Disclose

PURPOSE

Noncontrast CT routinely performed for different clinicalindications is good for opportunistic screening of liver cancer at noadditional cost or radiation exposure. We aim to develop a deep learning toolto assist radiologists in detecting hepatocellular carcinoma (HCC) and otherliver tumors.

METHODS AND MATERIALS

We collected multiphase liver CT images from 909 patientswith HCC, 307 patients with nonHCC (cholangiocarcinoma, metastasis,hemangioma), and 280 patients with normal liver. All HCC and nonHCC wereconfirmed by pathology. To obtain mask-level annotations, we applied nnUNet andsemi-supervised learning on five public abdomen CT datasets (BTCV and four MSDsub-datasets) to train an initial multi-class (liver, liver tumor, hepaticvessels, gallbladder, stomach, spleen) semantic segmentation model on venousphase CT images. It was then applied to the venous phase of our data togenerate initial multi-class masks. The HCC masks were reviewed and correctedby an experienced liver imaging specialist using a customized multiphase CTlabeling tool with referring to medical reports. The masks were then registeredto the noncontrast phase CT by DEEDS, to obtain annotations. We randomly splitour data into training, validation, and testing sets according to a radio of64%, 16%, and 20%. A nnUNet was trained to segment the HCC, nonHCC, and otherclasses. A patient was classified as HCC, nonHCC, or normal based on thesegmented tumor volumes, with the optimal cutoff determined on the validationset.

RESULTS

The testing set included 190 HCCs, 62 nonHCCs, and 51 normals.Our model achieved an AUC = 0.977. With the optimal cutoff volume (HCC+nonHCC)of 1.5 cm3, the patient-level sensitivity is 94.5%, and specificity is 98.5%.Defining successful tumor detection as the overlapping betweenauto-segmentation and ground-truth > 0 voxels, the sensitivity is 91.2%.When considering the segmented tumor type with a larger volume as thepatient-level tumor type, the classification accuracy of HCC vs. nonHCC is85.3% vs. 46.8%.

CONCLUSION

s The annotation-efficient semi-supervised learning methodenabled automated liver tumor detection from noncontrast CT scans with highsensitivity and specificity.

CLINICAL RELEVANCE/APPLICATION

The developed model can help reduce missing rate with lowfalse-positive rate in noncontrast CT scans. It can also be used as anopportunistic screening tool for liver cancer.

S3B-SPPH-4

Effective Doses Associated With Weight-Bearing Imaging of the Hip and Extremities on a New Dedicated Cone-Beam CT Scanner

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Jaydev K. Dave, PhD, Philadelphia, PA (*Presenter*) Research Grant, Koninklijke Philips NV;Equipment support, Lantheus Medical Imaging;Equipment support, General Electric Company;Research Consultant, Curvebeam LLC;Consultant, Rayscan, Inc.

PURPOSE

The purpose of this project was two-fold; first, to measure organ and effective doses associated with weight-bearing CT imaging of the hip with a new dedicated cone-beam CT (CBCT) scanner (HiRise, CurveBeam) and compare with hip imaging performed on a conventional multidetector CT (MDCT; iCT 256, Philips Healthcare) and second, to compare effective doses associated with hand/wrist imaging and weight-bearing imaging of knees and foot/ankle between HiRise CBCT and other CBCT scanner (LineUp, Curvebeam) designed for extremity imaging.

METHODS AND MATERIALS

Sectional and customized anthropomorphic phantoms of the adult hip (ATOM 701-G, CIRS), and hand/wrist (Model-XA231P), knee (Model-XA245L), and foot/ankle (Model-XA241R; The Phantom Laboratory) were used. Organ dose measurements were performed with OSL dosimeters (screened nanoDots, Landauer) readout by a calibrated microStar reader (Landauer). Adult hip phantom was scanned on the HiRise and iCT scanners, and other phantoms were scanned on the HiRise and LineUp scanners for dose comparisons using routine and manufacturer-recommended protocols. CBCT scans were repeated to assess reproducibility and rotational variability.

RESULTS

For hip imaging, average tissue-absorbed doses were significantly higher with MDCT (11.7±5.1 mGy) relative to CBCT (3.6±2.1 mGy; $p<0.001$), yielding effective dose values of 3.5 mSv and 0.9 mSv, respectively. No differences were noted in dose measurements while assessing reproducibility ($p=0.89$) and rotational dependency ($p=0.26$). The effective doses for imaging of the hand/wrist, knees and foot/ankle were significantly higher ($p=0.001$) for the HiRise system (1.6-6.8 µSv) relative to the LineUp system (0.3-3.2 µSv).

CONCLUSION

s Effective doses for hip imaging with CBCT could be substantially lower than with MDCT. The reported effective dose values for weight-bearing imaging of the hip (0.9 mSv) and extremities (max 6.8 µSv) are low. Therefore, clinical appropriateness/applicability should be considered for imaging using dedicated CBCT scanners.

CLINICAL RELEVANCE/APPLICATION

Weight-bearing imaging of the hip and extremities permits diagnosis and surgical management by assessing misalignment and concomitant deformities.

Spectral Physical Density Quantifications for Non-invasive, Real-Time Spectral CT Thermometry

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Leening Liu, Philadelphia, PA (*Presenter*) Nothing to Disclose

PURPOSE

Hepatocellular carcinoma (HCC) is typically treated with thermal ablation under the guidance of computed tomography (CT). Though it is the best performing procedure, the rate of local recurrence is high. Real-time temperature feedback may provide the means to ensure complete ablation while preventing damage to surrounding healthy tissue and critical structures. We assess the feasibility of non-invasive spectral CT thermometry by the principle of thermal volumetric expansion that relates temperature and physical density.

METHODS AND MATERIALS

To evaluate the relationship between physical density and temperature, a fiber optic temperature sensor was placed within a specifically designed tissue mimicking phantom that emulates the attenuation and thermal properties of liver. The phantom was subjected to a range of temperatures through heating and cooling while simultaneously being scanned with a dual-layer spectral CT at varying radiation doses (5 - 56.8 mGy). Clinically available spectral results were then utilized to generate physical density maps. Physical density was measured in regions of interest corresponding to the temperature sensor every 5 °C for each dose. A linear fit based on thermal volumetric expansion was applied to assess the relationship, and temperature sensitivity was calculated for different reconstruction parameters to inform future protocol optimization.

RESULTS

Physical density reflected thermal volumetric expansion with a slope of 0.000491 mL/g/°C and a R value of 0.9942, demonstrating a strong positively correlated relationship. Temperature sensitivity improved with larger slice thickness, a smooth iterative reconstruction kernel, and higher iterative reconstruction level. With radiation dose, it varied from 6.0 to 1.6 °C/g/mL between 5 and 56.8 mGy.

CONCLUSION

s Spectral physical density quantifications of the tissue mimicking phantom affirmed a strong relationship with temperature that corresponded to thermal volumetric expansion. With this relationship, changes in physical density can be utilized to determine changes in temperature to provide non-invasive, real-time thermometry in thermal ablation with a temperature sensitivity of 1.6 °C/g/mL.

CLINICAL RELEVANCE/APPLICATION

Thermal ablation procedures, using spectral CT thermometry with physical density measurements, may be effectively carried out for reducing local tumor recurrences by providing non-invasive, real-time feedback.

Patients were divided into 2 groups using the T-score for the 1st lumbar vertebra on DXA: non-osteoporosis with T>-2.5 (n=101) and Osteoporosis with T=-2.5 (n=55). The chest DEsCT was performed on a 256-row Revolution CT (GE Healthcare) using 80-140kVp switching, 200mA and 0.5s/r. All images were reconstructed with 1.25mm thickness and analyzed using the GSI Viewer software on an AW4.7 workstation. CT values of the 1st lumbar vertebra were measured on the 120kVp-like images. According to CT histogram, the CT values were divided into 4 levels: A, <100HU; B, 100-199HU; C, 200-299 HU; D, =300HU. The distribution percentage in each level was compered between osteoporosis and non-osteoporosis groups. The cutoff of CT value distribution percentage for differentiating osteoporosis from non-osteoporosis was obtained by drawing a receiver operating characteristic (ROC) curve. The sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) were calculated. All statistical analyses were performed using the IBM SPSS statistical software (version 22.0), and two-tailed $p<0.05$ was considered statistically significant.

RESULTS

The CT value distribution percentages in all four levels in osteoporosis group were significant different from those in non-osteoporosis group (all $p<0.05$). Specifically, the percentage in level A showed the best diagnostic performance for osteoporosis, and provided the area-under-the-curve (AUC), sensitivity, specificity, PPV and NPV of 0.805, 0.818, 0.745, 0.654 and 0.748, respectively with a cutoff of 18.74%.

CONCLUSION

s The distribution percentage of CT value based on spectral histogram could predict osteoporosis and have a good diagnostic performance.

CLINICAL RELEVANCE/APPLICATION

CT value distribution percentage based on DEsCT could provide more information about osteoporosis.

S3B-SPPH-9

Technical Performance Study of the First Mobile Photon-Counting Detector CT

Sunday, Nov. 27 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Junyoung Park, Suwon-Si, Korea, Republic Of (*Presenter*) Employee, Samsung Electronics Co, Ltd

PURPOSE

The purpose of this study is to evaluate the unique applications of photon-counting detectors (PCD) CT. The first is ability to "on demand" changes the scanner spatial resolution. The second is the ability to do "simultaneous" multi-energy scanning for material decomposition.

METHODS AND MATERIALS

In this study, the FDA 510(k) cleared mobile PCD-CT (OmniTom Elite) was used. The diagnostic performance of the scanner was proven using three clinical scans. The spatial resolution of the PCD-CT scanner was tested using the high contrast module of ACR accreditation phantom. The spatial resolutions of a large detector pitch of 0.71-mm (14 lp/cm) and a smaller pitch of 0.35-mm (28 lp/cm) for PCD-CT were tested. For multi-energy CT feasibility, Gammex phantom containing solid iodine and calcium inserts was scanned with three energy thresholds using PCD-CT. For material decomposition capability of PCD-CT, the iodine, calcium, and water maps were generated. Virtual mono-energetic images (VMI) from 40 keV to 120 keV were synthesized and the linear attenuation coefficients (LAC) of all the inserts of Gammex phantom were compared against manufacturer reference values.

RESULTS

The small pitch acquisition mode shows the highest resolution pattern of 11 lp/cm while only the resolution pattern of 7 lp/cm is seen when the same kernel (Posterior Fossa-kernel) is used in large pitch acquisition mode. For the quantitative multi-energy CT performance, the measured LAC in VMI of inserts of Gammex phantom matched the manufacturer reference values with mean percent error of 0.986%. In addition, the decomposition results with PCD-CT show that the iodine, calcium, and water can be well separated and quantified.

CONCLUSION

s We have shown that the PCD detector CT can accommodate a multiple resolution acquisition mode without physically changing the detector CT. The first clinical mobile PCD-CT can provide superior spatial resolution than large pitch acquisition mode which is equivalent with conventional mobile CT. Additionally, the results from quantitative multi-energy CT performance demonstrated that the PCD-CT was able to provide reliable simultaneous multi-energy images for material decomposition with single exposure.

CLINICAL RELEVANCE/APPLICATION

The validated unique characteristics of PCD-CT are highly desirable in clinical scanning. The ability to switch between different acquisition modes expands the clinical use of the scanner, e.g., high resolution temporal bone scans and lower resolution abdominal imaging. The capability of simultaneous multi-energy imaging leads to a precise registration that is needed to ensure the success of various multi-energy applications, including generation of material decomposition maps, VMI and virtual non-contrast images.

S3B-SPRO-1 The Effects of Human Placental Mesenchymal Stem Cells Labelled With Ultra Small Superparamagnetic Iron Oxides on the Growth of Colorectal Cancer (CRC) Cells

Participants
Hua He, MMedSc, MMedSc, Yinchuan, China (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the effects of human placental mesenchymal stem cells (PMSCs) labelled with ultrasmall superparamagnetic iron oxides (USPIO) on the growth of colorectal cancer (CRC) cells.

METHODS AND MATERIALS

PMSCs were labeled with USPIOs, and their biological characteristics were identified. A subcutaneous CRC HT-29 xenograft model in immunodeficient mice was established, and we attempted to consider the labeled cells as experimental group and the unlabeled cells as control group. USPIOs and poly-L-lysine (PLL) were mixed at a ratio of 1:0.03, placed in a vortex mixer at 2200 r/min, and shaken for 30 min to form PLL-USPIO complex. The number of Prussian blue-stained and unstained cells were counted using hemocytometer (× 100) under an inverted microscope and labeling efficiency is determined by percentage of Prussian blue-stained positive cells over total cells. The growth of xenograft tumors of nude mice was assessed, then, diameter of each transplanted tumor was measured every 3-4 days, and the growth curve was plotted to calculate the volume of tumor.

RESULTS

? USPIO labelled PMSCs had no significant influence on biological characteristics, such as cell viability, proliferation ability, and apoptosis rate (P> 0.05). ?The low signal area can be seen in the experimental group on the first day, on the 7th day, the regions with low signal intensity were narrowed, and these regions in the tumor partly showed poor clarity, whereas the signal intensities did not significantly change. On the 14th day, the tumor volume was 420mm3, CD31 and CD34 is (65±15.7), (58±14.5), and the positive expression rate of Ki67 >50%. ?The T2*mapping has the best tracking ability for USPIO-labeled cells.

CONCLUSION

s USPIO labeled PMSCs had high labeling efficiency, while cell viability, proliferation ability, and apoptotic rate were not markedly influenced. It has a certain inhibitory effect on the growth of the transplanted tumor volume, but has no obvious effect on the proliferation and angiogenesis of the tumor.

CLINICAL RELEVANCE/APPLICATION

Provide basic research data for the targeted therapy of placental mesenchymal stem cells in colorectal cancer.

T2-SPBR-1 Different Imaging Modalities for The Diagnosis of Axillary Lymph Node Metastases in Breast Cancer: A Systematic Review and Network Meta-analysis

Participants
Zhifan Li, (*Presenter*) Nothing to Disclose

PURPOSE

We conducted this network meta-analysis (NMA) to evaluate the diagnostic performance of different imaging modalities for the detection of axillary lymph node metastasis (ALNM) in patients with breast cancer.

METHODS AND MATERIALS

PubMed, EMBASE, Cochrane Library, and Web of Science were searched from inception to November 2021 to identify relevant studies. The Quality Assessment of Diagnostic Accuracy Studies-2 (QUADAS-2) tool was used to assess the methodological quality of the included studies. Meta-analyses of individual imaging modalities, pairwise meta-analyses and Bayesian network meta-analyses were applied for data analysis. Sensitivity and specificity, relative sensitivity and specificity, diagnostic odds ratio (DOR), and superiority index, and their associated 95% confidence intervals (CI) were used to assess the diagnostic value of different imaging modalities.

RESULTS

A total of 61 studies were identified, including 8011 participants across 9 imaging modalities. The 9 imaging modalities included US, MRI, MMG, PET/CT, UE, CT, PET, SMM, and PET/MRI. On patient-based level, network meta-analysis showed that UE had the highest superiority index (5.95) with the highest sensitivity of 0.75 (95%CI: 0.62-0.85) and moderate specificity of 0.85 (95%CI: 0.76-0.92). At the lymph node level, network meta-analysis revealed that MRI had the highest superiority index (6.91) with the highest sensitivity of 0.91 (95%CI: 0.82-0.97) and the highest specificity of 0.87 (95%CI: 0.75-0.95).

CONCLUSION

s UE and MRI were recommended for the diagnosis of ALNM in breast cancer patients at the patient level and at the lymph node level, respectively. Given the low quality of some diagnostic accuracy studies and the imbalance in the number of studies among different imaging methods, further studies are needed to provide strong evidence to validate the conclusions.

CLINICAL RELEVANCE/APPLICATION

Axillary lymph node metastasis (ALNM) is considered to be a significant prognostic indicator in breast cancer. Accurate diagnosis of axillary lymph node (ALN) status of breast cancer patients is critical to guide local and systemic treatment. In addition to US, imaging modalities such as MMG, MRI, PET, CT, PET/CT are also increasingly used to assess LN status in breast cancer patients. However, the jury is still out on which imaging mothed has the best diagnostic performance. Therefore, we conducted this network meta-analysis to evaluate the diagnostic performance of different imaging modalities for the ALNM in patients with breast cancer. Our results provide a comprehensive overview of the existing evidence on the imaging diagnosis of ALNM in breast cancer patients and have implications for clinicians, researchers, radiologists, and guideline committees.

T2-SPBR-2 Prediction of Primary Tumour and Axillary Lymph Node Response to Neoadjuvant Systemic Therapy with Dedicated Breast [18F]FDG PET/MRI in Breast Cancer

Participants
Thiemo Van Nijnatten, Maastricht, Netherlands (*Presenter*) Nothing to Disclose

PURPOSE

To investigate whether sequential dedicated breast hybrid [18F]FDG PET/MRI can be used to predict pathologic response to neoadjuvant systemic therapy (NST) in breast cancer.

METHODS AND MATERIALS

Between February 2015 and July 2017, patients were planned for [18F]FDG PET/MRI before, halfway and following completion NST followed by surgery. Qualitative response evaluation following NST was based on [18F]FDG-activity on PET and residual enhancement on MRI. Quantitatively, maximum standardized uptake value (SUVmax) on PET and signal enhancement ratio (SER) on dynamic contrast enhanced (DCE)-MRI were determined on the primary tumour. For response of axillary lymph node metastases (ALNMs), SUVmax was determined on the most FDG-avid ALN. Receiver operating characteristic (ROC) curves were generated to

determine optimal cut-off values for absolute and percentage change in quantitative variables in predicting response. Diagnostic performance in predicting primary tumour response was assessed with the area under the ROC curve (AUC). Similar analyses were performed in clinically node-positive (cN+) patients for ALNM response.

RESULTS

Forty-one breast cancer patients with 42 primary tumours and 26 pathologically proven cN+ axillae were prospectively included. Pathological complete response (pCR) of the primary tumour occurred in 16 of all patients and pCR of the ALNMs in 14 of cN+ patients. The AUC of the qualitative evaluation was 0.71 (95% CI 0.53 - 0.89) for primary tumour and 0.54 (95% CI 0.27 - 0.80) for ALNM response. For primary tumour response, combining the percentage decrease in SUVmax and SER halfway NST achieved an AUC of 0.78 (0.63 - 0.93). Additionally, combining the absolute as well as the percentage decrease in SUVmax halfway NST improved AUC for ALNM response prediction to 0.92 (0.79 - 1.00).

CONCLUSION

s Qualitative PET/MRI following NST can predict final pathologic primary tumour but not ALNM response.

CLINICAL RELEVANCE/APPLICATION

Combining quantitative variables from sequential imaging halfway NST can improve the diagnostic accuracy for final pathologic ALNM response prediction.

T2-SPBR-3 Predicting Recurrence Risk of Breast Cancer with Machine Learning in Patients Receiving Adjuvant Tamoxifen/Aromatase Inhibitors

Participants
Saba Dadsetan, BSc, PhD, Pittsburgh, PA (*Presenter*) Nothing to Disclose

PURPOSE

Clinical factors, radiomics, and deep learning (DL) were used to assess recurrence risk in women undergoing tamoxifen/aromatase inhibitor (AI) therapy in a retrospective cohort.

METHODS AND MATERIALS

Baseline (before tamoxifen/AI) and follow-up (after tamoxifen/AI) processed digital mammograms for 679 women (aged 28-93) with unilateral breast cancer were reviewed under an IRB-approved protocol, including: 58 recurrences (16 in breast, 42 distant), 121 new primary cancers, and 500 "control" cases without recurrence and at least 5-year follow-up. Using radiomics extracted from dense/whole breast tissue (unaffected breast) and DL, we classified two binary tasks: Task 1) controls (500 cases) vs. new primary (121 cases), and Task 2) controls vs. any recurrence (179 cases). CC- and MLO-views were incorporated separately and together at baseline and follow-up. We evaluated 15 adding clinical variables (e.g., initial tumor T, N stage, receptors, etc.). We used logistic regression and LASSO to model radiomics. DL used InceptionResnetV2 as its backbone. Breast dense area was segmented using LIBRA and breast density was quantified. For each task, patients were randomly divided 70-15-15% for training, validation, and testing. We used area under the ROC curve (AUC) as evaluation metric.

RESULTS

Clinical factors alone yielded AUCs of 0.68 (Task 1) and 0.69 (Task 2). By using both baseline and follow-up mammograms, MLO-view whole-breast radiomics produced AUCs of 0.75 (Task 1) and 0.63 (Task 2), while radiomics of the dense area revealed AUCs of 0.73 (Task 1) and 0.62 (Task 2). Combining radiomics and clinical factors increased AUC for Task 1 and Task 2 for the whole breast to 0.80 (p=0.03) and 0.80 (p=0.001), respectively, and for the dense area, AUCs rose to 0.79 (p=0.04) and 0.75 (p=0.001), respectively. With DL on whole-breast, Tasks 1 and 2 had AUCs of 0.86 and 0.74, respectively, when using baseline MLO-view only, and 0.77 and 0.79 when using both MLO- and CC-views at baseline and follow-up. DL outperformed (all p<0.03) radiomics when compared at the same settings. Adding clinical factors did not improve DL results (p>0.05). Quantitative change in breast density between baseline and follow-up was not predictive of recurrence risk (AUC=0.50 Task 1 and 0.52 Task 2).

CONCLUSION

s In patients with tamoxifen/AI treatment, radiomics and DL of contralateral cancer-unaffected mammograms and clinical factors predicted risk of recurrence. DL outperformed radiomics. The baseline mammograms show the highest AUC with DL for predicting new primary cancers.

CLINICAL RELEVANCE/APPLICATION

In patients undergoing tamoxifen/AI treatment, machine learning may enhance prediction of risk of recurrent breast cancer and provide model-based biomarkers of treatment responsiveness.

T2-SPBR-4 Head-to Head Comparison of 18F-FDG and 18F-FEC PET/MRI in Breast Cancer Patients: What Is the Difference?

Participants
Nina Poetsch, MD, Wien, Austria (*Presenter*) Nothing to Disclose

PURPOSE

18F-Fluoroethylcholine (18F-FEC) is a PET tracer able to evaluate choline metabolism. Its usefulness for breast cancer is underinvestigated, and no studies compared the performance with the current standard (18F-Fluorodesoxyglucose, 18F-FDG). We compared 18F-FDG to 18F-FEC in a matched PET/MRI cohort.

METHODS AND MATERIALS

Local staging PET/MRI scans of patients > 18 years with histologically verified breast cancer were retrospectively analyzed. Patients were matched based on age, tumor size, nodal status, histologic- and molecular subtype. SUVmax and parenchyma uptake were measured by a nuclear medicine physician, tumor to background (T/B) was calculated. Tumor visibility was rated on a 5-point Likert scale (1-no tumor detectable; 5-excellent tumor visualization) by a breast radiology fellow. Mann-Whitney-U test was used to compare SUV and T/B with tumor characteristics.

RESULTS

We investigated 104 patients with 106 malignant breast lesions matched in 52 pairs. On a 5-point Likert scale lesion visibility was rated equal in 18F-FEC and 18F-FDG studies (mean 4.6 and 4.4). SUVmax values were higher for 18F-FDG compared to 18F-FEC (4.6 vs. 3.7, p=0.037). The T/B ratio was higher in 18F-FEC (6.2 vs. 13.3, p<0.001). Both tracers showed higher SUVmax (p<0.001) in tumors with a higher proliferation index (MIB >20%). 18F-FDG showed higher SUVmax in ER negative tumors (p=0.032). No difference was observed in SUVmax for 18F-FDG and 18F-FEC regarding Her2 status and for 18F-FEC regarding ER status.

CONCLUSION

s Tumor visibility and metabolic activity were equal between 18F-FDG and 18F-FEC.Both were higher in tumors with higher proliferation index. 18F- FDG showed higher metabolic activity in ER negative tumors while 18F-FEC performs diagnostically independent from receptor status.

CLINICAL RELEVANCE/APPLICATION

These results confirm the in vivo equality of 18F-FEC to 18F-FDG as a potential alternative tracer for PET/MRI imaging in breast cancer patients. While 18F-FDG may indicate hormonal receptor status, 18F-FEC is applicable independent of receptor status.

T2-SPBR-5 High-resolution Diffusion-weighted Breast MRI: Improved Lesion Visibility and Image Quality with Water-excitation and Inversion-Recovery Fat Suppression

Participants
Stephanie Sauer, Wuerzburg, 97080, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To investigate subjective and semiquantitative criteria of image quality in high-resolution breast MRI with different fat suppression techniques for diffusion-weighted imaging (DWI).

METHODS AND MATERIALS

Three 5-minute echo-planar DWI sequences with different fat suppression techniques were acquired on a 3-Tesla MRI scanner in 83 patients (age 50.1 ± 12.6 years). DWI methods included fat suppression with non-product optimized water-excitation with spectral fat saturation (WE), spectral attenuated inversion recovery (SPAIR), and standard spectral fat saturation (FS). Three radiologists assessed overall image quality and lesion visibility (28 malignant, 60 benign) on images with b value of 800 s/mm2and apparent diffusion coefficient (ADC) maps. For all fat suppression methods, the longest diameter, mean signal intensity in DWI, and average ADC value of each lesion were measured.

RESULTS

Image quality and lesion visibility in WE and SPAIR DWI was considered better than in standard FS DWI (p<.001). Correspondingly, mean signal-intensity ratios of WE (3.0 ± 2.2) and SPAIR sequences (3.3 ± 2.8) were superior to DWI with spectral fat saturation (2.0 ± 1.1; p<.001). Estimated lesion size difference between DWI and contrast-enhanced subtraction T1 images was smaller in WE (0.5 ± 2.6 mm) and SPAIR DWI (0.4 ± 2.5 mm) compared to FS DWI (2.0 ± 3.5 mm; all p<.001). Differences in mean ADC values between malignant and benign lesions were comparable between all three DWI methods (WE 0.524 x 10-3; SPAIR 0.509 x 10-3; FS 0.509 x 10-3 mm2/s).

CONCLUSION

s Both WE and SPAIR DWI provide better image quality, subjective lesion visibility, and signal-intensity ratios than DWI with standard spectral fat saturation, resulting in a more accurate estimation of lesion size.

CLINICAL RELEVANCE/APPLICATION

The choice of fat suppression method may influence diagnostic assessment in diffusion-weighted breast MRI. Both water excitation and inversion recovery techniques allow for excellent depiction of benign and malignant lesions at 3 Tesla.

T2-SPBR-6 Utility of Kaiser Score for Focal Incidental Breast Uptake In a Diagnosed Malignant Population Undergoing 18 FDG PET-CT

Participants
Ankush Jajodia, MD, MBBS, New Delhi, India (*Presenter*) Nothing to Disclose

PURPOSE

We compared the diagnostic accuracies of ACR BIRADS, Kaiser score, and SUVmax in focal incidental breast uptake (FIBU) on 18FDG PET-CT in a diagnosed population with primary cancers excluding breast.

METHODS AND MATERIALS

A retrospective analysis in 21,657 female subjects with "FIBU" on 18 FDG PET-CT imaging in two hundred six subjects, between January 2010 and January 2020, including mass and non-mass enhancement (NME). ACR-BI-RADS category, Kaiser score, and SUVmax was derived for each lesion. Upgrade or downgrade was tabulated in an excel sheet. Independent samples t-test, diagnostic test calculator, and MedCalc 12.2.1 were used for statistical analysis.

RESULTS

According to the ACR lexicon, eighty lesions with eighteen BI-RADS 3 lesions, forty-seven BI-RADS 4, and fifteen BI-RADS 5 lesions with benign histology in 13% (10/80) and malignant in 87% (70/80). For benign lesions, SUV max range was 1.6-29.3, while for malignant lesions, it was 2.1-22.7(p=0.257). Kaiser score (p=0.002) assignment was statistically significant between the two groups. Kaiser score AUC (0.878; 95% CI: 0.786-0.94) was significantly high than ACR BIRADS (0.610; 95% CI :0.494-0.717) and SUVmax (0.566;95% CI:0.451-0.677). Ninety-four percent (48/51) of upgraded lesions were found to be malignant; benign histology was found in the remaining 5.9% percent (3/51). All (100%) of lesions (4/4) were correctly downgraded. All (100 %) lesions (18/18) which were incorrectly classified as ACR BIRADS 3 were correctly classified now as suspicious 4/5 category. When we used a Kaiser score of >4 as a cut-off for malignancy, we got 100% sensitivity. Using six as a cut-off score, sensitivity dropped to 85.7%, but specificity went up to 60% from 40%, with a positive likelihood ratio of 2.14. (vs. 1.67 with a cut-off score of 4).

When we used a high cut-off value >8 to rule-in malignancy, we were correct in 96.4% of the cases (54/56), with a specificity of 80% and a positive likelihood ratio of 3.71. We were able to identify all four lesions that had been downgraded from suspicious (BIRADS 4/5 category) to benign (BIRADS 5) when we set a cut-off Kaiser score of 5, thus potentially avoiding biopsies 100% of the time.

CONCLUSION

s Kaiser score has meaningfully better diagnostic accuracy than ACR BIRADS and SUVmax for focal incidentally breast uptake.

CLINICAL RELEVANCE/APPLICATION

Kaiser score has highest diagnostic accuracy than ACR BIRADS and SUVmax for focal incidentally breast uptake. Our study validates the clinical benefit of Kaiser score in correctly assigning suspicious 4/5 category to lesions falsely classified as ACR BIRADS 3.

T2-SPBR-7 Quantitative Analysis of Enhancement Characteristics of Contrast-enhanced Spectral Mammography in Differentiating Malignant from Benign Breast Lesions

Participants
Huizhi Cao, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

To quantitatively analyze the enhancement Characteristics of breast lesions on contrast-enhanced spectral mammography (CESM) to improve the diagnostic efficiency.

METHODS AND MATERIALS

A total of 283 patients with breast lesions admitted from August 2021 to Feb 2022 were retrospectively analyzed. Quantitative analysis of all enhancing lesions was performed to measure the ehancement values of the lesion area of interest (ROI), tissue surrounding the lesion (ROI1), tissue away from the lesion and close to the chest (ROI2), and the tissue at the level of the maximum diameter of the normal pectoralis major muscle on the ipsilateral side of the lesion (ROI3). rROI1, rROI2 and rROI3 were relative enhancement value between (ROI1,ROI2 and ROI3) and ROI . Differences in enhancement values between different ROIs of benign and malignant lesions were compared. Taking the pathological results as the gold standard, we used the receiver operating characteristic (ROC) curve to evaluate the diagnostic efficacy of the ROI enhancement value and rROI for the lesions.

RESULTS

A total of 299 lesions were found in 283 patients, including 101 benign lesions and 198 malignant lesions. The ROI enhancement value, rROI1, rROI2, and rROI3 of malignant lesions were all significantly greater than those of benign lesions. For enhancement values of benign and malignant lesions of ROI, rROI1, rROI2 and rROI3 , AUC was 0.795, 0.833, 0.812 and 0.741, respectively. The statistically significant difference in the AUC was only found between rROI1 and ROI enhancement value, and rROI1 had the greatest diagnostic value.

CONCLUSION

s The enhancement value of malignant breast lesions was higher than that of benign lesions. The quantitative analysis of the enhancement value was of great value in the differential diagnosis of benign and malignant breast lesions.

CLINICAL RELEVANCE/APPLICATION

Quantitative analysis in Contrast-enhanced spectral mammography has the potential value in the differential diagnosis of benign and malignant breast lesions.

Different Imaging Modalities for The Diagnosis of Axillary Lymph Node Metastases in Breast Cancer: A Systematic Review and Network Meta-analysis

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - BR DPS

Participants
Zhifan Li, (*Presenter*) Nothing to Disclose

PURPOSE

We conducted this network meta-analysis (NMA) to evaluate the diagnostic performance of different imaging modalities for the detection of axillary lymph node metastasis (ALNM) in patients with breast cancer.

METHODS AND MATERIALS

PubMed, EMBASE, Cochrane Library, and Web of Science were searched from inception to November 2021 to identify relevant studies. The Quality Assessment of Diagnostic Accuracy Studies-2 (QUADAS-2) tool was used to assess the methodological quality of the included studies. Meta-analyses of individual imaging modalities, pairwise meta-analyses and Bayesian network meta-analyses were applied for data analysis. Sensitivity and specificity, relative sensitivity and specificity, diagnostic odds ratio (DOR), and superiority index, and their associated 95% confidence intervals (CI) were used to assess the diagnostic value of different imaging modalities.

RESULTS

A total of 61 studies were identified, including 8011 participants across 9 imaging modalities. The 9 imaging modalities included US, MRI, MMG, PET/CT, UE, CT, PET, SMM, and PET/MRI. On patient-based level, network meta-analysis showed that UE had the highest superiority index (5.95) with the highest sensitivity of 0.75 (95%CI: 0.62-0.85) and moderate specificity of 0.85 (95%CI: 0.76-0.92). At the lymph node level, network meta-analysis revealed that MRI had the highest superiority index (6.91) with the highest sensitivity of 0.91 (95%CI: 0.82-0.97) and the highest specificity of 0.87 (95%CI: 0.75-0.95).

CONCLUSION

s UE and MRI were recommended for the diagnosis of ALNM in breast cancer patients at the patient level and at the lymph node level, respectively. Given the low quality of some diagnostic accuracy studies and the imbalance in the number of studies among different imaging methods, further studies are needed to provide strong evidence to validate the conclusions.

CLINICAL RELEVANCE/APPLICATION

Axillary lymph node metastasis (ALNM) is considered to be a significant prognostic indicator in breast cancer. Accurate diagnosis of axillary lymph node (ALN) status of breast cancer patients is critical to guide local and systemic treatment. In addition to US, imaging modalities such as MMG, MRI, PET, CT, PET/CT are also increasingly used to assess LN status in breast cancer patients. However, the jury is still out on which imaging mothed has the best diagnostic performance. Therefore, we conducted this network meta-analysis to evaluate the diagnostic performance of different imaging modalities for the ALNM in patients with breast cancer. Our results provide a comprehensive overview of the existing evidence on the imaging diagnosis of ALNM in breast cancer patients and have implications for clinicians, researchers, radiologists, and guideline committees.

T2-SPBR-2

Prediction of Primary Tumour and Axillary Lymph Node Response to Neoadjuvant Systemic Therapy with Dedicated Breast [18F]FDG PET/MRI in Breast Cancer

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - BR DPS

Participants
Thiemo Van Nijnatten, Maastricht, Netherlands (*Presenter*) Nothing to Disclose

PURPOSE

To investigate whether sequential dedicated breast hybrid [18F]FDG PET/MRI can be used to predict pathologic response to neoadjuvant systemic therapy (NST) in breast cancer.

METHODS AND MATERIALS

Between February 2015 and July 2017, patients were planned for [18F]FDG PET/MRI before, halfway and following completion NST followed by surgery. Qualitative response evaluation following NST was based on [18F]FDG-activity on PET and residual enhancement on MRI. Quantitatively, maximum standardized uptake value (SUVmax) on PET and signal enhancement ratio (SER) on dynamic contrast enhanced (DCE)-MRI were determined on the primary tumour. For response of axillary lymph node metastases (ALNMs), SUVmax was determined on the most FDG-avid ALN. Receiver operating characteristic (ROC) curves were generated to determine optimal cut-off values for absolute and percentage change in quantitative variables in predicting response. Diagnostic performance in predicting primary tumour response was assessed with the area under the ROC curve (AUC). Similar analyses were performed in clinically node-positive (cN+) patients for ALNM response.

RESULTS

Forty-one breast cancer patients with 42 primary tumours and 26 pathologically proven cN+ axillae were prospectively included. Pathological complete response (pCR) of the primary tumour occurred in 16 of all patients and pCR of the ALNMs in 14 of cN+ patients. The AUC of the qualitative evaluation was 0.71 (95% CI 0.53 - 0.89) for primary tumour and 0.54 (95% CI 0.27 - 0.80) for ALNM response. For primary tumour response, combining the percentage decrease in SUVmax and SER halfway NST achieved an AUC of 0.78 (0.63 - 0.93). Additionally, combining the absolute as well as the percentage decrease in SUVmax halfway NST improved AUC for ALNM response prediction to 0.92 (0.79 - 1.00).

CONCLUSION

s Qualitative PET/MRI following NST can predict final pathologic primary tumour but not ALNM response.

CLINICAL RELEVANCE/APPLICATION

Combining quantitative variables from sequential imaging halfway NST can improve the diagnostic accuracy for final pathologic ALNM response prediction.

T2-SPBR-3

Predicting Recurrence Risk of Breast Cancer with Machine Learning in Patients Receiving Adjuvant Tamoxifen/Aromatase Inhibitors

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - BR DPS

Participants
Saba Dadsetan, BSc, PhD, Pittsburgh, PA (*Presenter*) Nothing to Disclose

PURPOSE

Clinical factors, radiomics, and deep learning (DL) were used to assess recurrence risk in women undergoing tamoxifen/aromatase inhibitor (AI) therapy in a retrospective cohort.

METHODS AND MATERIALS

Baseline (before tamoxifen/AI) and follow-up (after tamoxifen/AI) processed digital mammograms for 679 women (aged 28-93) with unilateral breast cancer were reviewed under an IRB-approved protocol, including: 58 recurrences (16 in breast, 42 distant), 121 new primary cancers, and 500 "control" cases without recurrence and at least 5-year follow-up. Using radiomics extracted from dense/whole breast tissue (unaffected breast) and DL, we classified two binary tasks: Task 1) controls (500 cases) vs. new primary (121 cases), and Task 2) controls vs. any recurrence (179 cases). CC- and MLO-views were incorporated separately and together at baseline and follow-up. We evaluated 15 adding clinical variables (e.g., initial tumor T, N stage, receptors, etc.). We used logistic regression and LASSO to model radiomics. DL used InceptionResnetV2 as its backbone. Breast dense area was segmented using LIBRA and breast density was quantified. For each task, patients were randomly divided 70-15-15% for training, validation, and testing. We used area under the ROC curve (AUC) as evaluation metric.

RESULTS

Clinical factors alone yielded AUCs of 0.68 (Task 1) and 0.69 (Task 2). By using both baseline and follow-up mammograms, MLO-view whole-breast radiomics produced AUCs of 0.75 (Task 1) and 0.63 (Task 2), while radiomics of the dense area revealed AUCs of 0.73 (Task 1) and 0.62 (Task 2). Combining radiomics and clinical factors increased AUC for Task 1 and Task 2 for the whole breast to 0.80 (p=0.03) and 0.80 (p=0.001), respectively, and for the dense area, AUCs rose to 0.79 (p=0.04) and 0.75 (p=0.001), respectively. With DL on whole-breast, Tasks 1 and 2 had AUCs of 0.86 and 0.74, respectively, when using baseline MLO-view only, and 0.77 and 0.79 when using both MLO- and CC-views at baseline and follow-up. DL outperformed (all p<0.03) radiomics when compared at the same settings. Adding clinical factors did not improve DL results (p>0.05). Quantitative change in breast density between baseline and follow-up was not predictive of recurrence risk (AUC=0.50 Task 1 and 0.52 Task 2).

CONCLUSION

s In patients with tamoxifen/AI treatment, radiomics and DL of contralateral cancer-unaffected mammograms and clinical factors predicted risk of recurrence. DL outperformed radiomics. The baseline mammograms show the highest AUC with DL for predicting new primary cancers.

CLINICAL RELEVANCE/APPLICATION

In patients undergoing tamoxifen/AI treatment, machine learning may enhance prediction of risk of recurrent breast cancer and provide model-based biomarkers of treatment responsiveness.

T2-SPBR-4

Head-to Head Comparison of 18F-FDG and 18F-FEC PET/MRI in Breast Cancer Patients: What Is the Difference?

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - BR DPS

Participants
Nina Poetsch, MD, Wien, Austria (*Presenter*) Nothing to Disclose

PURPOSE

18F-Fluoroethylcholine (18F-FEC) is a PET tracer able to evaluate choline metabolism. Its usefulness for breast cancer is underinvestigated, and no studies compared the performance with the current standard (18F-Fluorodesoxyglucose, 18F-FDG). We compared 18F-FDG to 18F-FEC in a matched PET/MRI cohort.

METHODS AND MATERIALS

Local staging PET/MRI scans of patients > 18 years with histologically verified breast cancer were retrospectively analyzed. Patients were matched based on age, tumor size, nodal status, histologic- and molecular subtype. SUVmax and parenchyma uptake were measured by a nuclear medicine physician, tumor to background (T/B) was calculated. Tumor visibility was rated on a 5-point Likert scale (1-no tumor detectable; 5-excellent tumor visualization) by a breast radiology fellow. Mann-Whitney-U test was used to compare SUV and T/B with tumor characteristics.

RESULTS

We investigated 104 patients with 106 malignant breast lesions matched in 52 pairs. On a 5-point Likert scale lesion visibility was rated equal in 18F-FEC and 18F-FDG studies (mean 4.6 and 4.4). SUVmax values were higher for 18F-FDG compared to 18F-FEC (4.6 vs. 3.7, p=0.037). The T/B ratio was higher in 18F-FEC (6.2 vs. 13.3, p<0.001). Both tracers showed higher SUVmax (p<0.001) in tumors with a higher proliferation index (MIB >20%). 18F-FDG showed higher SUVmax in ER negative tumors (p=0.032). No difference was observed in SUVmax for 18F-FDG and 18F-FEC regarding Her2 status and for 18F-FEC regarding ER status.

CONCLUSION

s Tumor visibility and metabolic activity were equal between 18F-FDG and 18F-FEC.Both were higher in tumors with higher proliferation index. 18F- FDG showed higher metabolic activity in ER negative tumors while 18F-FEC performs diagnostically independent from receptor status.

CLINICAL RELEVANCE/APPLICATION

These results confirm the in vivo equality of 18F-FEC to 18F-FDG as a potential alternative tracer for PET/MRI imaging in breast cancer patients. While 18F-FDG may indicate hormonal receptor status, 18F-FEC is applicable independent of receptor status.

High-resolution Diffusion-weighted Breast MRI: Improved Lesion Visibility and Image Quality with Water-excitation and Inversion-Recovery Fat Suppression

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - BR DPS

Participants
Stephanie Sauer, Wuerzburg, 97080, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To investigate subjective and semiquantitative criteria of image quality in high-resolution breast MRI with different fat suppression techniques for diffusion-weighted imaging (DWI).

METHODS AND MATERIALS

Three 5-minute echo-planar DWI sequences with different fat suppression techniques were acquired on a 3-Tesla MRI scanner in 83 patients (age 50.1 ± 12.6 years). DWI methods included fat suppression with non-product optimized water-excitation with spectral fat saturation (WE), spectral attenuated inversion recovery (SPAIR), and standard spectral fat saturation (FS). Three radiologists assessed overall image quality and lesion visibility (28 malignant, 60 benign) on images with b value of 800 s/mm2and apparent diffusion coefficient (ADC) maps. For all fat suppression methods, the longest diameter, mean signal intensity in DWI, and average ADC value of each lesion were measured.

RESULTS

Image quality and lesion visibility in WE and SPAIR DWI was considered better than in standard FS DWI ($p<.001$). Correspondingly, mean signal-intensity ratios of WE (3.0 ± 2.2) and SPAIR sequences (3.3 ± 2.8) were superior to DWI with spectral fat saturation (2.0 ± 1.1; $p<.001$). Estimated lesion size difference between DWI and contrast-enhanced subtraction T1 images was smaller in WE (0.5 ± 2.6 mm) and SPAIR DWI (0.4 ± 2.5 mm) compared to FS DWI (2.0 ± 3.5 mm; all $p<.001$). Differences in mean ADC values between malignant and benign lesions were comparable between all three DWI methods (WE 0.524 x 10-3; SPAIR 0.509 x 10-3; FS 0.509 x 10-3 mm2/s).

CONCLUSION

s Both WE and SPAIR DWI provide better image quality, subjective lesion visibility, and signal-intensity ratios than DWI with standard spectral fat saturation, resulting in a more accurate estimation of lesion size.

CLINICAL RELEVANCE/APPLICATION

The choice of fat suppression method may influence diagnostic assessment in diffusion-weighted breast MRI. Both water excitation and inversion recovery techniques allow for excellent depiction of benign and malignant lesions at 3 Tesla.

T2-SPBR-6

Utility of Kaiser Score for Focal Incidental Breast Uptake In a Diagnosed Malignant Population Undergoing 18 FDG PET-CT

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - BR DPS

Participants
Ankush Jajodia, MD, MBBS, New Delhi, India (*Presenter*) Nothing to Disclose

PURPOSE

We compared the diagnostic accuracies of ACR BIRADS, Kaiser score, and SUVmax in focal incidental breast uptake (FIBU) on 18FDG PET-CT in a diagnosed population with primary cancers excluding breast.

METHODS AND MATERIALS

A retrospective analysis in 21,657 female subjects with "FIBU" on 18 FDG PET-CT imaging in two hundred six subjects, between January 2010 and January 2020, including mass and non-mass enhancement (NME). ACR-BI-RADS category, Kaiser score, and SUVmax was derived for each lesion. Upgrade or downgrade was tabulated in an excel sheet. Independent samples t-test, diagnostic test calculator, and MedCalc 12.2.1 were used for statistical analysis.

RESULTS

According to the ACR lexicon, eighty lesions with eighteen BI-RADS 3 lesions, forty-seven BI-RADS 4, and fifteen BI-RADS 5 lesions with benign histology in 13% (10/80) and malignant in 87% (70/80). For benign lesions, SUV max range was 1.6-29.3, while for malignant lesions, it was 2.1-22.7(p=0.257). Kaiser score (p=0.002) assignment was statistically significant between the two groups. Kaiser score AUC (0.878; 95% CI: 0.786-0.94) was significantly high than ACR BIRADS (0.610; 95% CI :0.494-0.717) and SUVmax (0.566;95% CI:0.451-0.677). Ninety-four percent (48/51) of upgraded lesions were found to be malignant; benign histology was found in the remaining 5.9% percent (3/51). All (100%) of lesions (4/4) were correctly downgraded. All (100 %) lesions (18/18) which were incorrectly classified as ACR BIRADS 3 were correctly classified now as suspicious 4/5 category. When we used a Kaiser score of >4 as a cut-off for malignancy, we got 100% sensitivity. Using six as a cut-off score, sensitivity dropped to 85.7%, but specificity went up to 60% from 40%, with a positive likelihood ratio of 2.14. (vs. 1.67 with a cut-off score of 4). When we used a high cut-off value >8 to rule-in malignancy, we were correct in 96.4% of the cases (54/56), with a specificity of 80% and a positive likelihood ratio of 3.71. We were able to identify all four lesions that had been downgraded from suspicious (BIRADS 4/5 category) to benign (BIRADS 5) when we set a cut-off Kaiser score of 5, thus potentially avoiding biopsies 100% of the time.

CONCLUSION

s Kaiser score has meaningfully better diagnostic accuracy than ACR BIRADS and SUVmax for focal incidentally breast uptake.

CLINICAL RELEVANCE/APPLICATION

Kaiser score has highest diagnostic accuracy than ACR BIRADS and SUVmax for focal incidentally breast uptake. Our study validates the clinical benefit of Kaiser score in correctly assigning suspicious 4/5 category to lesions falsely classified as ACR BIRADS 3.

Quantitative Analysis of Enhancement Characteristics of Contrast-enhanced Spectral Mammography in Differentiating Malignant from Benign Breast Lesions

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - BR DPS

Participants
Huizhi Cao, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

To quantitatively analyze the enhancement Characteristics of breast lesions on contrast-enhanced spectral mammography (CESM) to improve the diagnostic efficiency.

METHODS AND MATERIALS

A total of 283 patients with breast lesions admitted from August 2021 to Feb 2022 were retrospectively analyzed. Quantitative analysis of all enhancing lesions was performed to measure the ehancement values of the lesion area of interest (ROI), tissue surrounding the lesion (ROI1), tissue away from the lesion and close to the chest (ROI2), and the tissue at the level of the maximum diameter of the normal pectoralis major muscle on the ipsilateral side of the lesion (ROI3). rROI1, rROI2 and rROI3 were relative enhancement value between (ROI1,ROI2 and ROI3) and ROI . Differences in enhancement values between different ROIs of benign and malignant lesions were compared. Taking the pathological results as the gold standard, we used the receiver operating characteristic (ROC) curve to evaluate the diagnostic efficacy of the ROI enhancement value and rROI for the lesions.

RESULTS

A total of 299 lesions were found in 283 patients, including 101 benign lesions and 198 malignant lesions. The ROI enhancement value, rROI1, rROI2, and rROI3 of malignant lesions were all significantly greater than those of benign lesions. For enhancement values of benign and malignant lesions of ROI, rROI1, rROI2 and rROI3 , AUC was 0.795, 0.833, 0.812 and 0.741, respectively. The statistically significant difference in the AUC was only found between rROI1 and ROI enhancement value, and rROI1 had the greatest diagnostic value.

CONCLUSION

s The enhancement value of malignant breast lesions was higher than that of benign lesions. The quantitative analysis of the enhancement value was of great value in the differential diagnosis of benign and malignant breast lesions.

CLINICAL RELEVANCE/APPLICATION

Quantitative analysis in Contrast-enhanced spectral mammography has the potential value in the differential diagnosis of benign and malignant breast lesions.

T2-SPCA-1 Epicardial Adipose Tissue Radiomics Features May Help Predict the Presence of Coronary Artery Disease on Unenhanced Computed Tomography Scans

Participants
Francesco Secchi, MD, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

our aim was to assess the potential of radiomics features of epicardial adipose tissue (EAT) quantified on unenhanced computed tomography (CT) scans for predicting the presence of coronary artery disease (CAD).

METHODS AND MATERIALS

Consecutive patients undergoing contrast enhanced cardiac CT were retrospectively included in this study. The pericardium was manually segmented on the most representative slice for EAT on unenhanced scans, and subsequently thresholded for the Hounsfield Units (HU) of adipose tissue to obtain a mask for EAT. The presence of CAD defined as at least one moderate or two mild stenoses in the coronary tree was assessed on contrast-enhanced, gated scans. Radiomics features were then extracted from the EAT mask, and utilized to construct a machine learning model to predict the presence of CAD at contrast-enhanced, cardiac CT.

RESULTS

our final study population was composed by 480 patients, 294 (61%) of whom males, with a median age of 66 years (interquartile range 56-73 years), 164 (34%) of whom presenting with CAD. Using a support vector machine-based model, trained on a 80:20 split with 10-fold cross validation, the area under the curve for predicting the presence of CAD on the testing was 77%.

CONCLUSION

s radiomics features of EAT may help predict the presence of CAD through the assessment of unenhanced CT scans for calcium scoring.

CLINICAL RELEVANCE/APPLICATION

the risk of CAD may also be predicted in patients undergoing unenhanced CT scans from the analysis of EAT features.

T2-SPCH-1 Comparison of CT Findings of Coronavirus Disease 2019 (COVID-19) Pneumonia Caused by Different Major Variants

Participants
Shohei Inui, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To explore the CT findings and progression pattern of the Alpha and Delta variants of COVID-19 by comparing them with the pre-existing wild type.

METHODS AND MATERIALS

In this retrospective comparative study, a total of 392 patients with COVID-19 were included: 118 patients with wild type (70 men, 56.8 ± 20.7 years), 137 with Alpha variant (93 men, 49.4 ± 17 years), and 137 with Delta variant (94 men, 45.4 ± 12.4). Chest CT evaluation included opacities and repairing changes as well as lesion distribution and laterality. Chest CT severity score was also calculated. These parameters were statistically compared across the variants.

RESULTS

Ground glass opacity (GGO) with consolidation and repairing changes were more frequent in the order of Delta variant, Alpha variant, and wild type throughout the disease course. Delta variant showed GGO with consolidation more conspicuously than did the other two on days 1 to 4 (vs. wild type, Bonferroni corrected-p=0.01; vs. Alpha variant, Bonferroni corrected-p=0.003) and days 5 to 8 (vs. wild type, Bonferroni corrected-p<0.001; vs. Alpha variant, Bonferroni corrected-p=0.003). Total lung CT severity scores of Delta variant were higher than those of wild type on days 1 to 4 and 5 to 8 (Bonferroni corrected-p=0.01 and Bonferroni corrected-p=0.005, respectively) and that of Alpha variant on days 1 to 4 (Bonferroni corrected-p=0.002). There were no differences in the CT findings between wild type and Alpha variant.

CONCLUSION

s Delta variant of COVID-19 showed GGO with reticulation or consolidation and repairing changes more conspicuously than did wild type and Alpha variant in the early phase. Chest CT scores of Delta variant were also higher than those of wild type during day 1 to 8 and Alpha variant during day 1 to 4.

CLINICAL RELEVANCE/APPLICATION

Pneumonia progression of Delta variant may be more rapid and severe in the early stage than in the other two. In contrast, there was no evidence of any difference in the CT findings between wild type and Alpha variant. The results of this study may be valuable for the ongoing and future battle with COVID-19 variants, reminding that different CT patterns may predispose different subtype infection and different clinical course.

T2-SPCH-2 Uncertainty Quantification in COVID-19 Detection Using Evidential Deep Learning

Participants
Shahriar Faghani, MD, BSc, Rochester, MN (*Presenter*) Nothing to Disclose

PURPOSE

One of the factors that hinders the adoption of deep learning (DL) in clinical settings is the presence of performance errors. Most studies in recent years have been focused on developing novel approaches to improve models' accuracy. However, current models lack the implicit ability to say "I don't know" when provided input data that is out-of-distribution for the training data; compared to radiologists who tend to be careful when unsure about the diagnosis. Therefore, measuring and reporting the uncertainty level of DL models can be an important factor in their application in medicine.

METHODS AND MATERIALS

We used evidential deep learning (EDL) to quantify the uncertainty of a DL model. In this approach, by replacing the softmax function with the parameters of a Dirichlet density distribution, the model learns to recognize data instances that contribute efficiently to the performance during training, while providing an uncertainty estimate. This model has a specific loss function that can be optimized through backpropagation. We first trained the model on anteroposterior (AP) pneumonia negative and typical COVID-19 pneumonia chest x-rays (CXRs) of the SIIM-FISABIO-RSNA dataset (n=4,531; 90% train set, 10% test set) to detect typical COVID-19 CXRs. We used images of atypical (n=474) and indeterminate (n=1049) COVID-19 CXRs from the same dataset to

measure models' uncertainty on unseen data. We also trained another DL model with cross-entropy loss for performance comparison. All the evaluation metrics are reported based on model performance on the holdout test set.

RESULTS

The EDL model reached a final accuracy of 88.77%, though training the same model with the cross-entropy loss yielded an accuracy of 87.22% over the test set. On the test set, the EDL model provided a median uncertainty score of 0.25 and 0.07 for normal and typical COVID-19 CXRs, respectively. The misclassified samples had higher uncertainty levels compared to the correctly classified ones. The EDL model was able to provide a wide range of uncertainty scores for CXRs with typical COVID-19 infection. Moreover, we tested our model on the indeterminate and atypical subsets and the median uncertainty scores were 0.32 and 0.35, respectively.

CONCLUSION

s Overall, this study demonstrates applicability of EDL in disease detection that could facilitate the use of DL in practice by providing uncertainty scores.

CLINICAL RELEVANCE/APPLICATION

When a deep learning model is going to be used in clinical practice, it should convey how uncertain it is when making a prediction, especially in out-of-distribution samples. This study shows a proof of concept of EDL technique in quantifying the level of uncertainty in a classification task, which can help guide the physicians on when a model cannot be trusted.

T2-SPCH-3 Results of Post-PCNB (Percutaneous Core Needle Biopsy) Sputum Cytology: Diagnostic Yield and Factors for Positive Prediction

Participants
Heejeong Yu, MD, Busan, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

We evaluated the results of the post-PCNB sputum cytology for diagnosing malignancy.

METHODS AND MATERIALS

This retrospective study included the 987 patients who underwent percutaneous CT or fluoroscopy guided PCNB from January 2014 to March 2022. Patients' demographics, lung lesions' characteristics including solid, subsolid, open-bronchus, necrosis, location, underlying pulmonary disease including COPD or fibrosis, histopathologic results of the biopsy specimens of PCNB, post-PCNB sputum and final diagnosis were reviewed.

RESULTS

Total 182 consecutive patients whose sputum specimens were obtained after PCNB for the intrapulmonary lesions were enrolled. Mean time between the day of PCNB and the day sputum specimens were obtained was 2 days (range 0-13). Final diagnoses of the patients were primary or metastatic lung cancer (n=157), benign pulmonary tumor (n=2), infection including bacteria, mycobacterium, fungus or parasite (n=22), and pneumoconiosis (n=1). Sufficient sputum specimens were obtained in 88 patients. The sufficient sputum was defined as containing =10 leukocytes and < 25 squamous epithelial cells per low-power field. The diagnostic sputum specimens with atypical or malignant cells were obtained in 12 patients. The mean size of the lesion was 57.1 mm (range 15-100) and the mean distance of the lesion from the pleura was 6.3 mm (range 0-38) in the diagnostic sputum specimens. The sensitivity, specificity, accuracy, PPV and NPV of post-PCNB sputum cytology were 7.64%, 100%, 20.33%, 100% and 14.71% respectively. There were no significant differences in the location, solidity, multiplicity, presence of mediastinal lymph node, necrosis and underlying pulmonary disease between the diagnostic and non-diagnostic sputum specimens. The lesion size (p=0.009, OR=1.037), open-bronchus (p=0.006, OR=23.232) and subtype of squamous cell (p=0.007, OR=7.108) were significantly related to diagnostic sputum results.

CONCLUSION

s Post-PCNB sputum cytology could be diagnostic in some peripheral lung cancer patients who have cell types of squamous cell, relatively large tumors and open-bronchi to the lesions.

CLINICAL RELEVANCE/APPLICATION

In some cases of peripheral lung cancer, malignant or atypical cells in the sputum cytology after PCNB can appear. It could be affected by the tumor size, presence of the open-bronchus to the tumor and subtype of squamous cell.

T2-SPCH-4 Worldwide Performance of Lung-RADS in Lung Cancer Screening: A Systematic Review and Meta-Analysis

Participants
Yifei Mao, (*Presenter*) Nothing to Disclose

PURPOSE

After the publication of Lung CT Screening Reporting and Data System (Lung-RADS), several lung cancer screenings have reported its performance, but it hasn't been validated systematically. In addition, compared to the initial version 1.0, there are multiple changes in updated version 1.1. Our aim of this meta-analysis is to evaluate and compare the diagnostic performance of Lung-RADS protocols version 1.0 and 1.1, and thereby explore whether Lung-RADS could be applicable for lung cancer screening worldwide.

METHODS AND MATERIALS

Literature search for original diagnostic studies of Lung-RADS in LDCT lung cancer screening was conducted in PubMed, Web of Science, Cochrane Library, and Embase databases up to June 1, 2021. Pooled sensitivity and specificity were calculated using a bivariate random-effects model. The potential cause of heterogeneity between studies was explored using stratified analysis and meta-regression analysis. The following covariates were evaluated: population type (high-risk population, or general population), geographic area (Asia, or Non-Asia), study design (retrospective or prospective), reference standard (pathology alone, or pathology and other methods), and lung cancer prevalence (>1.8%, or =1.8%).

RESULTS

Twenty-seven studies with 90,635 participants were included. Pooled sensitivity and specificity of Lung-RADS version 1.0 (24 studies) were 0.81 (95% confidence interval [CI]: 0.74-0.88) and 0.91 (95%CI: 0.89-0.93), respectively. Pooled sensitivity and specificity of Lung-RADS version 1.1 (three studies) were 0.91(95%CI: 0.83-0.99) and 0.66 (95%CI: 0.46-0.86), respectively. Population type (high-risk Vs. general population, p = 0.02), geographic area (Asia Vs. Non-Asia, p = 0.04), and prevalence of lung cancer (>1.8% Vs. =1.8%, p = 0.04) were significant factors for substantial heterogeneity among studies using Lung-RADS version 1.0.

CONCLUSION

s Substantial higher sensitivity and relatively smaller decrease in specificity of Lung-RADS version 1.0 were noted especially for studies with a high-risk population in Non-Asia areas. Lung-RADS version 1.1 might have higher sensitivity, but lower specificity than version 1.0 in LDCT lung cancer screening; however, there were only three studies using version 1.1. More evidence in Asia is still required to determine the worldwide applicability of Lung-RADS 1.1 protocol.

CLINICAL RELEVANCE/APPLICATION

1. This meta-analysis provides a sight to the applicability of Lung-RADS protocol in lung cancer screening worldwide. 2. Lung-RADS version 1.0 might be more applicable for the high-risk population in Non-Asia areas. Specifically tailored algorithm for Lung-RADS protocol might be needed for general population in Asia.

T2-SPCH-5 The Image Classification of Abnormal Lipiodol Distribution in Thoracic Lymphatic Reflux on MDCT Lymphangiography

Participants
Qi Hao, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

The aim of this study was to analyze the different types of lipiodol distribution and characteristic findings on MDCT lymphangiography in patients with thoracic lymphatic reflux.

METHODS AND MATERIALS

151 patients (84 males and 67 females) with thoracic lymphatic reflux underwent MDCT lymphangiography and abnormal lipiodol distributions in chest were retrospectively reviewed. The diseases spectrum included chylothorax (n=58) single or multiple lymphangiomas (n=46), diffuse pulmonary lymphangiomatosis (n=16), pulmonary lymphangioectasis (n=10), pulmonary lymphedema (n=12), pulmonary lymphangiomyomatosis (n=9) and chylopulmonary disease (n=6). There were 61 males and 90 females aged from 5.5 to 78 years (median age 35.8).

RESULTS

These patients were classified into 4 types according to lipiodol abnormal distribution on MDCTL: (1) type A is central type in 16 cases, lipiodol spotted distribution along peribronchovascular interstitium; (2) type B is superficial type in 91 cases: lipiodol diffused in peripheral lung tissue and visceral pleura; (3) type C is Intercostal type in 15 cases, lipiodol spotted distribution in parietal pleura and thoracic wall; (4) type D is mixed type in 29 cases, two or more types were exhibited at the same time. MDCTL findings including thoracic duct abnormalities in 147 patients with thoracic duct outlet stenosis in 108. Thoracic duct partially visible in group C were higher than that in the other 3 groups, with an incidence of 60.0%. Other image findings: type A was found with the highest incidence of peribronchovascular interstitium thickening(93.8%) and hydropericardium(81.3%), but the lowest incidence of atelectasis(62.5%), parietal pleura thickening(0) and ascites(0). Type B showed the highest incidence of atelectasis(97.8%) and ascites(69.2%), but the lowest incidence of peribronchovascular interstitium thickening(26.4%). In type C, the highest incidence of parietal pleura thickening(66.7%) was found. However, there was no characteristic performance in group D.

CONCLUSION

s This study summarized a classification of four different types according to the lipiodol deposition in patients with thoracic lymphatic reflux, which provide more information for clinical diagnosis.

CLINICAL RELEVANCE/APPLICATION

The four types of lipiodol abnormal distribution on MDCT lymphangiography provide more information for clinical diagnosis Thoracic lymphatic reflux .

T2-SPCH-6 Safe Zone to Avoid Pneumothorax in a CT-guided Lung Biopsy

Participants
Nour Maalouf, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Pneumothorax is one of the most frequent complications of a CT-guided lung biopsy. This study aims to define the safe window of the biopsy needle’s angle to the pleura during a CT-guided lung biopsy to diminish the risk of Pneumothorax.

METHODS AND MATERIALS

Forty-three patients underwent CT-guided lung biopsies between January 2020 and January 2022 (24 m, 19 f, median age 70 years). All the interventions were carried out with a semi-automatic 18G needle and a 17G trocar in a prone or supine position. Right and left angles were measured and correlated to the presence of pneumothorax as an intraprocedural or early postprocedural complication. The minimum delta was calculated as the absolute value of the difference between a 90-degree angle (perpendicular to the chest wall) and the right and left angles. T-test p-value for the minimum delta was calculated.

RESULTS

Out of the 43 patients, 28 experienced pneumothorax; intraprocedural and transient, postprocedural with minimal symptoms, or postprocedural with pronounced symptoms and requiring a chest tube insertion. 27 of the 43 patients had a minimum delta = 10, while 17 of them had a minimum delta < 10 degrees. 35% of the patients with a minimum delta < 10 degrees had pneumothorax,

while 81% of the patients with a minimum delta = 10 degrees had a pneumothorax (two-sided t-test p-value = 0.0017). A needle angle deviating from the perpendicular by more than 10 degrees correlated with a higher risk of pneumothorax development.

CONCLUSION

s The study results show that as the needle's angle deviates from the perpendicular with an absolute value of more than 10 degrees, the pleural surface area experiencing trauma increases, and the likelihood of pneumothorax occurrence increases significantly.

CLINICAL RELEVANCE/APPLICATION

CT-guided lung biopsy is widely used to gather valuable diagnostic information. On the downside, it still puts the patient at risk of developing pneumothorax. The present study provides quantitative data proving that adjusting the angle between the needle and the pleura can diminish the pneumothorax risk associated with a CT-guided lung biopsy. Opting for an angle close to 90 degrees between the needle and the pleura has been shown to reduce the risk of developing pneumothorax.

T2-SPCH-7 Four Efficacy Types of Chest CT Imaging Manifestations of Lung Metastasis of Digestive System Tumors after CART Treatment

Participants
Yiting Liu, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

Chimeric antigen receptor T cells (CART) are more lethal and specific than other immunotherapies. However, the immune response of lung metastases has not been investigated. Here, we evaluated the efficacy of CART on the pulmonary CT immune response.

METHODS AND MATERIALS

Fifteen patients were enrolled from clinical trial NCT03874897. Patients had digestive system cancer with lung metastases and received CART therapy together with complete plain chest CT before and after treatment. Tumor responses were assessed according to RECIST 1.1.

RESULTS

Four response types to CART therapy were observed, ranked from best to worst: ? Immuno-enrichment of metastasis nodule (IE-MN) Three patients showed expanded metastasis foci 2-4 days after treatment suggestive of progressive disease. However, the foci shrank within 4-23 days, indicative of pseudoprogression. Halo signs (ground glass density shadows) and/or thickening of interlobular septa were observed around the nodules, forming a "paving stone" sign. These reactions were synchronous with pseudoprogression of the metastatic nodules. ? Immuno-enrichment of normal lung (IE-NL) This was seen in six patients, appeared similar to type 1, and was characterized by: diffuse ground glass shadow (6/6); interstitial thickening, with significant axial interstitial thickening (4/6); paving stone signs (3/6); consolidation (4/6). As with type 1, the timelines were synchronized with pseudoprogression. The OS was 149-546 days. ? No immuno-enrichment of normal lung (nIE-NL) None of the five patients showed signs of immune hyperplasia or immune pneumonia. Metastatic nodules progressed in two patients and remained stable in three patients. Survival was poorer than in 1 and 2. ? Immuno-enrichment of lymphangitic carcinomatosis (IE-LC) The two patients showed obvious axial interstitial thickening. Peri-lymphatic nodules were diffused along the broncho-vascular bundle, subpleural, and interlobular septa. Patchy ground-glass shadow signs caused by exudative changes were rare.

CONCLUSION

s The first two types are indicative of treatment effectiveness. The response was better (60% vs 12.6%) and faster (median 13 d vs 84 d) compared with ICIs. Lymphangitic spread of carcinoma is often a sign of poor prognosis.

CLINICAL RELEVANCE/APPLICATION

Imaging of the chest response after CART therapy for solid tumors was classified to elucidate the biological mechanism and judge the overall response according to different chest responses.

Comparison of CT Findings of Coronavirus Disease 2019 (COVID-19) Pneumonia Caused by Different Major Variants

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - CH DPS

Participants
Shohei Inui, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To explore the CT findings and progression pattern of the Alpha and Delta variants of COVID-19 by comparing them with the pre-existing wild type.

METHODS AND MATERIALS

In this retrospective comparative study, a total of 392 patients with COVID-19 were included: 118 patients with wild type (70 men, 56.8 ± 20.7 years), 137 with Alpha variant (93 men, 49.4 ± 17 years), and 137 with Delta variant (94 men, 45.4 ± 12.4). Chest CT evaluation included opacities and repairing changes as well as lesion distribution and laterality. Chest CT severity score was also calculated. These parameters were statistically compared across the variants.

RESULTS

Ground glass opacity (GGO) with consolidation and repairing changes were more frequent in the order of Delta variant, Alpha variant, and wild type throughout the disease course. Delta variant showed GGO with consolidation more conspicuously than did the other two on days 1 to 4 (vs. wild type, Bonferroni corrected-p=0.01; vs. Alpha variant, Bonferroni corrected-p=0.003) and days 5 to 8 (vs. wild type, Bonferroni corrected-p<0.001; vs. Alpha variant, Bonferroni corrected-p=0.003). Total lung CT severity scores of Delta variant were higher than those of wild type on days 1 to 4 and 5 to 8 (Bonferroni corrected-p=0.01 and Bonferroni corrected-p=0.005, respectively) and that of Alpha variant on days 1 to 4 (Bonferroni corrected-p=0.002). There were no differences in the CT findings between wild type and Alpha variant.

CONCLUSION

s Delta variant of COVID-19 showed GGO with reticulation or consolidation and repairing changes more conspicuously than did wild type and Alpha variant in the early phase. Chest CT scores of Delta variant were also higher than those of wild type during day 1 to 8 and Alpha variant during day 1 to 4.

CLINICAL RELEVANCE/APPLICATION

Pneumonia progression of Delta variant may be more rapid and severe in the early stage than in the other two. In contrast, there was no evidence of any difference in the CT findings between wild type and Alpha variant. The results of this study may be valuable for the ongoing and future battle with COVID-19 variants, reminding that different CT patterns may predispose different subtype infection and different clinical course.

T2-SPCH-2

Uncertainty Quantification in COVID-19 Detection Using Evidential Deep Learning

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - CH DPS

Participants
Shahriar Faghani, MD, BSc, Rochester, MN (*Presenter*) Nothing to Disclose

PURPOSE

One of the factors that hinders the adoption of deep learning (DL) in clinical settings is the presence of performance errors. Most studies in recent years have been focused on developing novel approaches to improve models' accuracy. However, current models lack the implicit ability to say "I don't know" when provided input data that is out-of-distribution for the training data; compared to radiologists who tend to be careful when unsure about the diagnosis. Therefore, measuring and reporting the uncertainty level of DL models can be an important factor in their application in medicine.

METHODS AND MATERIALS

We used evidential deep learning (EDL) to quantify the uncertainty of a DL model. In this approach, by replacing the softmax function with the parameters of a Dirichlet density distribution, the model learns to recognize data instances that contribute efficiently to the performance during training, while providing an uncertainty estimate. This model has a specific loss function that can be optimized through backpropagation. We first trained the model on anteroposterior (AP) pneumonia negative and typical COVID-19 pneumonia chest x-rays (CXRs) of the SIIM-FISABIO-RSNA dataset (n=4,531; 90% train set, 10% test set) to detect typical COVID-19 CXRs. We used images of atypical (n=474) and indeterminate (n=1049) COVID-19 CXRs from the same dataset to measure models' uncertainty on unseen data. We also trained another DL model with cross-entropy loss for performance comparison. All the evaluation metrics are reported based on model performance on the holdout test set.

RESULTS

The EDL model reached a final accuracy of 88.77%, though training the same model with the cross-entropy loss yielded an accuracy of 87.22% over the test set. On the test set, the EDL model provided a median uncertainty score of 0.25 and 0.07 for normal and typical COVID-19 CXRs, respectively. The misclassified samples had higher uncertainty levels compared to the correctly classified ones. The EDL model was able to provide a wide range of uncertainty scores for CXRs with typical COVID-19 infection. Moreover, we tested our model on the indeterminate and atypical subsets and the median uncertainty scores were 0.32 and 0.35, respectively.

CONCLUSION

s Overall, this study demonstrates applicability of EDL in disease detection that could facilitate the use of DL in practice by providing uncertainty scores.

CLINICAL RELEVANCE/APPLICATION

When a deep learning model is going to be used in clinical practice, it should convey how uncertain it is when making a prediction, especially in out-of-distribution samples. This study shows a proof of concept of EDL technique in quantifying the level of uncertainty in a classification task, which can help guide the physicians on when a model cannot be trusted.

T2-SPCH-3

Results of Post-PCNB (Percutaneous Core Needle Biopsy) Sputum Cytology: Diagnostic Yield and Factors for Positive Prediction

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - CH DPS

Participants
Heejeong Yu, MD, Busan, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

We evaluated the results of the post-PCNB sputum cytology for diagnosing malignancy.

METHODS AND MATERIALS

This retrospective study included the 987 patients who underwent percutaneous CT or fluoroscopy guided PCNB from January 2014 to March 2022. Patients' demographics, lung lesions' characteristics including solid, subsolid, open-bronchus, necrosis, location, underlying pulmonary disease including COPD or fibrosis, histopathologic results of the biopsy specimens of PCNB, post-PCNB sputum and final diagnosis were reviewed.

RESULTS

Total 182 consecutive patients whose sputum specimens were obtained after PCNB for the intrapulmonary lesions were enrolled. Mean time between the day of PCNB and the day sputum specimens were obtained was 2 days (range 0-13). Final diagnoses of the patients were primary or metastatic lung cancer (n=157), benign pulmonary tumor (n=2), infection including bacteria, mycobacterium, fungus or parasite (n=22), and pneumoconiosis (n=1). Sufficient sputum specimens were obtained in 88 patients. The sufficient sputum was defined as containing =10 leukocytes and < 25 squamous epithelial cells per low-power field. The diagnostic sputum specimens with atypical or malignant cells were obtained in 12 patients. The mean size of the lesion was 57.1 mm (range 15-100) and the mean distance of the lesion from the pleura was 6.3 mm (range 0-38) in the diagnostic sputum specimens. The sensitivity, specificity, accuracy, PPV and NPV of post-PCNB sputum cytology were 7.64%, 100%, 20.33%, 100% and 14.71% respectively. There were no significant differences in the location, solidity, multiplicity, presence of mediastinal lymph node, necrosis and underlying pulmonary disease between the diagnostic and non-diagnostic sputum specimens. The lesion size (p=0.009, OR=1.037), open-bronchus (p=0.006, OR=23.232) and subtype of squamous cell (p=0.007, OR=7.108) were significantly related to diagnostic sputum results.

CONCLUSION

s Post-PCNB sputum cytology could be diagnostic in some peripheral lung cancer patients who have cell types of squamous cell, relatively large tumors and open-bronchi to the lesions.

CLINICAL RELEVANCE/APPLICATION

In some cases of peripheral lung cancer, malignant or atypical cells in the sputum cytology after PCNB can appear. It could be affected by the tumor size, presence of the open-bronchus to the tumor and subtype of squamous cell.

Worldwide Performance of Lung-RADS in Lung Cancer Screening: A Systematic Review and Meta-Analysis

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - CH DPS

Participants
Yifei Mao, (*Presenter*) Nothing to Disclose

PURPOSE

After the publication of Lung CT Screening Reporting and Data System (Lung-RADS), several lung cancer screenings have reported its performance, but it hasn't been validated systematically. In addition, compared to the initial version 1.0, there are multiple changes in updated version 1.1. Our aim of this meta-analysis is to evaluate and compare the diagnostic performance of Lung-RADS protocols version 1.0 and 1.1, and thereby explore whether Lung-RADS could be applicable for lung cancer screening worldwide.

METHODS AND MATERIALS

Literature search for original diagnostic studies of Lung-RADS in LDCT lung cancer screening was conducted in PubMed, Web of Science, Cochrane Library, and Embase databases up to June 1, 2021. Pooled sensitivity and specificity were calculated using a bivariate random-effects model. The potential cause of heterogeneity between studies was explored using stratified analysis and meta-regression analysis. The following covariates were evaluated: population type (high-risk population, or general population), geographic area (Asia, or Non-Asia), study design (retrospective or prospective), reference standard (pathology alone, or pathology and other methods), and lung cancer prevalence (>1.8%, or =1.8%).

RESULTS

Twenty-seven studies with 90,635 participants were included. Pooled sensitivity and specificity of Lung-RADS version 1.0 (24 studies) were 0.81 (95% confidence interval [CI]: 0.74-0.88) and 0.91 (95%CI: 0.89-0.93), respectively. Pooled sensitivity and specificity of Lung-RADS version 1.1 (three studies) were 0.91(95%CI: 0.83-0.99) and 0.66 (95%CI: 0.46-0.86), respectively. Population type (high-risk Vs. general population, p = 0.02), geographic area (Asia Vs. Non-Asia, p = 0.04), and prevalence of lung cancer (>1.8% Vs. =1.8%, p = 0.04) were significant factors for substantial heterogeneity among studies using Lung-RADS version 1.0.

CONCLUSION

s Substantial higher sensitivity and relatively smaller decrease in specificity of Lung-RADS version 1.0 were noted especially for studies with a high-risk population in Non-Asia areas. Lung-RADS version 1.1 might have higher sensitivity, but lower specificity than version 1.0 in LDCT lung cancer screening; however, there were only three studies using version 1.1. More evidence in Asia is still required to determine the worldwide applicability of Lung-RADS 1.1 protocol.

CLINICAL RELEVANCE/APPLICATION

1. This meta-analysis provides a sight to the applicability of Lung-RADS protocol in lung cancer screening worldwide. 2. Lung-RADS version 1.0 might be more applicable for the high-risk population in Non-Asia areas. Specifically tailored algorithm for Lung-RADS protocol might be needed for general population in Asia.

The Image Classification of Abnormal Lipiodol Distribution in Thoracic Lymphatic Reflux on MDCT Lymphangiography

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - CH DPS

Participants
Qi Hao, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

The aim of this study was to analyze the different types of lipiodol distribution and characteristic findings on MDCT lymphangiography in patients with thoracic lymphatic reflux.

METHODS AND MATERIALS

151 patients (84 males and 67 females) with thoracic lymphatic reflux underwent MDCT lymphangiography and abnormal lipiodol distributions in chest were retrospectively reviewed. The diseases spectrum included chylothorax (n=58) single or multiple lymphangiomas (n=46), diffuse pulmonary lymphangiomatosis (n=16), pulmonary lymphangioectasis (n=10), pulmonary lymphedema (n=12), pulmonary lymphangiomyomatosis (n=9) and chylopulmonary disease (n=6). There were 61 males and 90 females aged from 5.5 to 78 years (median age 35.8).

RESULTS

These patients were classified into 4 types according to lipiodol abnormal distribution on MDCTL: (1) type A is central type in 16 cases, lipiodol spotted distribution along peribronchovascular interstitium; (2) type B is superficial type in 91 cases: lipiodol diffused in peripheral lung tissue and visceral pleura; (3) type C is Intercostal type in 15 cases, lipiodol spotted distribution in parietal pleura and thoracic wall; (4) type D is mixed type in 29 cases, two or more types were exhibited at the same time. MDCTL findings including thoracic duct abnormalities in 147 patients with thoracic duct outlet stenosis in 108. Thoracic duct partially visible in group C were higher than that in the other 3 groups, with an incidence of 60.0%. Other image findings: type A was found with the highest incidence of peribronchovascular interstitium thickening(93.8%) and hydropericardium(81.3%), but the lowest incidence of atelectasis(62.5%), parietal pleura thickening(0) and ascites(0). Type B showed the highest incidence of atelectasis(97.8%) and ascites(69.2%), but the lowest incidence of peribronchovascular interstitium thickening(26.4%). In type C, the highest incidence of parietal pleura thickening(66.7%) was found. However, there was no characteristic performance in group D.

CONCLUSION

s This study summarized a classification of four different types according to the lipiodol deposition in patients with thoracic lymphatic reflux, which provide more information for clinical diagnosis.

CLINICAL RELEVANCE/APPLICATION

The four types of lipiodol abnormal distribution on MDCT lymphangiography provide more information for clinical diagnosis Thoracic lymphatic reflux .

T2-SPCH-6

Safe Zone to Avoid Pneumothorax in a CT-guided Lung Biopsy

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - CH DPS

Participants
Nour Maalouf, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Pneumothorax is one of the most frequent complications of a CT-guided lung biopsy. This study aims to define the safe window of the biopsy needle's angle to the pleura during a CT-guided lung biopsy to diminish the risk of Pneumothorax.

METHODS AND MATERIALS

Forty-three patients underwent CT-guided lung biopsies between January 2020 and January 2022 (24 m, 19 f, median age 70 years). All the interventions were carried out with a semi-automatic 18G needle and a 17G trocar in a prone or supine position. Right and left angles were measured and correlated to the presence of pneumothorax as an intraprocedural or early postprocedural complication. The minimum delta was calculated as the absolute value of the difference between a 90-degree angle (perpendicular to the chest wall) and the right and left angles. T-test p-value for the minimum delta was calculated.

RESULTS

Out of the 43 patients, 28 experienced pneumothorax; intraprocedural and transient, postprocedural with minimal symptoms, or postprocedural with pronounced symptoms and requiring a chest tube insertion. 27 of the 43 patients had a minimum delta = 10, while 17 of them had a minimum delta < 10 degrees. 35% of the patients with a minimum delta < 10 degrees had pneumothorax, while 81% of the patients with a minimum delta = 10 degrees had a pneumothorax (two-sided t-test p-value = 0.0017). A needle angle deviating from the perpendicular by more than 10 degrees correlated with a higher risk of pneumothorax development.

CONCLUSION

s The study results show that as the needle's angle deviates from the perpendicular with an absolute value of more than 10 degrees, the pleural surface area experiencing trauma increases, and the likelihood of pneumothorax occurrence increases significantly.

CLINICAL RELEVANCE/APPLICATION

CT-guided lung biopsy is widely used to gather valuable diagnostic information. On the downside, it still puts the patient at risk of developing pneumothorax. The present study provides quantitative data proving that adjusting the angle between the needle and the pleura can diminish the pneumothorax risk associated with a CT-guided lung biopsy. Opting for an angle close to 90 degrees between the needle and the pleura has been shown to reduce the risk of developing pneumothorax.

Four Efficacy Types of Chest CT Imaging Manifestations of Lung Metastasis of Digestive System Tumors after CART Treatment

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - CH DPS

Participants
Yiting Liu, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

Chimeric antigen receptor T cells (CART) are more lethal and specific than other immunotherapies. However, the immune response of lung metastases has not been investigated. Here, we evaluated the efficacy of CART on the pulmonary CT immune response.

METHODS AND MATERIALS

Fifteen patients were enrolled from clinical trial NCT03874897. Patients had digestive system cancer with lung metastases and received CART therapy together with complete plain chest CT before and after treatment. Tumor responses were assessed according to RECIST 1.1.

RESULTS

Four response types to CART therapy were observed, ranked from best to worst: ? Immuno-enrichment of metastasis nodule (IE-MN) Three patients showed expanded metastasis foci 2-4 days after treatment suggestive of progressive disease. However, the foci shrank within 4-23 days, indicative of pseudoprogression. Halo signs (ground glass density shadows) and/or thickening of interlobular septa were observed around the nodules, forming a "paving stone" sign. These reactions were synchronous with pseudoprogression of the metastatic nodules. ? Immuno-enrichment of normal lung (IE-NL) This was seen in six patients, appeared similar to type 1, and was characterized by: diffuse ground glass shadow (6/6); interstitial thickening, with significant axial interstitial thickening (4/6); paving stone signs (3/6); consolidation (4/6). As with type 1, the timelines were synchronized with pseudoprogression. The OS was 149-546 days. ? No immuno-enrichment of normal lung (nIE-NL) None of the five patients showed signs of immune hyperplasia or immune pneumonia. Metastatic nodules progressed in two patients and remained stable in three patients. Survival was poorer than in 1 and 2. ? Immuno-enrichment of lymphangitic carcinomatosis (IE-LC) The two patients showed obvious axial interstitial thickening. Peri-lymphatic nodules were diffused along the broncho-vascular bundle, subpleural, and interlobular septa. Patchy ground-glass shadow signs caused by exudative changes were rare.

CONCLUSION

s The first two types are indicative of treatment effectiveness. The response was better (60% vs 12.6%) and faster (median 13 d vs 84 d) compared with ICIs. Lymphangitic spread of carcinoma is often a sign of poor prognosis.

CLINICAL RELEVANCE/APPLICATION

Imaging of the chest response after CART therapy for solid tumors was classified to elucidate the biological mechanism and judge the overall response according to different chest responses.

Emergency Tuesday Poster Discussions

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - ER DPS

Participants
Claire Sandstrom, MD, Seattle, WA (*Moderator*) Nothing to Disclose

Sub-Events

T2-SPER-1 CT features provide additional predictive value to clinical factors in predicting outcomes for patients with spontaneous rectus sheath hematoma

Participants
Hadiseh Kavandi, MD, Boston, MA (*Presenter*) Nothing to Disclose

PURPOSE

To identify clinical and radiological features that predict outcomes of patients with spontaneous rectus sheath hematoma (RSH).

METHODS AND MATERIALS

In this retrospective IRB-approved, HIPAA-compliant study, consecutive patients with the diagnosis of RSH on CT scan between 1/1/2000 and 8/30/2021 in a tertiary care hospital were included. Patients with recent trauma or abdominal laparotomy were excluded. Clinical information and radiological features (size of hematoma and presence of active extravasation) were collected. Outcomes assessed included endovascular embolization, hospital stay greater than 5 days, RBC transfusion, the incidence of adverse events (surgery, readmission, and death), and the incidence of acute kidney injury (AKI).

RESULTS

261 patients (age 69±14 years, 154/261 (59%) females) were included. 157/261 (59%) patients underwent contrast-enhanced CT. Active extravasation was detected in 60/157 (38%) patients. Epigastric artery embolization was performed for 35/261 (13%) patients. Adverse events occurred in 18/261 (7%): 6/261 (2%) undergoing surgery, 7/261 (3%) being readmitted, and 5/261 (2%) with rectus sheath hematoma related deaths. Female sex, number of comorbidities, and anticoagulation medications were associated with longer hospital stay and need for transfusion ($p<0.05$). Lower diastolic pressure and lower hematocrit at presentation were associated with adverse events, transfusions, and longer hospital stay ($p<0.002$ for all). Active extravasation on CT was associated with adverse events, embolization, and transfusion ($p<0.003$ for all). Larger hematomas were associated with a longer hospital stay, embolization, and transfusions ($p<0.02$ for all). Radiological features of bleeding provided added predictive value to clinical predictors for RBC transfusion ($p=0.005$, AUC=0.88 vs. 0.78) and adverse events ($p=0.003$, AUC=0.99 vs. 0.80). 40/261 (15%) patients developed AKI; however, it did not correlate with contrast administration, $p=0.4$.

CONCLUSION

s Rectus sheath hematoma size and active extravasation on CT are associated with worse outcomes. Radiological features provided added predictive value to clinical predictors for future RBC transfusion and adverse events.

CLINICAL RELEVANCE/APPLICATION

In patients with spontaneous rectus sheath hematoma, CT features (size of hematoma and dimensions) provide additional predictive value to clinical predictors for adverse events and RBC transfusions.

T2-SPER-1

CT features provide additional predictive value to clinical factors in predicting outcomes for patients with spontaneous rectus sheath hematoma

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - ER DPS

Participants
Hadiseh Kavandi, MD, Boston, MA (*Presenter*) Nothing to Disclose

PURPOSE

To identify clinical and radiological features that predict outcomes of patients with spontaneous rectus sheath hematoma (RSH).

METHODS AND MATERIALS

In this retrospective IRB-approved, HIPAA-compliant study, consecutive patients with the diagnosis of RSH on CT scan between 1/1/2000 and 8/30/2021 in a tertiary care hospital were included. Patients with recent trauma or abdominal laparotomy were excluded. Clinical information and radiological features (size of hematoma and presence of active extravasation) were collected. Outcomes assessed included endovascular embolization, hospital stay greater than 5 days, RBC transfusion, the incidence of adverse events (surgery, readmission, and death), and the incidence of acute kidney injury (AKI).

RESULTS

261 patients (age 69±14 years, 154/261 (59%) females) were included. 157/261 (59%) patients underwent contrast-enhanced CT. Active extravasation was detected in 60/157 (38%) patients. Epigastric artery embolization was performed for 35/261 (13%) patients. Adverse events occurred in 18/261 (7%): 6/261 (2%) undergoing surgery, 7/261 (3%) being readmitted, and 5/261 (2%) with rectus sheath hematoma related deaths. Female sex, number of comorbidities, and anticoagulation medications were associated with longer hospital stay and need for transfusion ($p<0.05$). Lower diastolic pressure and lower hematocrit at presentation were associated with adverse events, transfusions, and longer hospital stay ($p<0.002$ for all). Active extravasation on CT was associated with adverse events, embolization, and transfusion ($p<0.003$ for all). Larger hematomas were associated with a longer hospital stay, embolization, and transfusions ($p<0.02$ for all). Radiological features of bleeding provided added predictive value to clinical predictors for RBC transfusion ($p=0.005$, AUC=0.88 vs. 0.78) and adverse events ($p=0.003$, AUC=0.99 vs. 0.80). 40/261 (15%) patients developed AKI; however, it did not correlate with contrast administration, $p=0.4$.

CONCLUSION

s Rectus sheath hematoma size and active extravasation on CT are associated with worse outcomes. Radiological features provided added predictive value to clinical predictors for future RBC transfusion and adverse events.

CLINICAL RELEVANCE/APPLICATION

In patients with spontaneous rectus sheath hematoma, CT features (size of hematoma and dimensions) provide additional predictive value to clinical predictors for adverse events and RBC transfusions.

T2-SPGI-1 Photon-counting CT vs conventional CT - Evaluation of incidental lesions in the liver and kidney.

Participants
Leonid Roshkovan, MD, Philadelphia, PA (*Presenter*) Nothing to Disclose

PURPOSE

Incidental liver and renal lesions are extremely common in clinical practice and are often difficult to fully characterize on a single-phase CT examination. We hypothesized that photon-counting CT (PCCT) would be able to characterize incidental hypoattenuating lesions more accurately in the liver and kidneys compared to conventional single-phase CT.

METHODS AND MATERIALS

Patients who had undergone a clinical CT scan of the abdomen and pelvis on a clinical PCCT scanner (Naeotom Alpha, Siemens Healthineers) and a conventional CT scan (Definition Edge, Definition AS+, Somatom Force, Siemens Healthineers) within six months were identified. Incidental hypoattenuating lesions that were visible on both scans were included, but lesions less than five pixels in size were excluded since their density could not be accurately determined. Mean Hounsfield units (HU) and standard deviation (SD) were recorded, and signal to noise ratio (SNR) was calculated. To characterize the spectral signature of the individual lesions, iodine density maps and virtual monoenergetic images (VMI, at 40, 70, 100, and 190 keV) were used to cluster low density lesions into subgroups using K-means clustering. Clinical and scan variables including patient BMI, radiation dose and contrast volume were also recorded.

RESULTS

30 patients with a total of 61 lesions (16 and 45 lesions from unenhanced and enhanced CT scans, respectively) were included in the analysis, with lesions averaging a diameter of.3 ± 2.1 mm. Mean HU values and SD as well as SNR were similar between both groups when values were obtained from VMI 70 keV (19.0 ± 17.5 HU, SNR 1.5) compared to conventional CT (21.1 ± 13.7 HU, SNR 1.5). With the spectral information from PCCT, hypoattenuating lesions in the liver and kidneys were automatically separated into three groups that corresponded to 10 fat-containing, 46 water-containing, and 5 iodine-containing lesions.

CONCLUSION

s No significant difference in SNR and mean HU was identified between conventional CT and VMI 70 keV images on PCCT. Based on the spectral data from PCCT, it was possible to separate lesions into subgroups. Our ongoing work will focus on expanding our cohort size, comparing PCCT lesion characterization to other spectral scanners, and potentially utilizing spectral data for developing automatic lesion characterization.

CLINICAL RELEVANCE/APPLICATION

PCCT can more accurately characterize incidental hypoattenuating lesions compared to conventional CT regardless of the presence of contrast, thus increasing confidence in interpretation.

T2-SPGI-10 Potential Predictors of Long-term Outcomes of the LI-RADS Equivocal Category after Locoregional Therapy of Hepatocellular Carcinoma

Participants
Mohamed Tantawi, MBBCh, (*Presenter*) Nothing to Disclose

PURPOSE

The Liver Imaging and Reporting Data System (LI-RADS) has introduced a treatment response algorithm to assess the viability of hepatocellular carcinoma (HCC) tumors after locoregional therapy (LRT). Treated tumors can be classified as viable, nonviable, equivocal, or non-evaluable. Equivocal viability is defined as enhancement atypical for treatment-specific expected enhancement pattern and not meeting the criteria for probably or definitely viable. This study aimed to identify the potential predictors of long-term viability outcome of lesions classified as equivocal following LRT.

METHODS AND MATERIALS

The study included 136 HCC lesions in 115 patients classified as equivocal at least once following LRT. Then, we excluded patients who were retreated, died, or were lost to follow-up before a viable/nonviable outcome. Clinical characteristics and imaging features were compared between tumors with later viable vs. nonviable outcomes. Viability outcomes were defined by the subsequent viable/nonviable evaluation on cross-sectional imaging or pathologic findings on explant. T-tests and chi-square tests were used to

compare the variables between the two outcome groups.

RESULTS

Across all treatment types, 74 lesions (72.6%) were nonviable on later assessments, while 28 (27.4%) were viable. A shorter time between treatment and LI-RADS equivocal read was significantly associated with a longer-term nonviable outcome (p=0.004). Recurrent tumors after previous LRT were significantly more likely to have a viable outcome than those treated for the first time (p<0.001). No single imaging feature or treatment type was associated with a longer-term definite viability outcome.

CONCLUSION

s History of recurrence after LRT and time between treatment and equivocal read can be indicators of long-term viability outcome of HCC after LRTs.

CLINICAL RELEVANCE/APPLICATION

In recently treated patients, equivocal findings on LI-RADS tend to represent evolving posttreatment changes and eventually become nonviable. Alternatively, equivocal findings in patients with a prior history of recurrence trend towards longer term viability.

T2-SPGI-2 Application of selective photon shield on image quality and radiation dose of dual energy CT-Enterography

Participants
Zengmiao Xu, Xian, China (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the influence of selective photon shield on image quality and radiation dose of dual-energy CT enterography (CTE).

METHODS AND MATERIALS

A total of 70 patients, 37 females and 33 males, aged (mean 48.19±15.53 years, range 15~81 years) between January 2019 and April 2022 were retrospectively and consecutively enrolled. Exclusion criteria: 1) small bowel preparation failure; 2) Poor image quality or scanning failure; 3) Contrast agent allergy . All patients were divided into control group (SP group) of 36 patients (19 females, 17 males, mean age 46.75±14.69 years) and experimental group (TF group) of 34 patients, (18 females, 16 males, mean aged 49.62±16.88 years), CTE were performed with SOMATOM Force 256 CT (SOMATOM). SP group used standard CTE scheme with 100kV, CARE Dose 4D, a pitch of 0.6. TF group used ultra-low-dose CTE scheme with 100/Sn150kV, CARE Dose 4D, a pitch of 0.6. The CT dose index (CTDI) and dose-length product (DLP) of the two groups were compared, and the signal-to-noise ratio (SNR) and contrast-to-noise ratio (CNR) of the two groups were calculated, respectively. All images were evaluated independently by two radiologists, who were blinded by clinical diagnosis. Any disagreements were resolved by consensus.

RESULTS

1)The DLP, CDTI and ED of TF group were 236.75±11.90mGy·cm, 6.02±0.25mGy, 3.55±0.19mSv, respectively, which were significantly lower than those of SP group (1540.58±66.58mGy·cm, 40.48±1.26mGy, 23.11±0.99mSv, all p<0.001). (Table 2) 2)There was no significant difference in the SNR and CNR of the abdominal aorta , superior mesenteric artery and superior mesenteric vein between TF group and SP group. (p>0.01) 3)There was no significant difference in the subjective scores of image quality between the TF group and SP group.

CONCLUSION

s Compared with standard CTE, selective photon shield of dual-energy CTE could significantly reduce radiation dose and obtain similar imaging quality. Clinical application: Selective photon shield of dual-energy CTE could be widely used in clinic instead of standard CTE.

CLINICAL RELEVANCE/APPLICATION

.

T2-SPGI-3 An evaluation of photon counting computed tomography of the abdomen and pelvis compared to dual energy CT in clinical routine

Participants
Manoj Mathew, MD, Philadelphia, PA (*Presenter*) Nothing to Disclose

PURPOSE

This work presents a direct comparison of the image quality, contrast attenuation, and radiation dose of photon-counting computed tomography (PCCT) and dual-energy computed tomography (DECT) on contrast-enhanced abdomen and pelvic scans obtained in routine clinical practice.

METHODS AND MATERIALS

In this institutional review board-approved retrospective study, we identified patients (n = 30) who had undergone a routine contrast enhanced CT of the abdomen and pelvis on a clinical PCCT scanner (Naeotom Alpha, Siemens Healthineers) and who had also undergone a DECT (Somatom Force, Siemens Healthineers) within twelve months. The following patient and scan characteristics were recorded: the patient's weight, radiation dose (CTDIvol), and contrast volume. For quantitative comparison, we calculated contrast to noise ratio (CNR), signal to noise ratio (SNR), and image noise for organ parenchyma as well as the great vessels for both PCCT and DECT exams.

RESULTS

Average BMI of patients undergoing contrast enhanced PCCT was 25.9 (range: 14.1 to 41.8). Average BMI change between contrast enhanced PCCT and DECT was 1.7 (range: 0 to 5.8). Average time between contrast enhanced PCCT and DECT was 50 days (range: 1 to 355 days). There was a statistically significant decrease in CTDIvol in PCCT compared to DECT of 11.1 versus 13.9, respectively (p=0.01). There was no significant difference in CNR or SNR for organ parenchyma or vessels on contrast enhanced PCCT compared to DECT.

CONCLUSION

s Our early, real-world, comparison of routine contrast enhanced abdomen and pelvis studies on PCCT and DECT indicates decreased radiation exposure (CTDIvol) can be achieved on clinical PCCT with comparable image quality (CNR and SNR). Future planned analysis will focus on rigorous comparison of qualitative and quantitative metrics of image quality utilizing direct comparison of spectral data from both PCCT and DECT.

CLINICAL RELEVANCE/APPLICATION

The introduction of PCCT has opened the opportunity of providing diagnostic image quality for contrast enhanced scans that are as good or better than conventional DECT at a reduced radiation dose.

T2-SPGI-4 Quantitative Multi-Parameters Derived From Contrast-Enhanced Dual Layer Spectral CT on Predicting the Aggressiveness in Single Hepatocellular Carcinoma

Participants
Anqi Li, Guangzhou, China (*Presenter*) Nothing to Disclose

PURPOSE

Microvascular invasion (MVI) and vessels encapsulating tumor clusters (VETC) pattern of HCC are associated with aggressive biological behavior and early recurrent after liver surgery. We aim to evaluate the potential diagnostic performance of quantitative multi-parameters obtained from contrast-enhanced Dual Layer Spectral CT (DLSCT) to non-invasively predict MVI and VETC in single HCC.

METHODS AND MATERIALS

Fifty-seven histopathology-proven HCC patients with preoperative DLSCT examinations (+/-MVI, n = 17/40; +/-VETC, n=14/43) before liver resection were enrolled retrospectively from 06/2020 to 07/2021. The CT attenuation values on virtual monoenergetic images (VMIs) at 40keV, 70keV and 120keV, effective atomic number (Zeff), iodine density (ID) and the normalized iodine density (NID) values of tumor areas (without hemorrhage or necrosis regions) in both arterial phase (AP) and portal venous phase (PVP) were measured. NID was calculated by taking the ratio of iodine density between the tumor and the aorta of the same scan slice. Differences and ratios of CT attenuation values at different VMIs, Zeff, ID and NID values between AP and PVP were also calculated. The area under the receiver operating characteristic curve (AUC) was used to assess the diagnostic performance of quantitative multi-parameters for predicting MVI and VETC.

RESULTS

Among the twenty-four quantitative parameters, CT attenuation values at 40keV (AUC:0.73) and 70keV (AUC:0.71), Zeff (AUC:0.77) and ID (AUC: 0.76) in PVP showed good performances in identifying positive-MVI (all $p<0.05$), but without significantly different AUCs. Only Zeff (AUC:0.71) and ID (AUC: 0.69) values in PVP were found that could identify positive-VETC (all $p<0.05$).

CONCLUSION

s Zeff and ID values in PVP derived from DLSCT were promising biomarkers for identifying the status of MVI and VETC in single HCC, and CT attenuation values at 40keV and 70keV in PVP could predict positive MVI.

CLINICAL RELEVANCE/APPLICATION

Zeff and ID values in PVP may be more suitable to be recommended as the effective quantitative parameters for predicting the aggressiveness in patients with HCC.

T2-SPGI-5 Application value of enhanced CT based Radiomics in prognosis assessment of patients with gastric neuroendocrine neoplasm

Participants
Yi Jing Han, (*Presenter*) Nothing to Disclose

PURPOSE

The present study aimed to investigate the clinical prognostic significance of radiomics signature (R-signature) in patients with gastric neuroendocrine neoplasm(GNEN).

METHODS AND MATERIALS

A retrospective study of 182 patients with GNEN who underwent dual-phase enhanced scanning at two tertiary health-care institutions was conducted. LASSO-Cox regression analysis was used to screen the features and establish the arterial, venous and the arteriovenous phase combined radiomics model respectively. The radiomics model with the best prognostic performance was selected for subsequent analysis by calculating Harrell's concordance index (C-index). The association between the optimal R-signature and overall survival (OS) was assessed in the training group and verified in the validation group. Furthermore, the performance of a nomogram integrating the R-signature and significant clinicopathological risk factors was evaluated.

RESULTS

The arteriovenous phase combined radiomics model had the best performance in predicting OS, and its C-index values was better than the independent arterial and venous phase radiomics model (0.803 vs 0.784 and and 0.803 vs 0.756, $P<0.001$, respectively). The combined radiomics model of the arteriovenous phase included 14 radiomics features, and the corresponding R-signature was significantly associated with OS in the training group and validation group. GNEN patients could be successfully divided into high and low prognostic risk groups with radiomics score median. The combined radiomics-clinical model combining this R-signature and independent clinicopathological risk factors (sex, age, treatment methods, T stage, N stage, M stage, tumor boundary, Ki67, CD56) exhibited significant prognostic superiority over clinical model, R-signature alone, and traditional TNM staging system (C-index, 0.882 vs 0.861, 882 vs 0.803, and 0.882 vs 0.870 respectively, $P<0.001$). All calibration curves showed remarkable consistency between predicted and actual survival, and decision curve analysis verified the usefulness of the combined radiomics-clinical nomogram for clinical practice.

CONCLUSION

s The R-signature could be used to stratify patients with GNEN into high and low risk groups. Furthermore, the combined radiomics-clinical nomogram provided better predictive accuracy than other predictive models and might aid clinicians with therapeutic decision-making and patient counseling.

CLINICAL RELEVANCE/APPLICATION

The newly developed combined radiomics-clinical nomogram is a powerful predictor of OS for GNEN patients, which demonstrated incremental value of the R-signature to the traditional staging system for individualized survival estimation.

T2-SPGI-6 Combination of clinical and spectral-CT parameters in evaluating the lymphovascular and perineural invasion of gastric cancer

Participants
Tiezhu Ren, (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this study was to investigate the utility of combining clinical and spectral computed tomography (CT) parameters in the preoperative evaluation of lymphovascular invasion (LVI) and perineural invasion (PNI) in gastric cancer (GC).

METHODS AND MATERIALS

We retrospectively analysed 121 patients with GC. All cases were confirmed by pathology, underwent spectral-CT examination, and were divided into positive group (n=87) and negative group (n=34) depending on LVI/PNI occurrence. Clinical characteristics, including demographic information, serum tumour markers, and gastroscopic pathological information, were collected. The effective atomic number (Zeff), iodine concentration (IC), and water concentration were measured in the arterial (AP) and venous (VP) phases. Parameter differences between the two groups were compared, and diagnostic performance was evaluated.

RESULTS

The LVI/PNI-positive group's serum tumour marker CA125, histological grade, Borrmann type, Zeff, and IC were substantially greater than those of the negative group (CA125, 16.29±14.95 vs 8.45±2.53; AP-Zeff, 8.73±0.41 vs 8.40±0.24; VP-Zeff, 8.78±0.26 vs 8.54±0.20; AP-IC, 19.77±8.17 vs 13.43±4.31; VP-IC, 20.53±5.34 vs 15.88±3.66, all $p<0.05$). Predictive efficacy analysis demonstrated that CA125 exhibited a favourable performance (AUC=0.714), and the VP parameters' diagnostic efficacy was superior to that of the AP parameters (all AUC>0.75). The evaluated efficiency of the combination of clinical and spectral-CT parameters was superior to that of individual parameters (all AUC>0.85). The clinical parameters combined with Zeff and IC in AP and VP exhibited good evaluation efficacy (AUC=0.890, F1 score=0.888, accuracy=0.843, sensitivity=86.2%, specificity=79.4%, +RL=10.71, and -RL=0.44).

CONCLUSION

s Clinical and energy spectral-CT parameters exhibited considerable value in the preoperative evaluation of LVI and PNI in GC. The combination of clinical and spectral-CT parameters exhibited a favourable performance in predicting LVI and PNI in GC.

CLINICAL RELEVANCE/APPLICATION

The combination of clinical parameters and spectral-CT is a valuablec approach to predicting LVI and PNI in GC.

T2-SPGI-7 Dual source CT-based dual energy radiomics model in diagnosis of enlarged benign and malignant lymph nodes for gastric adenocarcinoma

Participants
Yan Wang, Shijiazhuang, Hebei Province, China (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the efficacy of a radiomics model derived from dual energy image for discriminating benign and malignant enlarged lymph nodes (LNs) in gastric adenocarcinoma.

METHODS AND MATERIALS

This study retrospectively collected 62 gastric adenocarcinoma patients including 37 patients with postoperative pathological findings of pN3(Pathological N3 stage)and 25 pN0 patients. LNs with a short-axis diameter (SAD)=6 mm were divided into a metastasis group and a non-metastasis group according to pathological result. The LNs were randomly allocated into the training (n = 126) and test (n = 54) cohort. The region of interest (ROI) segmentation and radiomic feature extraction were performed on the slice of LNs with maximum diameter in 120kv-equivalent mixed image and automatically synchronized with iodine image in a dedicated radiomic software. Intraclass correlation coefficient (ICC) and Boruta were used for feature dimension reduction for the Random Forest radiomics model construction. Traditional features including clinical, CT features of primary lesion and LNs, and quantitative features were collected by two physicians. The clinical and combined model integrating the radiomic and traditional features were developed by univariate and multivariate analysis using Generalized Estimating Equations (GEE). The diagnostic performance of models was evaluated by receiver operating characteristic (ROC) and decision curve analysis (DCA) curve.

RESULTS

A total of 115 and 65 LNs were included in the metastatic group and the non-metastatic group.188 features with ICC>0.75 and the 8 radiomic features with highest importance selected by Boruta were utilized for radiomics model construction. The radiomics model yields an AUC 0.96(95% confidence interval [CI]:0.93, 0.99) and 0.95(95% CI: 0.89, 1) in training and test cohort, it showed significant improved discrimination efficacy compared to the clinical model in training (AUC, 0.88 [95% CI: 0.81, 0.94]; P = 0.02) and test (AUC, 0.76 [95% CI: 0.63, 0.89]; P=0.01). The combined model integrating the radiomic features and traditional (primary lesion axial maximum diameter and LNs fat fraction) performed well in training (AUC ,0.965[95% CI:0.939-0.991]), test (AUC , 0.929[95% CI:0.862-0.997]).

CONCLUSION

s Dual energy radiomics model showed higher diagnostic efficacy of benign and malignant enlarged LNs in gastric adenocarcinoma compared to the clinical model.

CLINICAL RELEVANCE/APPLICATION

Accurate preoperative identification of metastatic LNs is important for the scope of surgery in patients with gastric adenocarcinoma. The combination of dual energy and radiomics has shown high diagnostic value for quantitative assessment and prediction of benign and malignant enlarged LNs.

T2-SPGI-8 Predictive value of iodine mixed map of dual-source dual-energy enhanced CT in esophagogastric variceal bleeding in liver cirrhosis

Participants
Jiang Changqin, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the clinical value of iodine mixed map of dual-source dual-energy CT in diagnosing EV(esophagogastric varices) and predicting EVB (esophagogastric variceal bleeding) in patients with liver cirrhosis.

METHODS AND MATERIALS

Patients with liver cirrhosis were included and divided into significant EV group and non-significant EV group according to the gastroscopy, they were also divided into EVB group and non-EVB group. All patients underwent enhanced CT examination of the upper abdomen. Dual-energy post-processing software "syngo. Via" was used to obtain the iodine mixed map. Two doctors evaluated the EV and draw ROIs from the mixed map by a blind way. The IC (iodine concentration), iodine overlay value, relative IC and relative overlay value at the lower end plane of esophagus were measured. Kappa test was used to evaluate the consistency of two doctors' evaluation of EV. Spearman test was used to detect the consistency of iodine map and gastroscope for EV. Pearson correlation test was used to evaluate the correlation between relative IC and relative overlay value. ROC was drawn to evaluate the diagnosis power of iodine parameters.

RESULTS

Eighty-eight patients with liver cirrhosis were finally enrolled, including 50 males and 38 females, aged 38 ~ 67 years. Forty one cases in significant EV group and 47 cases in non-significant EV group, 36 cases with EVB and 52 cases without EVB. Comparison of iodine parameters between non-significante EV group and significant group were IC (1.44 ± 0.31mg/ml, 1.76 ± 0.32mg/ml, $P < 0.05$), iodine overlay value (26.7 ± 5.1, 31.9 ± 7.3, , $P < 0.001$), relative IC(0.76 ± 0.20, 1.09 ± 0.25, $P < 0.001$), relative iodine overlay value (0.84 ± 0.22, 1.0 ± 0.29, $P < 0.001$). Comparison of iodine parameters between non EVB and EVB groups were IC (1.44 ± 0.31mg/ml, 1.80 ± 0.30mg/ml, $P< 0.001$)), iodine overlay value (25.7 ± 4.1, 34.1 ± 6.7, $P < 0.001$), relative IC (0.75 ± 0.21, 1.20 ± 0.23, $P< 0.001$), relative overlay value (0.80 ± 0.16, 1.18 ± 0.27, $P < 0.001$). The Kappa value of the consistency of two observers in evaluating EV was 0.84. The consistency between iodine map and gastroscope in the evaluation of EV was 0.728. The AUC of ROC curve for the diagnosis of significant EV was 0.844, with sensitivity of 78.0% and specificity of 80.9%. The AUC of relative IC in predicting EVB was 0.940, with sensitivity of 91.7% and specificity of 84.6%.

CONCLUSION

s The iodine mixed map of dual-source dual-energy CT can be used to diagnose EV and be a predicted method for EVB in patients with liver cirrhosis.

CLINICAL RELEVANCE/APPLICATION

Iodine mixed map shows preferable clinical value in diagnosing EV and predicting EVB in liver cirrhosis patients.

T2-SPGI-9 NEW INSIGHTS INTO THE RELATIONSHIP BETWEEN GASTRIC EMPTYING CUT-OFF, ETIOLOGY OF GASTROPARESIS AND THE CORRELATION WITH CLINICAL SYMPTOMS

Participants
Jesus R. Diaz, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Gastric emptying scintigraphy (GES) is the gold standard for the diagnosis of gastric motility disorders such as gastroparesis (GP). However, current literature suggests that GES results and symptom scores do not correlate. This may warrant a further investigation into reassessing cut-off values.

METHODS AND MATERIALS

Different isotope retention values at 4 hours were assessed in an effort to explain the difficulty in correlating the reliability of GES with symptom scores. Additionally, diabetic and idiopathic patients were separated in order to assess differences between symptom scores and GES values. Data was collected via a retrospective review of 386 GES conducted at our institution between 2013 and 2021. Patients with rapid GES or those with insufficient data were excluded. A total of 89 patients were evaluated by separating them into groups based on their GES results (>25% or <10% retention) and their symptoms (nausea/vomiting, post-prandial fullness/early satiety, and bloating), were graded based on the gastroparesis cardinal symptom index (GCSI) scale in addition to retching, loss of appetite and belly enlargement. The mean of the symptoms between the groups was compared and a p-value of <0.05 was considered statistically significant.

RESULTS

Patients with diabetic GP with retention =25% had significantly higher overall mean scores compared to idiopathic GP patients with =25% retention at 4 hours ($p < 0.05$). Of note, diabetic patients with normal GES had a higher symptom score compared to non-diabetics with normal GES. However, patients with idiopathic GP (>10% at 4hrs) had higher symptom scores than non-diabetics with normal GES. Data shows that diabetic GP patients with =25% retention on GES at 4 hours had a higher overall mean symptom score than patients with idiopathic GP when the cut-off point of =25% retention on GES at 4 hours was utilized. Additionally, in diabetic patients, GES results, whether normal or delayed, do not correlate with their symptoms in contrast to the idiopathic patients whose symptoms worsened with worsening GES.

CONCLUSION

s These results demonstrate the need to separate the diabetic and idiopathic GP etiologies in order to correct discrepancies found

when utilizing GES to grade symptoms.

CLINICAL RELEVANCE/APPLICATION

When analyzing GES data, the interpreting physician should consider the etiology of GP for the explanation of symptoms.

Photon-counting CT vs conventional CT - Evaluation of incidental lesions in the liver and kidney.

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - GI DPS

Participants
Leonid Roshkovan, MD, Philadelphia, PA (*Presenter*) Nothing to Disclose

PURPOSE

Incidental liver and renal lesions are extremely common in clinical practice and are often difficult to fully characterize on a single-phase CT examination. We hypothesized that photon-counting CT (PCCT) would be able to characterize incidental hypoattenuating lesions more accurately in the liver and kidneys compared to conventional single-phase CT.

METHODS AND MATERIALS

Patients who had undergone a clinical CT scan of the abdomen and pelvis on a clinical PCCT scanner (Naeotom Alpha, Siemens Healthineers) and a conventional CT scan (Definition Edge, Definition AS+, Somatom Force, Siemens Healthineers) within six months were identified. Incidental hypoattenuating lesions that were visible on both scans were included, but lesions less than five pixels in size were excluded since their density could not be accurately determined. Mean Hounsfield units (HU) and standard deviation (SD) were recorded, and signal to noise ratio (SNR) was calculated. To characterize the spectral signature of the individual lesions, iodine density maps and virtual monoenergetic images (VMI, at 40, 70, 100, and 190 keV) were used to cluster low density lesions into subgroups using K-means clustering. Clinical and scan variables including patient BMI, radiation dose and contrast volume were also recorded.

RESULTS

30 patients with a total of 61 lesions (16 and 45 lesions from unenhanced and enhanced CT scans, respectively) were included in the analysis, with lesions averaging a diameter of.3 ± 2.1 mm. Mean HU values and SD as well as SNR were similar between both groups when values were obtained from VMI 70 keV (19.0 ± 17.5 HU, SNR 1.5) compared to conventional CT (21.1 ± 13.7 HU, SNR 1.5). With the spectral information from PCCT, hypoattenuating lesions in the liver and kidneys were automatically separated into three groups that corresponded to 10 fat-containing, 46 water-containing, and 5 iodine-containing lesions.

CONCLUSION

s No significant difference in SNR and mean HU was identified between conventional CT and VMI 70 keV images on PCCT. Based on the spectral data from PCCT, it was possible to separate lesions into subgroups. Our ongoing work will focus on expanding our cohort size, comparing PCCT lesion characterization to other spectral scanners, and potentially utilizing spectral data for developing automatic lesion characterization.

CLINICAL RELEVANCE/APPLICATION

PCCT can more accurately characterize incidental hypoattenuating lesions compared to conventional CT regardless of the presence of contrast, thus increasing confidence in interpretation.

Potential Predictors of Long-term Outcomes of the LI-RADS Equivocal Category after Locoregional Therapy of Hepatocellular Carcinoma

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - GI DPS

Participants
Mohamed Tantawi, MBBCh, (*Presenter*) Nothing to Disclose

PURPOSE

The Liver Imaging and Reporting Data System (LI-RADS) has introduced a treatment response algorithm to assess the viability of hepatocellular carcinoma (HCC) tumors after locoregional therapy (LRT). Treated tumors can be classified as viable, nonviable, equivocal, or non-evaluable. Equivocal viability is defined as enhancement atypical for treatment-specific expected enhancement pattern and not meeting the criteria for probably or definitely viable. This study aimed to identify the potential predictors of long-term viability outcome of lesions classified as equivocal following LRT.

METHODS AND MATERIALS

The study included 136 HCC lesions in 115 patients classified as equivocal at least once following LRT. Then, we excluded patients who were retreated, died, or were lost to follow-up before a viable/nonviable outcome. Clinical characteristics and imaging features were compared between tumors with later viable vs. nonviable outcomes. Viability outcomes were defined by the subsequent viable/nonviable evaluation on cross-sectional imaging or pathologic findings on explant. T-tests and chi-square tests were used to compare the variables between the two outcome groups.

RESULTS

Across all treatment types, 74 lesions (72.6%) were nonviable on later assessments, while 28 (27.4%) were viable. A shorter time between treatment and LI-RADS equivocal read was significantly associated with a longer-term nonviable outcome ($p=0.004$). Recurrent tumors after previous LRT were significantly more likely to have a viable outcome than those treated for the first time ($p<0.001$). No single imaging feature or treatment type was associated with a longer-term definite viability outcome.

CONCLUSION

s History of recurrence after LRT and time between treatment and equivocal read can be indicators of long-term viability outcome of HCC after LRTs.

CLINICAL RELEVANCE/APPLICATION

In recently treated patients, equivocal findings on LI-RADS tend to represent evolving posttreatment changes and eventually become nonviable. Alternatively, equivocal findings in patients with a prior history of recurrence trend towards longer term viability.

Application of selective photon shield on image quality and radiation dose of dual energy CT-Enterography

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - GI DPS

Participants
Zengmiao Xu, Xian, China (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the influence of selective photon shield on image quality and radiation dose of dual-energy CT enterography (CTE).

METHODS AND MATERIALS

A total of 70 patients, 37 females and 33 males, aged (mean 48.19±15.53 years, range 15~81 years) between January 2019 and April 2022 were retrospectively and consecutively enrolled. Exclusion criteria: 1) small bowel preparation failure; 2) Poor image quality or scanning failure; 3) Contrast agent allergy . All patients were divided into control group (SP group) of 36 patients (19 females, 17 males, mean age 46.75±14.69 years) and experimental group (TF group) of 34 patients, (18 females, 16 males, mean aged 49.62±16.88 years), CTE were performed with SOMATOM Force 256 CT (SOMATOM). SP group used standard CTE scheme with 100kV, CARE Dose 4D, a pitch of 0.6. TF group used ultra-low-dose CTE scheme with 100/Sn150kV, CARE Dose 4D, a pitch of 0.6. The CT dose index (CTDI) and dose-length product (DLP) of the two groups were compared, and the signal-to-noise ratio (SNR) and contrast-to-noise ratio (CNR) of the two groups were calculated, respectively. All images were evaluated independently by two radiologists, who were blinded by clinical diagnosis. Any disagreements were resolved by consensus.

RESULTS

1)The DLP, CDTI and ED of TF group were 236.75±11.90mGy·cm, 6.02±0.25mGy, 3.55±0.19mSv, respectively, which were significantly lower than those of SP group (1540.58±66.58mGy·cm, 40.48±1.26mGy, 23.11±0.99mSv, all $p<0.001$). (Table 2) 2)There was no significant difference in the SNR and CNR of the abdominal aorta , superior mesenteric artery and superior mesenteric vein between TF group and SP group. ($p>0.01$) 3)There was no significant difference in the subjective scores of image quality between the TF group and SP group.

CONCLUSION

s Compared with standard CTE, selective photon shield of dual-energy CTE could significantly reduce radiation dose and obtain similar imaging quality. Clinical application: Selective photon shield of dual-energy CTE could be widely used in clinic instead of standard CTE.

CLINICAL RELEVANCE/APPLICATION

.

T2-SPGI-3

An evaluation of photon counting computed tomography of the abdomen and pelvis compared to dual energy CT in clinical routine

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - GI DPS

Participants
Manoj Mathew, MD, Philadelphia, PA (*Presenter*) Nothing to Disclose

PURPOSE

This work presents a direct comparison of the image quality, contrast attenuation, and radiation dose of photon-counting computed tomography (PCCT) and dual-energy computed tomography (DECT) on contrast-enhanced abdomen and pelvic scans obtained in routine clinical practice.

METHODS AND MATERIALS

In this institutional review board-approved retrospective study, we identified patients (n = 30) who had undergone a routine contrast enhanced CT of the abdomen and pelvis on a clinical PCCT scanner (Naeotom Alpha, Siemens Healthineers) and who had also undergone a DECT (Somatom Force, Siemens Healthineers) within twelve months. The following patient and scan characteristics were recorded: the patient's weight, radiation dose (CTDIvol), and contrast volume. For quantitative comparison, we calculated contrast to noise ratio (CNR), signal to noise ratio (SNR), and image noise for organ parenchyma as well as the great vessels for both PCCT and DECT exams.

RESULTS

Average BMI of patients undergoing contrast enhanced PCCT was 25.9 (range: 14.1 to 41.8). Average BMI change between contrast enhanced PCCT and DECT was 1.7 (range: 0 to 5.8). Average time between contrast enhanced PCCT and DECT was 50 days (range: 1 to 355 days). There was a statistically significant decrease in CTDIvol in PCCT compared to DECT of 11.1 versus 13.9, respectively (p=0.01). There was no significant difference in CNR or SNR for organ parenchyma or vessels on contrast enhanced PCCT compared to DECT.

CONCLUSION

s Our early, real-world, comparison of routine contrast enhanced abdomen and pelvis studies on PCCT and DECT indicates decreased radiation exposure (CTDIvol) can be achieved on clinical PCCT with comparable image quality (CNR and SNR). Future planned analysis will focus on rigorous comparison of qualitative and quantitative metrics of image quality utilizing direct comparison of spectral data from both PCCT and DECT.

CLINICAL RELEVANCE/APPLICATION

The introduction of PCCT has opened the opportunity of providing diagnostic image quality for contrast enhanced scans that are as good or better than conventional DECT at a reduced radiation dose.

T2-SPGI-4

Quantitative Multi-Parameters Derived From Contrast-Enhanced Dual Layer Spectral CT on Predicting the Aggressiveness in Single Hepatocellular Carcinoma

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - GI DPS

Participants
Anqi Li, Guangzhou, China (*Presenter*) Nothing to Disclose

PURPOSE

Microvascular invasion (MVI) and vessels encapsulating tumor clusters (VETC) pattern of HCC are associated with aggressive biological behavior and early recurrent after liver surgery. We aim to evaluate the potential diagnostic performance of quantitative multi-parameters obtained from contrast-enhanced Dual Layer Spectral CT (DLSCT) to non-invasively predict MVI and VETC in single HCC.

METHODS AND MATERIALS

Fifty-seven histopathology-proven HCC patients with preoperative DLSCT examinations (+/-MVI, n = 17/40; +/-VETC, n=14/43) before liver resection were enrolled retrospectively from 06/2020 to 07/2021. The CT attenuation values on virtual monoenergetic images (VMIs) at 40keV, 70keV and 120keV, effective atomic number (Zeff), iodine density (ID) and the normalized iodine density (NID) values of tumor areas (without hemorrhage or necrosis regions) in both arterial phase (AP) and portal venous phase (PVP) were measured. NID was calculated by taking the ratio of iodine density between the tumor and the aorta of the same scan slice. Differences and ratios of CT attenuation values at different VMIs, Zeff, ID and NID values between AP and PVP were also calculated. The area under the receiver operating characteristic curve (AUC) was used to assess the diagnostic performance of quantitative multi-parameters for predicting MVI and VETC.

RESULTS

Among the twenty-four quantitative parameters, CT attenuation values at 40keV (AUC:0.73) and 70keV (AUC:0.71), Zeff (AUC:0.77) and ID (AUC: 0.76) in PVP showed good performances in identifying positive-MVI (all $p<0.05$), but without significantly different AUCs. Only Zeff (AUC:0.71) and ID (AUC: 0.69) values in PVP were found that could identify positive-VETC (all $p<0.05$).

CONCLUSION

s Zeff and ID values in PVP derived from DLSCT were promising biomarkers for identifying the status of MVI and VETC in single HCC, and CT attenuation values at 40keV and 70keV in PVP could predict positive MVI.

CLINICAL RELEVANCE/APPLICATION

Zeff and ID values in PVP may be more suitable to be recommended as the effective quantitative parameters for predicting the aggressiveness in patients with HCC.

T2-SPGI-5

Application value of enhanced CT based Radiomics in prognosis assessment of patients with gastric neuroendocrine neoplasm

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - GI DPS

Participants
Yi Jing Han, (*Presenter*) Nothing to Disclose

PURPOSE

The present study aimed to investigate the clinical prognostic significance of radiomics signature (R-signature) in patients with gastric neuroendocrine neoplasm(GNEN).

METHODS AND MATERIALS

A retrospective study of 182 patients with GNEN who underwent dual-phase enhanced scanning at two tertiary health-care institutions was conducted. LASSO-Cox regression analysis was used to screen the features and establish the arterial, venous and the arteriovenous phase combined radiomics model respectively. The radiomics model with the best prognostic performance was selected for subsequent analysis by calculating Harrell's concordance index (C-index). The association between the optimal R-signature and overall survival (OS) was assessed in the training group and verified in the validation group. Furthermore, the performance of a nomogram integrating the R-signature and significant clinicopathological risk factors was evaluated.

RESULTS

The arteriovenous phase combined radiomics model had the best performance in predicting OS, and its C-index values was better than the independent arterial and venous phase radiomics model (0.803 vs 0.784 and and 0.803 vs 0.756, P<0.001, respectively). The combined radiomics model of the arteriovenous phase included 14 radiomics features, and the corresponding R-signature was significantly associated with OS in the training group and validation group. GNEN patients could be successfully divided into high and low prognostic risk groups with radiomics score median. The combined radiomics-clinical model combining this R-signature and independent clinicopathological risk factors (sex, age, treatment methods, T stage, N stage, M stage, tumor boundary, Ki67, CD56) exhibited significant prognostic superiority over clinical model, R-signature alone, and traditional TNM staging system (C-index, 0.882 vs 0.861, 882 vs 0.803, and 0.882 vs 0.870 respectively, P<0.001). All calibration curves showed remarkable consistency between predicted and actual survival, and decision curve analysis verified the usefulness of the combined radiomics-clinical nomogram for clinical practice.

CONCLUSION

s The R-signature could be used to stratify patients with GNEN into high and low risk groups. Furthermore, the combined radiomics-clinical nomogram provided better predictive accuracy than other predictive models and might aid clinicians with therapeutic decision-making and patient counseling.

CLINICAL RELEVANCE/APPLICATION

The newly developed combined radiomics-clinical nomogram is a powerful predictor of OS for GNEN patients, which demonstrated incremental value of the R-signature to the traditional staging system for individualized survival estimation.

T2-SPGI-6

Combination of clinical and spectral-CT parameters in evaluating the lymphovascular and perineural invasion of gastric cancer

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - GI DPS

Participants
Tiezhu Ren, (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this study was to investigate the utility of combining clinical and spectral computed tomography (CT) parameters in the preoperative evaluation of lymphovascular invasion (LVI) and perineural invasion (PNI) in gastric cancer (GC).

METHODS AND MATERIALS

We retrospectively analysed 121 patients with GC. All cases were confirmed by pathology, underwent spectral-CT examination, and were divided into positive group (n=87) and negative group (n=34) depending on LVI/PNI occurrence. Clinical characteristics, including demographic information, serum tumour markers, and gastroscopic pathological information, were collected. The effective atomic number (Zeff), iodine concentration (IC), and water concentration were measured in the arterial (AP) and venous (VP) phases. Parameter differences between the two groups were compared, and diagnostic performance was evaluated.

RESULTS

The LVI/PNI-positive group's serum tumour marker CA125, histological grade, Borrmann type, Zeff, and IC were substantially greater than those of the negative group (CA125, 16.29±14.95 vs 8.45±2.53; AP-Zeff, 8.73±0.41 vs 8.40±0.24; VP-Zeff, 8.78±0.26 vs 8.54±0.20; AP-IC, 19.77±8.17 vs 13.43±4.31; VP-IC, 20.53±5.34 vs 15.88±3.66, all $p<0.05$). Predictive efficacy analysis demonstrated that CA125 exhibited a favourable performance (AUC=0.714), and the VP parameters' diagnostic efficacy was superior to that of the AP parameters (all AUC>0.75). The evaluated efficiency of the combination of clinical and spectral-CT parameters was superior to that of individual parameters (all AUC>0.85). The clinical parameters combined with Zeff and IC in AP and VP exhibited good evaluation efficacy (AUC=0.890, F1 score=0.888, accuracy=0.843, sensitivity=86.2%, specificity=79.4%, +RL=10.71, and -RL=0.44).

CONCLUSION

s Clinical and energy spectral-CT parameters exhibited considerable value in the preoperative evaluation of LVI and PNI in GC. The combination of clinical and spectral-CT parameters exhibited a favourable performance in predicting LVI and PNI in GC.

CLINICAL RELEVANCE/APPLICATION

The combination of clinical parameters and spectral-CT is a valuablec approach to predicting LVI and PNI in GC.

T2-SPGI-7

Dual source CT-based dual energy radiomics model in diagnosis of enlarged benign and malignant lymph nodes for gastric adenocarcinoma

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - GI DPS

Participants
Yan Wang, Shijiazhuang, Hebei Province, China (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the efficacy of a radiomics model derived from dual energy image for discriminating benign and malignant enlarged lymph nodes (LNs) in gastric adenocarcinoma.

METHODS AND MATERIALS

This study retrospectively collected 62 gastric adenocarcinoma patients including 37 patients with postoperative pathological findings of pN3(Pathological N3 stage)and 25 pN0 patients. LNs with a short-axis diameter (SAD)=6 mm were divided into a metastasis group and a non-metastasis group according to pathological result. The LNs were randomly allocated into the training (n = 126) and test (n = 54) cohort. The region of interest (ROI) segmentation and radiomic feature extraction were performed on the slice of LNs with maximum diameter in 120kv-equivalent mixed image and automatically synchronized with iodine image in a dedicated radiomic software. Intraclass correlation coefficient (ICC) and Boruta were used for feature dimension reduction for the Random Forest radiomics model construction. Traditional features including clinical, CT features of primary lesion and LNs, and quantitative features were collected by two physicians. The clinical and combined model integrating the radiomic and traditional features were developed by univariate and multivariate analysis using Generalized Estimating Equations (GEE). The diagnostic performance of models was evaluated by receiver operating characteristic (ROC) and decision curve analysis (DCA) curve.

RESULTS

A total of 115 and 65 LNs were included in the metastatic group and the non-metastatic group.188 features with ICC>0.75 and the 8 radiomic features with highest importance selected by Boruta were utilized for radiomics model construction. The radiomics model yields an AUC 0.96(95% confidence interval [CI]:0.93, 0.99) and 0.95(95% CI: 0.89, 1) in training and test cohort, it showed significant improved discrimination efficacy compared to the clinical model in training (AUC, 0.88 [95% CI: 0.81, 0.94]; P = 0.02) and test (AUC, 0.76 [95% CI: 0.63, 0.89]; P=0.01). The combined model integrating the radiomic features and traditional (primary lesion axial maximum diameter and LNs fat fraction) performed well in training (AUC ,0.965[95% CI:0.939-0.991]), test (AUC , 0.929[95% CI:0.862-0.997]).

CONCLUSION

s Dual energy radiomics model showed higher diagnostic efficacy of benign and malignant enlarged LNs in gastric adenocarcinoma compared to the clinical model.

CLINICAL RELEVANCE/APPLICATION

Accurate preoperative identification of metastatic LNs is important for the scope of surgery in patients with gastric adenocarcinoma. The combination of dual energy and radiomics has shown high diagnostic value for quantitative assessment and prediction of benign and malignant enlarged LNs.

T2-SPGI-8

Predictive value of iodine mixed map of dual-source dual-energy enhanced CT in esophagogastric variceal bleeding in liver cirrhosis

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - GI DPS

Participants
Jiang Changqin, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the clinical value of iodine mixed map of dual-source dual-energy CT in diagnosing EV(esophagogastric varices) and predicting EVB (esophagogastric variceal bleeding) in patients with liver cirrhosis.

METHODS AND MATERIALS

Patients with liver cirrhosis were included and divided into significant EV group and non-significant EV group according to the gastroscopy, they were also divided into EVB group and non-EVB group. All patients underwent enhanced CT examination of the upper abdomen. Dual-energy post-processing software "syngo. Via" was used to obtain the iodine mixed map. Two doctors evaluated the EV and draw ROIs from the mixed map by a blind way. The IC (iodine concentration), iodine overlay value, relative IC and relative overlay value at the lower end plane of esophagus were measured. Kappa test was used to evaluate the consistency of two doctors' evaluation of EV. Spearman test was used to detect the consistency of iodine map and gastroscope for EV. Pearson correlation test was used to evaluate the correlation between relative IC and relative overlay value. ROC was drawn to evaluate the diagnosis power of iodine parameters.

RESULTS

Eighty-eight patients with liver cirrhosis were finally enrolled, including 50 males and 38 females, aged 38 ~ 67 years. Forty one cases in significant EV group and 47 cases in non-significant EV group, 36 cases with EVB and 52 cases without EVB. Comparison of iodine parameters between non-significante EV group and significant group were IC (1.44 ± 0.31mg/ml, 1.76 ± 0.32mg/ml, $P < 0.05$), iodine overlay value (26.7 ± 5.1, 31.9 ± 7.3, , $P < 0.001$), relative IC(0.76 ± 0.20, 1.09 ± 0.25, $P < 0.001$), relative iodine overlay value (0.84 ± 0.22, 1.0 ± 0.29, $P < 0.001$). Comparison of iodine parameters between non EVB and EVB groups were IC (1.44 ± 0.31mg/ml, 1.80 ± 0.30mg/ml, $P< 0.001$)), iodine overlay value (25.7 ± 4.1, 34.1 ± 6.7, $P < 0.001$), relative IC (0.75 ± 0.21, 1.20 ± 0.23, $P< 0.001$), relative overlay value (0.80 ± 0.16, 1.18 ± 0.27, $P < 0.001$). The Kappa value of the consistency of two observers in evaluating EV was 0.84. The consistency between iodine map and gastroscope in the evaluation of EV was 0.728. The AUC of ROC curve for the diagnosis of significant EV was 0.844, with sensitivity of 78.0% and specificity of 80.9%. The AUC of relative IC in predicting EVB was 0.940, with sensitivity of 91.7% and specificity of 84.6%.

CONCLUSION

s The iodine mixed map of dual-source dual-energy CT can be used to diagnose EV and be a predicted method for EVB in patients with liver cirrhosis.

CLINICAL RELEVANCE/APPLICATION

Iodine mixed map shows preferable clinical value in diagnosing EV and predicting EVB in liver cirrhosis patients.

NEW INSIGHTS INTO THE RELATIONSHIP BETWEEN GASTRIC EMPTYING CUT-OFF, ETIOLOGY OF GASTROPARESIS AND THE CORRELATION WITH CLINICAL SYMPTOMS

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - GI DPS

Participants
Jesus R. Diaz, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Gastric emptying scintigraphy (GES) is the gold standard for the diagnosis of gastric motility disorders such as gastroparesis (GP). However, current literature suggests that GES results and symptom scores do not correlate. This may warrant a further investigation into reassessing cut-off values.

METHODS AND MATERIALS

Different isotope retention values at 4 hours were assessed in an effort to explain the difficulty in correlating the reliability of GES with symptom scores. Additionally, diabetic and idiopathic patients were separated in order to assess differences between symptom scores and GES values. Data was collected via a retrospective review of 386 GES conducted at our institution between 2013 and 2021. Patients with rapid GES or those with insufficient data were excluded. A total of 89 patients were evaluated by separating them into groups based on their GES results (>25% or <10% retention) and their symptoms (nausea/vomiting, post-prandial fullness/early satiety, and bloating), were graded based on the gastroparesis cardinal symptom index (GCSI) scale in addition to retching, loss of appetite and belly enlargement. The mean of the symptoms between the groups was compared and a p-value of <0.05 was considered statistically significant.

RESULTS

Patients with diabetic GP with retention =25% had significantly higher overall mean scores compared to idiopathic GP patients with =25% retention at 4 hours ($p < 0.05$). Of note, diabetic patients with normal GES had a higher symptom score compared to non-diabetics with normal GES. However, patients with idiopathic GP (>10% at 4hrs) had higher symptom scores than non-diabetics with normal GES. Data shows that diabetic GP patients with =25% retention on GES at 4 hours had a higher overall mean symptom score than patients with idiopathic GP when the cut-off point of =25% retention on GES at 4 hours was utilized. Additionally, in diabetic patients, GES results, whether normal or delayed, do not correlate with their symptoms in contrast to the idiopathic patients whose symptoms worsened with worsening GES.

CONCLUSION

s These results demonstrate the need to separate the diabetic and idiopathic GP etiologies in order to correct discrepancies found when utilizing GES to grade symptoms.

CLINICAL RELEVANCE/APPLICATION

When analyzing GES data, the interpreting physician should consider the etiology of GP for the explanation of symptoms.

Genitourinary Tuesday Poster Discussions

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - GU DPS

Sub-Events

T2-SPGU-1 Comparison between Conventional Cystourethrography and MRI with Coiding MR-cystourethrography in the Evaluation of Male Urethral Strictures

Participants
Marco Di Girolamo, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the accuracy of conventional retrograde and voiding cystourethrography and MRI together with voiding MR-cystourethrography in the evaluation of male urethral strictures.

METHODS AND MATERIALS

We evaluated 39 male patients with urethral strictures diagnosed with urine flow velocity recording and conventional retrograde and voiding cystourethrography. All these patients underwent MRI and voiding MR-cystourethrography using a 1.5T superconductive magnet. The patients had urine-filled bladders and high-resolution sagittal TSE T2-weighted scans were performed (TR:6250ms; TE:90ms;sl.thick.:3mm; acq.time:3'38"). Voiding MR-cystourethrography was performed with T1-weighted spoiled 3D gradient-echo acquisitions on sagittal plane (TR:12ms; TE:2,7ms; flip-angle:40°; sl.thickness: 2mm; acq.time:12s) after the filling of bladder lumen with contrast-material-enhanced urine obtainded by the i.v administration 20 mg of furosemide followed by ¾ of the normal dose of a paramagnetic contrast agent (Magnevist, Bayer Pharma, Germany). After micturition high-resolution coronal TSE T2-weighted scans were performed at the level of the stenosis. Two radiologists in consensus evaluated the morphology and length of the urethral stenosis with the two modalities and with MRI the entity and the site of spongio-fibrosis was assessed.

RESULTS

6 patients were not able to perform voiding MR-cystourethrography. In 33 patients evaluated with two imaging modalities 42 urethral strictures were detected. The measurement of the stenosis length was equal or superior with voiding MR cystourethrography and the analysis of 3D sagittal scans allowed a better evaluation of the morphology of the urethral strictures in comparison with conventional cystourethrography. 32 strictures with Spongio-fibrosis were found (76%). The site of spongio-fibrosis was always assessed with MRI (dorsal, ventral, dorsal and ventral and circular fibrosis).

CONCLUSION

s MRI with voiding MR-cystourethrography shows the morphology and the length of the urethral strictures better than conventional cystourethrography and allows the detection and site of spongio-fibrosis, avoiding radiation exposure to the gonads and urinary catheterization.

CLINICAL RELEVANCE/APPLICATION

MRI could be proposed as all-in-one technique for the evaluation of urethral stenosis, allowing their detection and length assessment and determining the presence and site of spongiofibrosis.

T2-SPGU-2 MR defecography revisited. Pelvic floor measurements with and without rectal gel. Is there a difference.

Participants
Charles Myers, DO, Lexington, KY (*Presenter*) Nothing to Disclose

PURPOSE

To test if there is a difference in pelvic floor measurements (H-line, M-line and anorectal angle) before and after rectal gel administration during MR defecography and if this difference can affect the degree of pelvic floor grading.

METHODS AND MATERIALS

After IRB approval was obtained, we conducted a retrospective review of patients who had MR defecography at our institution from January 2018 to June 2021. An abdominal fellow, trained in the interpretation of MRI defecography, reviewed all studies and performed measurements of the M-line, H-line and anorectal angle for each patient, on sagittal midline T2-weighted sequences, before and after the instillation of rectal gel. Statistical analysis was conducted using two-tailed t-tests to determine the significance of the observed differences.

RESULTS

A total of 111 scans were reviewed. All patients were female. 64% (71) of the patients had at least mild pelvic floor widening (defined as an H-line of greater than 5 cm) without rectal gel. This increased to 67.6% (75) after rectal gel administration. 14.4 %

(16) had at least mild pelvic floor descent (defined as an M-line of greater than 2 cm) before rectal gel which increased to 38.7% (43) after the administration of gel. The anorectal angle was noted to be on average wider by 3.2 degrees after the administration of rectal gel. Also, 67.6% (75) of patients were found to have an anorectal angle outside the normal range (108-127 degrees) before gel versus 58.6% (65) after gel. P-values for the before and after effect of rectal gel on the H-line, M-line and anorectal angle measurements were 0.08, 0.0000085 and 0.07 respectively.

CONCLUSION

s The filling of the rectum with gel during MR defecography increases the H-line, M-line and anorectal angle measurements and influences pelvic floor grading. A standardized manner of obtaining these measurements should be implemented to allow better reproducibility and by extension, patient management.

CLINICAL RELEVANCE/APPLICATION

The administration of rectal gel may alter the obtained measurements during dynamic pelvic floor imaging.

T2-SPGU-3 Comparison of three methods for lesion detection and classification on biparametric prostate MRI

Participants
Maria Sainz de Cea, PhD, Cambridge, MA (*Presenter*) Nothing to Disclose

PURPOSE

Detection of lesions in bi-parametric MRI (bp-MRI) and their classification according to PIRADS guidelines is part of the clinical workflow for patients identified to be at risk of prostate cancer. We propose a method for segmentation and classification of prostate lesions in bp-MRI based on semantic segmentation of lesions and compare it with two state-of-the-art methods based on RetinaNet object detection and Panoptic Segmentation.

METHODS AND MATERIALS

We propose the first multi-task deep convolutional model that performs lesion segmentation and classification. To improve the performance, we leverage information from prostate and zone by training the model to also predict their segmentation masks. Additionally, we include convolutional LSTM blocks to model the relationship between consecutive slices. The network training (on a large dataset) includes pre-processing and data augmentation. Performance was evaluated with five-fold cross validation and on a held-out test set. We report sensitivity, specificity, and accuracy for lesion classification for two classes: PIRADS 3 and PIRADS 4-5. Separately, we evaluate the lesion detection performance for both classes for our proposed network and the other two state-of-the-art methods.

RESULTS

Our model was trained on 2940 studies from 9 different providers across Europe, United States, South America, and Asia. The studies were acquired with different protocols and manufacturers and contain bi-parametric MRI. The algorithm was trained using T2-w series, high b-value DWI and ADC maps. When we fix the number of FPs in the FROC curve the sensitivity of our proposed multi-task network is 91%, higher than other methods (74% for RetinaNet and 89.3% for Panoptic Segmentation). The classification accuracy for the validation set is 76% and 73% for PIRADS 3 and PIRADS 4-5 lesions respectively (74% and 68% for RetinaNet). For PIRADS 4-5 lesions, we obtain a sensitivity of 76% and a specificity of 61% (66% and 76% for RetinaNet).

CONCLUSION

s We present a deep learning system for automated lesion segmentation and classification that also performs gland and prostate segmentation. The incorporation of multi-task learning has been shown to boost the performance of lesion detection achieving a high classification accuracy on a large multi-center dataset.

CLINICAL RELEVANCE/APPLICATION

Automated lesion segmentation and classification is clinically relevant and can be used for prostate cancer identification, biopsy, and treatment guidance.

Comparison between Conventional Cystourethrography and MRI with Coiding MR-cystourethrography in the Evaluation of Male Urethral Strictures

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - GU DPS

Participants
Marco Di Girolamo, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the accuracy of conventional retrograde and voiding cystourethrography and MRI together with voiding MR-cystourethrography in the evaluation of male urethral strictures.

METHODS AND MATERIALS

We evaluated 39 male patients with urethral strictures diagnosed with urine flow velocity recording and conventional retrograde and voiding cystourethrography. All these patients underwent MRI and voiding MR-cystourethrography using a 1.5T superconductive magnet. The patients had urine-filled bladders and high-resolution sagittal TSE T2-weighted scans were performed (TR:6250ms; TE:90ms;sl.thick.:3mm; acq.time:3'38"). Voiding MR-cystourethrography was performed with T1-weighted spoiled 3D gradient-echo acquisitions on sagittal plane (TR:12ms; TE:2,7ms; flip-angle:40°; sl.thickness: 2mm; acq.time:12s) after the filling of bladder lumen with contrast-material-enhanced urine obtainded by the i.v administration 20 mg of furosemide followed by ¾ of the normal dose of a paramagnetic contrast agent (Magnevist, Bayer Pharma, Germany). After micturition high-resolution coronal TSE T2-weighted scans were performed at the level of the stenosis. Two radiologists in consensus evaluated the morphology and length of the urethral stenosis with the two modalities and with MRI the entity and the site of spongio-fibrosis was assessed.

RESULTS

6 patients were not able to perform voiding MR-cystourethrography. In 33 patients evaluated with two imaging modalities 42 urethral strictures were detected. The measurement of the stenosis length was equal or superior with voiding MR cystourethrography and the analysis of 3D sagittal scans allowed a better evaluation of the morphology of the urethral strictures in comparison with conventional cystourethrography. 32 strictures with Spongio-fibrosis were found (76%). The site of spongio-fibrosis was always assessed with MRI (dorsal, ventral, dorsal and ventral and circular fibrosis).

CONCLUSION

s MRI with voiding MR-cystourethrography shows the morphology and the length of the urethral strictures better than conventional cystourethrography and allows the detection and site of spongio-fibrosis, avoiding radiation exposure to the gonads and urinary catheterization.

CLINICAL RELEVANCE/APPLICATION

MRI could be proposed as all-in-one technique for the evaluation of urethral stenosis, allowing their detection and length assessment and determining the presence and site of spongiofibrosis.

MR defecography revisited. Pelvic floor measurements with and without rectal gel. Is there a difference.

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - GU DPS

Participants
Charles Myers, DO, Lexington, KY (*Presenter*) Nothing to Disclose

PURPOSE

To test if there is a difference in pelvic floor measurements (H-line, M-line and anorectal angle) before and after rectal gel administration during MR defecography and if this difference can affect the degree of pelvic floor grading.

METHODS AND MATERIALS

After IRB approval was obtained, we conducted a retrospective review of patients who had MR defecography at our institution from January 2018 to June 2021. An abdominal fellow, trained in the interpretation of MRI defecography, reviewed all studies and performed measurements of the M-line, H-line and anorectal angle for each patient, on sagittal midline T2-weighted sequences, before and after the instillation of rectal gel. Statistical analysis was conducted using two-tailed t-tests to determine the significance of the observed differences.

RESULTS

A total of 111 scans were reviewed. All patients were female. 64% (71) of the patients had at least mild pelvic floor widening (defined as an H-line of greater than 5 cm) without rectal gel. This increased to 67.6% (75) after rectal gel administration. 14.4 % (16) had at least mild pelvic floor descent (defined as an M-line of greater than 2 cm) before rectal gel which increased to 38.7% (43) after the administration of gel. The anorectal angle was noted to be on average wider by 3.2 degrees after the administration of rectal gel. Also, 67.6% (75) of patients were found to have an anorectal angle outside the normal range (108-127 degrees) before gel versus 58.6% (65) after gel. P-values for the before and after effect of rectal gel on the H-line, M-line and anorectal angle measurements were 0.08, 0.0000085 and 0.07 respectively.

CONCLUSION

s The filling of the rectum with gel during MR defecography increases the H-line, M-line and anorectal angle measurements and influences pelvic floor grading. A standardized manner of obtaining these measurements should be implemented to allow better reproducibility and by extension, patient management.

CLINICAL RELEVANCE/APPLICATION

The administration of rectal gel may alter the obtained measurements during dynamic pelvic floor imaging.

Head and Neck Tuesday Poster Discussions

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - HN DPS

Sub-Events

T2-SPHN-1 Preliminary Evidence for Trans-synaptic Axonal Degeneration in Dysthyroid) Optic Neuropathy Due to Thyroid-associated Ophthalmopathy

Participants
Ping Liu, MS, (*Presenter*) Nothing to Disclose

PURPOSE

Diffusion tensor imaging (DTI) provides a noninvasive tool to detect the microstructure of the entire visual pathway. To assess the microstructural changes of the whole visual pathway associated with DON and to investigate the potential mechanism of trans-synaptic degeneration pathogenesis in DON by DTI.

METHODS AND MATERIALS

A total of 64 bilateral thyroid-associated ophthalmopathy (TAO) patients with and without DON, and 30 healthy controls were included. All of the subjects underwent DTI examination, DTI parameters of each segment of the whole visual pathway (optic nerve, optic tract, optic radiation, including fractional anisotropy) (FA), mean diffusivity (MD), axial diffusivity (AD) and radial diffusivity (RD), were calculated and compared among the three groups using one-way analysis of variance (ANOVA) with post-hoc testing. Optical coherence tomography were finished to measure the mean retinal nerve fiber layer(mRNFL). The associations between the ophthalmological measures and DTI metrics were analyzed using correlation analysis.

RESULTS

DON patients showed significantly reduced mRNFL thickness (P = 0.008) and abnormal visual evoked potential (VEP, delayed P100 latent time and/or reduced P100 amplitude, P = 0.001 and 0.064, respectively). There was a tendency for gradually reduced fractional anisotropy and increased diffusion in each segment of the whole visual pathway from overt DON and non-DON to HCs. For DON, the FA and MD of almost all segments of the visual pathway showed correlations with abnormal VEP.

CONCLUSION

s DTI is a useful tool for detecting microstructural changes in the entire visual pathway of DON due to TAO. Trans-synaptic degeneration may be a potential pathogenic mechanism of DON.

CLINICAL RELEVANCE/APPLICATION

Bidirectional trans-synaptic degeneration can be as a potential target for the neuroprotective treatment to DON. Additionally, DON is also an eye-brain neuropathy that is not confined to the eye but involves the entire visual pathway, providing evidence for a better understanding of the neuropathy mechanism of DON and the development of novel therapeutic regimens to slow or prevent the progression of neuropathy.

T2-SPHN-3 Clinical Value of 3D CT in Diagnosis of Unilateral Cricoarytenoid Joint Dislocation

Participants
Xueming Zeng, Nanjing City, China (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the value of 3D CT in diagnosis of unilateral cricoarytenoid joint dislocation, and evaluate the different types of cricoarytenoid joint dislocation, in order to improve the understanding of this disease.

METHODS AND MATERIALS

31 patients who had been diagnosed with unilateral cricoarytenoid joint dislocation retrospectively reviewed, all patients were treated by reduction forceps,the voice returned to normal or significantly improved in all patients. CT scans were made during rest(respiratory phase) and phonation(phonation phase).In phonation phase, each patient was asked to sustain the vowel /e/. Thin-layer CT images were reconstructed as volume imaging (3d VR). Two radiologists analysed all the CT images independently and subjectively. If there was any disagreement, the third senior radiologist made the final judgment.On 3D VR images, the arytenoid articular surface of cricoid cartilage exposed completely means total dislocation,exposed partially means subluxation; The posterior part of the arytenoid articular surface of cricoid cartilage exposed means anterior dislocation, the anterior part exposed means posterior dislocation; In phonation phase, the lateral part of the arytenoid articular surface of cricoid cartilage exposed means external dislocation, the medial part exposed means medial dislocation.

RESULTS

There were 28 cases of cricoarytenoid subluxation (90.3%, 28 / 31) and 3 cases of complete dislocation (9.7%, 3 / 31); 26 cases

(83.9%, 26 / 31) of left cricoarytenoid dislocation and 5 cases (16.1%, 5 / 31) of right dislocation; Posterior dislocation in 28 cases (90.3%, 28 / 31), anterior dislocation in 3 cases (9.7%, 3 / 31); There were 23 cases of medial dislocation (74.2%, 23 / 31), 2 cases of external dislocation (6.4%, 2 / 31), and 6 cases without obvious internal and external dislocation (19.4%, 6 / 31). Three cases of complete dislocation were left posterior internal dislocation; Among the 28 cases of subluxation, there were 24 cases of left posterior dislocation (77.4%, 24 / 31), 4 cases of right posterior dislocation (12.9%, 4 / 31), 2 cases of left anterior dislocation (6.4%, 2 / 31) and 1 case of right anterior dislocation (3.2%, 1 / 31).

CONCLUSION

s 3D CT is a reliable method for the diagnosis of cricoarytenoid dislocation.

CLINICAL RELEVANCE/APPLICATION

3D CT is a reliable method for the diagnosis of cricoarytenoid dislocation, it tell the accurate dislocation orientation reliably, and may have a guidance effect in reduction forceps.

T2-SPIN-1 Curation of the CANDID-II Dataset for Deep Learning Algorithm Development on Adult Chest Radiographs

Participants
Sijing Feng, MBChB, BMedSc, Mosgiel, New Zealand (*Presenter*) Nothing to Disclose

PURPOSE

One of the main barriers to artificial intelligence (AI) development in clinical radiology is the lack of high quality publicly available datasets, often due to significant time and labor costs. MIMIC-CXR, NIH-CXR, and CheXpert datasets are examples of large public chest radiograph datasets that have significantly advanced chest radiograph AI development. However, the number of radiological findings identified in these datasets are limited. The CANDID-II (Chest x-ray Anonymized Dataset In [location]) dataset aims to build on this by presenting a more comprehensively manually labeled multi-classification dataset. This dataset can be used for training and testing of a wide range of deep learning algorithms.

METHODS AND MATERIALS

295,613 chest radiographs were exported in DICOM format from the [location] Hospital PACS with their corresponding free text reports between January 2010 and April 2020. This was followed by algorithmic anonymization. Inclusion criteria included images of both frontal and lateral orientations, of patients aged at least 16 years old, images that were free of pre-annotations, and that had complete field coverage of both lungs. Preservation of temporal relationships between studies and anonymized patient grouping of studies were performed. Reports of included images were randomized and sampled with equal weighting across 11 years. Selected reports were then manually labeled for 45 radiographic findings in seven categories over six months and then were double read to ensure accuracy and quality of labels. All 45 labels were mapped to Unified Medical System Language (UMLS) and RadLex ontologies for consistency and standardization of their definitions.

RESULTS

53,235 adult frontal (67%) and lateral (33%) anonymized chest radiographs are included in the final CANDID-II dataset with 35,200 corresponding anonymized free-text reports. These images derive from 23,706 unique patients, with a gender proportion of 1.1:1.0 (M: F). The mean age of patients in the CANDID-II dataset is 64 years with a standard deviation of 19 years.

CONCLUSION

s The current project presents the curation of a large, publicly available anonymized comprehensively labeled chest radiograph dataset with corresponding free-text reports. After completion of ethics documentations, this dataset can be accessed at DOI: 10.17608/k6.auckland.19606921.

CLINICAL RELEVANCE/APPLICATION

The CANDID-II dataset can be used to train, test, and validate deep learning algorithms designed for a variety of clinical radiology applications including chest radiograph triaging, lung cancer screening, automated longitudinal follow up of abnormalities on chest radiographs as well as automated preliminary report generation.

T2-SPIN-2 Deep Learning for Pulmonary Embolism Response: A Validation of Artificial Intelligence-Guided RV/LV Analysis in Detecting and Predicting Outcomes

Participants
Anna Hu, BS, (*Presenter*) Nothing to Disclose

PURPOSE

Maximum right ventricle/left ventricle (RV/LV) ratio measurements from chest CT pulmonary angiograms (CTPA) and pulmonary embolism severity index (PESI) scoring are key risk indicators for life-threatening venous thromboembolic events (VTE), such as pulmonary embolism (PE). In practice, however, these indicators alone have limited prognostic value. This retrospective study was conducted using Imbio's artificial intelligence (AI)-guided RV/LV analysis software to assess its ability to evaluate success of Endovascular Thrombectomy (ET) and to predict the need for extracorporeal membrane oxygenation (ECMO) for treating PE.

METHODS AND MATERIALS

We retrospectively reviewed moderate to severe PE cases that were treated with Inari FlowTriever ET at our institution between December 2018 and March 2022. Out of 73 total cases, those that had both pre- and post-procedural CTPA were included (31 total cases, 12 patients who were placed on ECMO and 19 who were not). Selected patients were evaluated using PESI scoring and Imbio's RV/LV software was utilized to measure ventricular dilation. Clinical success was defined as an improvement of RV/LV ratio and no VTE or ET related complications.

RESULTS

Among the 31 patients included, the average PESI score was higher in patients who were placed on ECMO (130.2±40.8 (ECMO) vs 100.9±15.5 (non-ECMO), P<0.05). Similarly, the average change in pre- vs post-procedural RV/LV ratios was higher in patients who were placed on ECMO (0.936±0.420 (ECMO) vs 0.430±0.273 (non-ECMO), P<0.005). While the average post-procedural RV/LV ratios were not significantly different (P=0.484), average pre-procedural RV/LV ratios were significantly higher in patients who were placed on ECMO (1.977±0.370 (ECMO) vs. 1.480±0.312 (non-ECMO), P<0.0005). There was no significant difference in peak troponin levels prior to ET between the two groups (P=0.186). No complications were reported for any patients in both groups within 90 days post-operatively.

CONCLUSION

s Results from this study suggest that Inari FlowTriever ET is an effective therapy for patients with moderate to severe PE. Furthermore, AI-guided RV/LV analysis paired with PESI scoring can more reliably assess the need for ECMO therapy following ET than evaluating peak troponin values or radiologist-guided CTPA interpretations.

CLINICAL RELEVANCE/APPLICATION

PE are among the most fatal cardiovascular diseases, where acute and rapid diagnosis is essential to improve prognosis. AI-guided RV/LV analysis software can improve risk stratification and shorten treatment initiation time for patients with moderate to severe PE.

T2-SPIN-3 On-Demand Realistic Creation of Synthetic Chest Radiographs

Participants
Nicholas Primiano, MD, Buffalo, NY (*Presenter*) Nothing to Disclose

PURPOSE

Deep convolutional neural networks (dCNNs) have recently shown accuracy in identifying and quantifying disease on chest radiographs. Unfortunately, dCNNs require large amounts of labeled training data to yield desirable results. Labeling by expert radiologists is a costly and time-intensive process. Furthermore, there are a limited number of high quality public datasets and many of these datasets do not contain a variety of diseases. For example, only 2.4% of the CheXpert dataset and 1.2% of the NIH CXR-14 dataset is labeled “Pneumonia”. A generative adversarial network (GAN) can be used to create synthetic images that address these issues.

METHODS AND MATERIALS

A class conditional implementation of StyleGan3 was trained on a subset of the CheXpert dataset consisting of 191,027 frontal chest radiographs. It was trained on an Nvidia RTX 3090 GPU. Similarity metrics, Fréchet inception distance and kernel inception distance, were calculated with StyleGan3’s built-in metric generation tool. To determine if augmenting the dataset with synthetic images could improve the performance of a classification model, a DenseNet201 dCNN was trained on CheXpert as well as CheXpert augmented with 2,000 synthetic images per class label.

RESULTS

Synthetic chest radiographs with the following characteristics were generated: Atelectasis, Cardiomegaly, Consolidation, Edema, Enlarged Cardiomediastinum, Fracture, Lung Lesion, Lung Opacity, No Finding, Pleural Effusion, Pleural Other, Pneumonia, and Pneumothorax. The network performed well, yielding a Fréchet inception distance of 11.92 and a kernel inception distance of 0.0089. The DenseNet201 model, trained on the CheXpert dataset alone achieved an AUC of 0.80 on a multi-label classification task of the CheXpert validation dataset. Another DenseNet201 model was trained on the CheXpert dataset augmented with synthetic images and achieved an AUC of 0.87 on the same classification task.

CONCLUSION

s After training the network, high quality images of a particular disease state or radiographic finding can be produced on-demand. These images can augment existing datasets, resulting in improved classification of disease on chest radiographs.

CLINICAL RELEVANCE/APPLICATION

A large number of diverse synthetic chest radiographs can be created with a GAN. In contrast to real radiographs, GAN-generated radiographs do not require labeling or de-identification, making them ideal for deep learning research. In addition, they can be used to augment existing datasets to improve classification models that automatically classify disease. Finally, these techniques may be valuable educational tools, as they can be used to create on-demand realistic examples of rare pathologies with fine control over disease severity.

T2-SPIN-4 Not So Black and White: Convolutional Neural Networks and Vision Transformers Demonstrate Sex and Race-Based Bias For Chest Radiograph Diagnosis In Inconsistent Ways

Participants
Paul Yi, MD, Baltimore, MD (*Presenter*) Consultant, FH Orthopedics SAS;Consultant, BunkerHill Health

PURPOSE

Although convolutional neural networks (CNN) for thoracic disease diagnosis on chest radiographs (CXR) have demonstrated underperformance bias against underrepresented sex and racial groups, it is unclear if this is the case for vision transformers (VT), an emerging type of deep learning (DL) architecture with a fundamentally different mechanism of computer vision. We compared the presence and direction of bias based on sex and race in VT and CNN models trained to diagnose thoracic disease on CXR.

METHODS AND MATERIALS

We compared DenseNet 121 CNN and Data-efficient Image Transformer (DeiT) VT architectures, which have demonstrated state-of-the-art results in radiology and general computer vision tasks, respectively. We fine-tuned these models on the NIH CXR14 dataset of 112,120 CXRs annotated for 14 disease labels. There were more males than females (56% male); race was not reported. Data were randomly split into 70/10/20% train/validation/test splits with maintained sex/disease distributions. Hyperparameter optimization was performed via grid search. Test performance was assessed on the internal test set and external dataset of 25,000

images from Stanford's CheXpert dataset (56% male; 67% white). For each test set, we calculated AUROCs for each disease label, which were compared between demographic groups based on sex (both datasets) and race (CheXpert only).

RESULTS

AUROCs were significantly different between males and females for all disease labels in both test sets, as well as between white and non-white patients for all disease labels in CheXpert. However, the 'direction' of bias (group with worse diagnosis) was inconsistent between disease labels, datasets, and DL model type. For sex-based biases, in the NIH test set, the VT and CNN models had biases favoring males (higher AUROC) in 8/14 and 5/14 disease labels, respectively; in the CheXpert test set, they had biases favoring males in 1/7 and 3/7 disease labels, respectively (note CheXpert shares only 7 disease labels with the NIH dataset). For race-based biases, the VT and CNN models both had biases favoring white over non-white patients in 2/7 disease labels.

CONCLUSION

s Although CNN and VT models demonstrated biases based on sex and race, these biases were inconsistent between disease labels, testing datasets, and DL model architectures. Surprisingly, biases did not consistently disadvantage underrepresented groups, suggesting that bias in DL models stems from multiple and interacting factors that require further analysis and characterization.

CLINICAL RELEVANCE/APPLICATION

The widespread use of deep learning (DL) models for CXR diagnosis demands careful validation that controls for bias in under-represented groups, and these biases do not translate among different DL architectures.

T2-SPIN-5 Deep Learning Classification Model Can Predict Upgrade of DCIS Lesions To Invasive Breast Cancer

Participants
John Mayfield, MD, MS, Lithia, FL (*Presenter*) Nothing to Disclose

PURPOSE

A subset of ductal carcinoma in-situ (DCIS) lesions diagnosed on core biopsy will be upgraded to invasive breast cancer on surgical excision. Pre-operative identification of these lesions would inform clinical and surgical management of patients. The goal of our study was to train a Deep Convolutional Neural Network (DCNN) to classify DCIS lesions as non-upgraded or upgraded to invasive malignancy utilizing dynamic contrast-enhanced (DCE) breast MRI images, without the use of lesion segmentation.

METHODS AND MATERIALS

113 DCIS lesions (95 non-upgraded and 18 upgraded post-excision) were evaluated on pre-operative DCE-MRI. A board-certified breast radiologist identified each DCIS lesion. Subsequently, a single image of each lesion from the most delayed contrast-enhanced T1-weighted sequence was cropped to exclude the mediastinum and contralateral breast. To handle the class imbalance, a Deep Convolutional Generative Adversarial Network (DCGAN) created an additional 77 upgraded images (Fig. 1a). Images were randomly split 20 times into training, validation, and testing with a 60:20:20 ratio (Fig. 1b). Binary classification accuracy was separately reported with model loss. Bootstrap resampling was used to estimate the model confidence intervals.

RESULTS

The DCNN model was trained on 504,211,841 parameters with a dropout rate of 0.5 to reduce overfitting. Training and validation converged in 20 epochs with final reported validation accuracy of 78.2% (95% CI: 76.3 - 80.0). Testing on heldout DCIS images produced an 80.0% accuracy.

CONCLUSION

s Nonsegmented DCIS lesions can be classified into non-upgraded or upgraded predictive categorization prior to surgery using a DCNN. Given the class imbalance, next steps will include testing on a larger and independent dataset.

CLINICAL RELEVANCE/APPLICATION

Deep learning can assist in classifying DCIS lesions on DCE-MRI, impacting clinical and surgical management of patients. Application of the DCNN can be performed without the use of lesion segmentation, eliminating the interobserver variability encountered with manual or semi-automated segmentation methods.

T2-SPIN-6 Generalization of AI Analysis for Prostate Cancer Diagnostic Imaging to Multiple Centres and Scanners

Participants
Antony Rix, MEng, PhD, Cambridge, United Kingdom (*Presenter*) Stockholder, Lucida Medical Ltd;Director, Lucida Medical Ltd

PURPOSE

There has been little validation of AI to detect clinically significant prostate cancer (csPCa) beyond single site, mainly 3T, datasets, limiting translation to clinical practice. We evaluate how an AI system can generalise to real-world data from multiple sites, scanners, protocols, and field strengths, to provide stronger evidence to support clinical use.

METHODS AND MATERIALS

AI-based software (Lucida Medical, PI v2) was developed using PROSTATEx and retrospective data from three UK NHS sites (PAIR-1 study), 458 patients total, to assess generality of the AI. Data included 5 scanner models, 1.5T/3.0T field strengths, and different acquisition protocols. Data was split, balanced per site, 274 patients for training, 91 patients for development-validation, 94 patients for held-out-test. The software automatically outputs scores and ROIs intended to identify GS=3+4 csPCa per-patient, for biopsy selection, and per-lesion, for biopsy targeting. csPCa was confirmed by biopsy, with PI-RADS1/2 patients/lesions that did not receive a biopsy assumed negative.

RESULTS

For selecting patients for biopsy, the AI identified patients with csPCa with sensitivity 93% (95% CI 83-100%), specificity 41% (28-54%), NPV 92% (81-100%), and AUC 0.86 (0.76-0.93) using multiparametric MRI (mpMRI) data from the PROSTATEx/PAIR-1 held-out-test set (94 patients, 35% csPCa). On the whole PAIR-1 set (255 patients, PI-RADS=3), the reporting radiologists had

per-patient sensitivity 100% (95% CI 100-100%) due to the assumed ground truth, specificity 52% (44-60%), NPV 100% (100-100%), and AUC 0.93 (0.90-0.96). In meta-analysis of 12 major studies (37% csPCa), radiologists identified patients with GS=3+4 csPCa with sensitivity 86% and specificity 42%. For biopsy targeting (per-lesion), the AI identified csPCa lesions in the held-out-test set (140 lesions, 42% csPCa) with sensitivity 91% (82-98%), specificity 55% (45-65%), NPV 92% (85-98%), and AUC 0.82 (0.74-0.90) using mpMRI data. On the whole PAIR-1 set (344 lesions, PI-RADS=3), the reporting radiologists had per-lesion sensitivity 98% (95% CI 95-100%), specificity 49% (42-57%), NPV 98% (95-100%), and AUC 0.91 (0.88-0.94). The AI system has comparable sensitivity and specificity to radiologists in the PAIR-1 study, major radiology studies and AI literature, over this varied dataset.

CONCLUSION

s The proposed AI model shows promising results with both open and real-world multi-centre retrospective data with different field strengths and imaging.

CLINICAL RELEVANCE/APPLICATION

AI could support prostate cancer detection in diverse imaging settings including both 1.5T and 3T scanners, with sensitivity and specificity comparable to major radiology studies.

Curation of the CANDID-II Dataset for Deep Learning Algorithm Development on Adult Chest Radiographs

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - IN DPS

Participants
Sijing Feng, MBChB, BMedSc, Mosgiel, New Zealand (*Presenter*) Nothing to Disclose

PURPOSE

One of the main barriers to artificial intelligence (AI) development in clinical radiology is the lack of high quality publicly available datasets, often due to significant time and labor costs. MIMIC-CXR, NIH-CXR, and CheXpert datasets are examples of large public chest radiograph datasets that have significantly advanced chest radiograph AI development. However, the number of radiological findings identified in these datasets are limited. The CANDID-II (Chest x-ray Anonymized Dataset In [location]) dataset aims to build on this by presenting a more comprehensively manually labeled multi-classification dataset. This dataset can be used for training and testing of a wide range of deep learning algorithms.

METHODS AND MATERIALS

295,613 chest radiographs were exported in DICOM format from the [location] Hospital PACS with their corresponding free text reports between January 2010 and April 2020. This was followed by algorithmic anonymization. Inclusion criteria included images of both frontal and lateral orientations, of patients aged at least 16 years old, images that were free of pre-annotations, and that had complete field coverage of both lungs. Preservation of temporal relationships between studies and anonymized patient grouping of studies were performed. Reports of included images were randomized and sampled with equal weighting across 11 years. Selected reports were then manually labeled for 45 radiographic findings in seven categories over six months and then were double read to ensure accuracy and quality of labels. All 45 labels were mapped to Unified Medical System Language (UMLS) and RadLex ontologies for consistency and standardization of their definitions.

RESULTS

53,235 adult frontal (67%) and lateral (33%) anonymized chest radiographs are included in the final CANDID-II dataset with 35,200 corresponding anonymized free-text reports. These images derive from 23,706 unique patients, with a gender proportion of 1.1:1.0 (M: F). The mean age of patients in the CANDID-II dataset is 64 years with a standard deviation of 19 years.

CONCLUSION

s The current project presents the curation of a large, publicly available anonymized comprehensively labeled chest radiograph dataset with corresponding free-text reports. After completion of ethics documentations, this dataset can be accessed at DOI: 10.17608/k6.auckland.19606921.

CLINICAL RELEVANCE/APPLICATION

The CANDID-II dataset can be used to train, test, and validate deep learning algorithms designed for a variety of clinical radiology applications including chest radiograph triaging, lung cancer screening, automated longitudinal follow up of abnormalities on chest radiographs as well as automated preliminary report generation.

Deep Learning for Pulmonary Embolism Response: A Validation of Artificial Intelligence-Guided RV/LV Analysis in Detecting and Predicting Outcomes

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - IN DPS

Participants
Anna Hu, BS, (*Presenter*) Nothing to Disclose

PURPOSE

Maximum right ventricle/left ventricle (RV/LV) ratio measurements from chest CT pulmonary angiograms (CTPA) and pulmonary embolism severity index (PESI) scoring are key risk indicators for life-threatening venous thromboembolic events (VTE), such as pulmonary embolism (PE). In practice, however, these indicators alone have limited prognostic value. This retrospective study was conducted using Imbio's artificial intelligence (AI)-guided RV/LV analysis software to assess its ability to evaluate success of Endovascular Thrombectomy (ET) and to predict the need for extracorporeal membrane oxygenation (ECMO) for treating PE.

METHODS AND MATERIALS

We retrospectively reviewed moderate to severe PE cases that were treated with Inari FlowTriever ET at our institution between December 2018 and March 2022. Out of 73 total cases, those that had both pre- and post-procedural CTPA were included (31 total cases, 12 patients who were placed on ECMO and 19 who were not). Selected patients were evaluated using PESI scoring and Imbio's RV/LV software was utilized to measure ventricular dilation. Clinical success was defined as an improvement of RV/LV ratio and no VTE or ET related complications.

RESULTS

Among the 31 patients included, the average PESI score was higher in patients who were placed on ECMO (130.2±40.8 (ECMO) vs 100.9±15.5 (non-ECMO), $P<0.05$). Similarly, the average change in pre- vs post-procedural RV/LV ratios was higher in patients who were placed on ECMO (0.936±0.420 (ECMO) vs 0.430±0.273 (non-ECMO), $P<0.005$). While the average post-procedural RV/LV ratios were not significantly different ($P=0.484$), average pre-procedural RV/LV ratios were significantly higher in patients who were placed on ECMO (1.977±0.370 (ECMO) vs. 1.480±0.312 (non-ECMO), $P<0.0005$). There was no significant difference in peak troponin levels prior to ET between the two groups ($P=0.186$). No complications were reported for any patients in both groups within 90 days post-operatively.

CONCLUSION

s Results from this study suggest that Inari FlowTriever ET is an effective therapy for patients with moderate to severe PE. Furthermore, AI-guided RV/LV analysis paired with PESI scoring can more reliably assess the need for ECMO therapy following ET than evaluating peak troponin values or radiologist-guided CTPA interpretations.

CLINICAL RELEVANCE/APPLICATION

PE are among the most fatal cardiovascular diseases, where acute and rapid diagnosis is essential to improve prognosis. AI-guided RV/LV analysis software can improve risk stratification and shorten treatment initiation time for patients with moderate to severe PE.

T2-SPIN-3

On-Demand Realistic Creation of Synthetic Chest Radiographs

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - IN DPS

Participants
Nicholas Primiano, MD, Buffalo, NY (*Presenter*) Nothing to Disclose

PURPOSE

Deep convolutional neural networks (dCNNs) have recently shown accuracy in identifying and quantifying disease on chest radiographs. Unfortunately, dCNNs require large amounts of labeled training data to yield desirable results. Labeling by expert radiologists is a costly and time-intensive process. Furthermore, there are a limited number of high quality public datasets and many of these datasets do not contain a variety of diseases. For example, only 2.4% of the CheXpert dataset and 1.2% of the NIH CXR-14 dataset is labeled “Pneumonia”. A generative adversarial network (GAN) can be used to create synthetic images that address these issues.

METHODS AND MATERIALS

A class conditional implementation of StyleGan3 was trained on a subset of the CheXpert dataset consisting of 191,027 frontal chest radiographs. It was trained on an Nvidia RTX 3090 GPU. Similarity metrics, Fréchet inception distance and kernel inception distance, were calculated with StyleGan3’s built-in metric generation tool. To determine if augmenting the dataset with synthetic images could improve the performance of a classification model, a DenseNet201 dCNN was trained on CheXpert as well as CheXpert augmented with 2,000 synthetic images per class label.

RESULTS

Synthetic chest radiographs with the following characteristics were generated: Atelectasis, Cardiomegaly, Consolidation, Edema, Enlarged Cardiomediastinum, Fracture, Lung Lesion, Lung Opacity, No Finding, Pleural Effusion, Pleural Other, Pneumonia, and Pneumothorax. The network performed well, yielding a Fréchet inception distance of 11.92 and a kernel inception distance of 0.0089. The DenseNet201 model, trained on the CheXpert dataset alone achieved an AUC of 0.80 on a multi-label classification task of the CheXpert validation dataset. Another DenseNet201 model was trained on the CheXpert dataset augmented with synthetic images and achieved an AUC of 0.87 on the same classification task.

CONCLUSION

s After training the network, high quality images of a particular disease state or radiographic finding can be produced on-demand. These images can augment existing datasets, resulting in improved classification of disease on chest radiographs.

CLINICAL RELEVANCE/APPLICATION

A large number of diverse synthetic chest radiographs can be created with a GAN. In contrast to real radiographs, GAN-generated radiographs do not require labeling or de-identification, making them ideal for deep learning research. In addition, they can be used to augment existing datasets to improve classification models that automatically classify disease. Finally, these techniques may be valuable educational tools, as they can be used to create on-demand realistic examples of rare pathologies with fine control over disease severity.

Not So Black and White: Convolutional Neural Networks and Vision Transformers Demonstrate Sex and Race-Based Bias For Chest Radiograph Diagnosis In Inconsistent Ways

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - IN DPS

Participants
Paul Yi, MD, Baltimore, MD (*Presenter*) Consultant, FH Orthopedics SAS;Consultant, BunkerHill Health

PURPOSE

Although convolutional neural networks (CNN) for thoracic disease diagnosis on chest radiographs (CXR) have demonstrated underperformance bias against underrepresented sex and racial groups, it is unclear if this is the case for vision transformers (VT), an emerging type of deep learning (DL) architecture with a fundamentally different mechanism of computer vision. We compared the presence and direction of bias based on sex and race in VT and CNN models trained to diagnose thoracic disease on CXR.

METHODS AND MATERIALS

We compared DenseNet 121 CNN and Data-efficient Image Transformer (DeiT) VT architectures, which have demonstrated state-of-the-art results in radiology and general computer vision tasks, respectively. We fine-tuned these models on the NIH CXR14 dataset of 112,120 CXRs annotated for 14 disease labels. There were more males than females (56% male); race was not reported. Data were randomly split into 70/10/20% train/validation/test splits with maintained sex/disease distributions. Hyperparameter optimization was performed via grid search. Test performance was assessed on the internal test set and external dataset of 25,000 images from Stanford's CheXpert dataset (56% male; 67% white). For each test set, we calculated AUROCs for each disease label, which were compared between demographic groups based on sex (both datasets) and race (CheXpert only).

RESULTS

AUROCs were significantly different between males and females for all disease labels in both test sets, as well as between white and non-white patients for all disease labels in CheXpert. However, the 'direction' of bias (group with worse diagnosis) was inconsistent between disease labels, datasets, and DL model type. For sex-based biases, in the NIH test set, the VT and CNN models had biases favoring males (higher AUROC) in 8/14 and 5/14 disease labels, respectively; in the CheXpert test set, they had biases favoring males in 1/7 and 3/7 disease labels, respectively (note CheXpert shares only 7 disease labels with the NIH dataset). For race-based biases, the VT and CNN models both had biases favoring white over non-white patients in 2/7 disease labels.

CONCLUSION

s Although CNN and VT models demonstrated biases based on sex and race, these biases were inconsistent between disease labels, testing datasets, and DL model architectures. Surprisingly, biases did not consistently disadvantage underrepresented groups, suggesting that bias in DL models stems from multiple and interacting factors that require further analysis and characterization.

CLINICAL RELEVANCE/APPLICATION

The widespread use of deep learning (DL) models for CXR diagnosis demands careful validation that controls for bias in under-represented groups, and these biases do not translate among different DL architectures.

Deep Learning Classification Model Can Predict Upgrade of DCIS Lesions To Invasive Breast Cancer

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - IN DPS

Participants
John Mayfield, MD, MS, Lithia, FL (*Presenter*) Nothing to Disclose

PURPOSE

A subset of ductal carcinoma in-situ (DCIS) lesions diagnosed on core biopsy will be upgraded to invasive breast cancer on surgical excision. Pre-operative identification of these lesions would inform clinical and surgical management of patients. The goal of our study was to train a Deep Convolutional Neural Network (DCNN) to classify DCIS lesions as non-upgraded or upgraded to invasive malignancy utilizing dynamic contrast-enhanced (DCE) breast MRI images, without the use of lesion segmentation.

METHODS AND MATERIALS

113 DCIS lesions (95 non-upgraded and 18 upgraded post-excision) were evaluated on pre-operative DCE-MRI. A board-certified breast radiologist identified each DCIS lesion. Subsequently, a single image of each lesion from the most delayed contrast-enhanced T1-weighted sequence was cropped to exclude the mediastinum and contralateral breast. To handle the class imbalance, a Deep Convolutional Generative Adversarial Network (DCGAN) created an additional 77 upgraded images (Fig. 1a). Images were randomly split 20 times into training, validation, and testing with a 60:20:20 ratio (Fig. 1b). Binary classification accuracy was separately reported with model loss. Bootstrap resampling was used to estimate the model confidence intervals.

RESULTS

The DCNN model was trained on 504,211,841 parameters with a dropout rate of 0.5 to reduce overfitting. Training and validation converged in 20 epochs with final reported validation accuracy of 78.2% (95% CI: 76.3 - 80.0). Testing on heldout DCIS images produced an 80.0% accuracy.

CONCLUSION

s Nonsegmented DCIS lesions can be classified into non-upgraded or upgraded predictive categorization prior to surgery using a DCNN. Given the class imbalance, next steps will include testing on a larger and independent dataset.

CLINICAL RELEVANCE/APPLICATION

Deep learning can assist in classifying DCIS lesions on DCE-MRI, impacting clinical and surgical management of patients. Application of the DCNN can be performed without the use of lesion segmentation, eliminating the interobserver variability encountered with manual or semi-automated segmentation methods.

Generalization of AI Analysis for Prostate Cancer Diagnostic Imaging to Multiple Centres and Scanners

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - IN DPS

Participants
Antony Rix, MEng, PhD, Cambridge, United Kingdom (*Presenter*) Stockholder, Lucida Medical Ltd;Director, Lucida Medical Ltd

PURPOSE

There has been little validation of AI to detect clinically significant prostate cancer (csPCa) beyond single site, mainly 3T, datasets, limiting translation to clinical practice. We evaluate how an AI system can generalise to real-world data from multiple sites, scanners, protocols, and field strengths, to provide stronger evidence to support clinical use.

METHODS AND MATERIALS

AI-based software (Lucida Medical, PI v2) was developed using PROSTATEx and retrospective data from three UK NHS sites (PAIR-1 study), 458 patients total, to assess generality of the AI. Data included 5 scanner models, 1.5T/3.0T field strengths, and different acquisition protocols. Data was split, balanced per site, 274 patients for training, 91 patients for development-validation, 94 patients for held-out-test. The software automatically outputs scores and ROIs intended to identify GS=3+4 csPCa per-patient, for biopsy selection, and per-lesion, for biopsy targeting. csPCa was confirmed by biopsy, with PI-RADS1/2 patients/lesions that did not receive a biopsy assumed negative.

RESULTS

For selecting patients for biopsy, the AI identified patients with csPCa with sensitivity 93% (95% CI 83-100%), specificity 41% (28-54%), NPV 92% (81-100%), and AUC 0.86 (0.76-0.93) using multiparametric MRI (mpMRI) data from the PROSTATEx/PAIR-1 held-out-test set (94 patients, 35% csPCa). On the whole PAIR-1 set (255 patients, PI-RADS=3), the reporting radiologists had per-patient sensitivity 100% (95% CI 100-100%) due to the assumed ground truth, specificity 52% (44-60%), NPV 100% (100-100%), and AUC 0.93 (0.90-0.96). In meta-analysis of 12 major studies (37% csPCa), radiologists identified patients with GS=3+4 csPCa with sensitivity 86% and specificity 42%. For biopsy targeting (per-lesion), the AI identified csPCa lesions in the held-out-test set (140 lesions, 42% csPCa) with sensitivity 91% (82-98%), specificity 55% (45-65%), NPV 92% (85-98%), and AUC 0.82 (0.74-0.90) using mpMRI data. On the whole PAIR-1 set (344 lesions, PI-RADS=3), the reporting radiologists had per-lesion sensitivity 98% (95% CI 95-100%), specificity 49% (42-57%), NPV 98% (95-100%), and AUC 0.91 (0.88-0.94). The AI system has comparable sensitivity and specificity to radiologists in the PAIR-1 study, major radiology studies and AI literature, over this varied dataset.

CONCLUSION

s The proposed AI model shows promising results with both open and real-world multi-centre retrospective data with different field strengths and imaging.

CLINICAL RELEVANCE/APPLICATION

AI could support prostate cancer detection in diverse imaging settings including both 1.5T and 3T scanners, with sensitivity and specificity comparable to major radiology studies.

T2-SPIR

Interventional Tuesday Poster Discussions

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - IR DPS

Sub-Events

T2-SPIR-1 Safety and Effectiveness of Uterine Fibroid Embolization in Patients with Scarred Uterus

Participants
Saebyol Ma, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the safety and effectiveness of uterine fibroid embolization (UFE) in patients with a scarred uterus caused by a previous myomectomy or cesarean section

METHODS AND MATERIALS

A total of 140 patients who underwent embolization for symptomatic fibroids were included in this retrospective study. The patients were divided into two groups, those with a history of myomectomy and/or cesarean section (scarred uterus group, n = 56), and those without surgical history involving the uterus (no-scar group, n = 84). Demographics, embolization details, outcomes, and complications were analyzed and compared between the two groups.

RESULTS

The overall clinical success rate was 89.28% in the scarred uterus group and 95.24% in the no-scar group. There was no statistical difference in infarction rate or change in fibroid volume in follow-up magnetic resonance imaging (MRI) between the groups. There was one major complication in the no-scar group, but there was no statistical difference in minor and major complications between the groups. The mean follow-up period was 25.9 months. The mean symptom-free time was 27.2 months in the scarred uterus group and 21.9 months in the no-scar group without a significant difference. There were no statistically significant differences in symptom changes, recurrence, and complication rates between the groups. Recurrence seen on imaging or regrowth was more common in the group with myomectomy history (36.8% vs. 15.9%, P = 0.052). However, there was no significant difference in symptom recurrence rates (15.8% vs. 12.5%, P = 0.713).

CONCLUSION

s No statistically significant difference in technical and clinical outcomes was observed between the two groups. There was no significant increase in UFE complication rates in patients with a scarred uterus.

CLINICAL RELEVANCE/APPLICATION

UFE did not increase the risk of complications after myomectomy or cesarean section. Patients with a scarred uterus showed similar technical and clinical outcomes compared to the no-scar group in this study. Although caution should be taken, UFE can be a good option for symptomatic fibroid treatment in patients with a scarred uterus.

T2-SPIR-2 Cost Comparison of Prostatic Artery Embolization Between In-Hospital and Outpatient Lab Settings

Participants
Lucas Cusumano, MD, MPH, (*Presenter*) Nothing to Disclose

PURPOSE

To determine the costs associated with prostatic artery embolization (PAE) performed for treatment of benign prostatic hyperplasia (BPH) in hospital and outpatient-based lab (OBL) settings.

METHODS AND MATERIALS

Patients evaluated underwent outpatient PAE between January 2021 and December 2021, utilizing right common femoral artery access. Procedures were performed in similarly-equipped procedure suites located within a tertiary hospital or OBL. Costs were determined utilizing time-driven activity-based costing (TDABC), a micro-costing methodology for calculating procedural costs incurred by the institution. Process maps were created describing personnel, space, equipment, and materials. Time duration of each procedural step was recorded independently by a nurse caring for the patient at the time of the procedure and mean values were included in our model. Costs and capacity cost rates were determined using institutional and publicly available financial data.

RESULTS

37 PAE procedures met inclusion criteria with a mean patient age of 70.4 (+/- 6.7) years and mean prostate gland size of 129.7 (+/-56.4) cc. 26 procedures were performed within the hospital setting and 11 procedures were performed within the OBL. Reduction in International Prostate Symptom Score (IPSS) was not significantly different following hospital and OBL procedures (57.2% vs. 81.8%, P=0.1850). Mean procedural time was not significantly different between the hospital and OBL settings (132.0 vs. 147.4 minutes, P=0.1574). However, duration between admission to discharge was significantly longer for procedures performed

in a hospital setting (468.8 vs. 325.4 minutes, P<0.0001). Total costs for hospital-based procedures were marginally higher ($3,858.28 vs. $3,642.67). Personnel and material costs constitute the largest proportion costs of 54.7% and 41.6%, respectively.

CONCLUSION

s Total PAE cost was similar between the hospital and OBL settings. However, longer periprocedural times for hospital-based procedures and differences in reimbursement may favor performance of PAE in an OBL setting.

CLINICAL RELEVANCE/APPLICATION

PAE is a safe and effective treatment for BPH. However, there is a paucity of data regarding costs, especially comparing hospital and OBL settings. The ongoing shift towards value-based incentive models requires accurate assessment of cost drivers and cost inefficiencies.

T2-SPIR-3 SpaceOAR Hydrogel Distribution and Early Complications in Patients Undergoing Radiation Therapy for Prostate Cancer

Participants
Andrew Yates, MBBCh, BSc, Dublin 7, Ireland (*Presenter*) Nothing to Disclose

PURPOSE

Hydrogel spacers aim to separate the rectum from the prostate before radiation therapy for patients with prostate cancer to decrease the radiation dose to the rectum. The aim of this study was the evaluate the distribution of the hydrogel spacer between the rectum and the prostate, to assess for hydrogel rectal wall infiltration and to assess for immediate complications

METHODS AND MATERIALS

Retrospective study of 161 patients that underwent hydrogel spacer injection was performed. . Symmetry and distribution of the hydrogel were assessed on planning MRI, as was the separation of the rectum and prostate. The MRI was reviewed for rectal wall injection or other malplacement of gel. Immediate post-procedure complications were recorded.

RESULTS

117 (72.7%) patients had a symmetrical distribution of the hydrogel spacer with 44 (27.3%) patients having some asymmetry of the spacer. The mean anteroposterior rectoprostatic separation was 10.2 ± 3.7 mm with a range of 0 - 27 mm. Eight (5.0%) patients had some rectal wall infiltration on the MRI; 7 (4.3%) patients had minimal infiltration and one (0.6%) patient had moderate infiltration. One (0.6%) patient had intraprostatic injection of gel. Two (1.2%) patients required treatment in the emergency department after the procedure; one for urinary retention and one for pain.

CONCLUSION

s Hydrogel injection effectively separates the prostate from the rectum with a symmetrical distribution in the majority of cases prior to radiation therapy with a low rate of rectal wall injection and immediate complications.

CLINICAL RELEVANCE/APPLICATION

This study informs clinicians regarding the technique, outcomes and complications related to hydrogel spacer injection prior to radiation therapy.

T2-SPIR-5 Embolization Treatment of Primary Chylous Reflux Disease of Genitalia (PCRG)

Participants
Hee Eun Moon, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Primary chylous reflux disease of genitalia (PCRG) is a rare but devastating clinical condition manifested as genital chylolymphorrhea caused by the gravity-dependent reflux of abdominal chylous lymphatic fluid and consequent lymphatic dermal/mucosal backflow through megalymphatic vessels with incompetent valve.The purpose of this study is to evaluate the clinical efficacy and safety of lymphatic embolization as treatment of PCRG.

METHODS AND MATERIALS

This is a retrospective study conducted from May 2016 to January 2022 at two advanced lymphatic centers (Seoul National University Hospital, Hospital of the University of Pennsylvania). Lymphoscintigraphy, dynamic contrast MR lymphangiography (DCMRL) and lipiodol lymphangiography were used to confirm the lymphatic backflow to inguinal, genital and medial thigh area. Diseased lymphatic vessels were selectively embolized using N-butyl cyanoacrylate (NBCA) glue to stop the lymphatic reflux.

RESULTS

In total, 13 embolization procedures were performed. Three patients underwent additional treatments, two for residual symptoms and one for recurred symptoms. The technical and clinical success rate were 100% (13/13) and 90% (9/10), respectively. Major complication occurred in one patient (1/10), in whom leg lymphedema worsened without improvement of genital lymphorrhea. 9 patients (out of 10) experienced immediate symptom improvement after initial embolization. 3 patients underwent additional embolization, 2 for residual and 1 for recurred symptoms.

CONCLUSION

s Overall, lymphatic embolization provided high clinical success rate with relatively low complication rate. We propose lymphatic embolization as a treatment option for PCRG that can significantly improve quality of life when performed with appropriate techniques in selected patients.

CLINICAL RELEVANCE/APPLICATION

Same as conclusions.

T2-SPIR-8 Simultaneous Portal Vein Embolization and Percutaneous Transhepatic Biliary Drainage Prior to Major

Hepatectomy Is Feasible and Safe

Participants
Mohamed Soliman, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Demonstrate the feasibility and safety of simultaneous Percutaneous Transhepatic Biliary Drainage (PTBD) and Portal Vein Embolization (PVE) for pre-operative optimization prior to major hepatectomy for an obstructive hilar malignancy.

METHODS AND MATERIALS

Following IRB approval, all patients with a resectable obstructive hilar malignancy who underwent both PVE and biliary drainage for pre-operative optimization were retrospectively identified. Type of initial drainage attempt (Endoscopic vs. PTBD), type, indication and number of subsequent drainage procedures, PVE-to-biliary drainage (BD) time interval, and drainage complications were recorded. Number of PVE procedures, embolic agent, degree of future liver remnant (FLR) hypertrophy, PVE-to-resection interval, and complications were recorded. Three groups were devised based on the PVE-BD interval in days (Group 1: t=0, n=5; Group 2: t =7to=30, n=12; Group 3: t>30, n=18). All patients in group 1 underwent PTBD. Primary endpoint was the rate of Grade B/C Post-Hepatectomy Liver Failure (PHLF). Secondary outcomes included assessment of rates of surgical resection, complications, and comparison of initial biliary drainage techniques.

RESULTS

A total of 35 patients (males n=25, females n=10, average age=64 years old) underwent both BD and PVE prior to major hepatectomy for either hilar cholangiocarcinoma (n=31) or gallbladder carcinoma (n=4). Rates of surgical resection were comparable among the three groups: Group 1: 4/5 [80%], Group 2: 6/12 [50%], Group 3: 8/18 [44%], p=0.87). There was no statistical difference between the groups in incidence of grade B/C PHLF (p=0.56). Initial biliary decompression was more commonly performed with an endoscopic stent (20/35, 57%) or PTBD 12/35, 34%). The former was associated with higher rates of post-procedural complications (11/20 [55%] vs. 4/12 [33%], p=0.03). In addition, 13/20 (65%) patients who underwent initial endoscopic drainage required subsequent PTBD due to inadequate drainage of the FLR.

CONCLUSION

s Simultaneous BD and PVE for pre-operative optimization is safe and feasible. PTBD may be the optimal initial biliary drainage strategy.

CLINICAL RELEVANCE/APPLICATION

Patients with a hilar mass suspicious for malignancy often undergo initial endoscopic biopsy with plastic stent placement for obstructive jaundice relief. Plastic stents often result in inadequate drainage of the FLR requiring subsequent endoscopic and percutaneous procedures to achieve optimal drainage. Additionally, patients who are surgical candidates require a major hepatectomy necessitating pre-surgical optimization with PVE to reduce the risk of PHLF. This paper examines the feasibility and safety of simultaneous PVE and PTBD on postoperative outcomes.

T2-SPIR-9 Quantitative Evaluation and Spatial-visual Imaging of Liver Tissue Shrinkage Ex Vivo by Thermal Microwave Ablation Using Dynamic CT

Participants
Stefan Niehues, MD, Berlin, Germany (*Presenter*) Speaker, Bracco Group;Speaker, Guerbet SA;Speaker, Canon Medical Systems Corporation;Speaker, Teleflex Incorporated

PURPOSE

Microwave ablation of liver tissue has gained importance in recent years. However, ablations may show tissue shrinkage immediately after ablation, which complicates the evaluation of ablation and can lead to an incorrect assessment of ablation success. Knowing about the typical shrinkage progression could allow for better assessment of ablation zone, but has not been systematically described yet. This study aimed to experimentally characterize and visualize the spatial distribution of liver tissue shrinkage during microwave ablation using computed tomography (CT) with 2D and 3D post-processing.

METHODS AND MATERIALS

Eight injections of CT contrast agent were positioned in each of the six ex vivo bovine liver samples to form a three-dimensional reference grid around a microwave ablation antenna. Ablation was performed for 5 min at 100 W. CT scans of the liver sample were acquired every 30s during ablation and every 60s during subsequent cooling for an additional 10 min. 2D and 3D motion of the reference grid was tracked and used to calculate measures and spatial dimensions of enclosed tissue.

RESULTS

Spatial distortion of the reference-grid indicated volume change of liver tissue resulting in a total volume reduction of 8.0% ($p<0.001$) with a maximum extent located centrally. 6.6% of volume reduction appears during ablation ($p<0.001$) with an additional 1.4% during the cooling phase. After 5 min no further tissue change could be measured. Two-dimensional radius reduction ranged from -18% to -2% with random distribution.

CONCLUSION

s In microwave ablation significant tissue shrinking of up to -8% can occur. Shrinkage predominantly occurs during the ablation phase but also shows a random distribution making it challenging to predict.

CLINICAL RELEVANCE/APPLICATION

This study provides a better understanding of shrinkage after liver ablation, which is important for planning or evaluation. Because of its randomness, shrinkage cannot be systematically accounted for in post-ablation evaluation.

Safety and Effectiveness of Uterine Fibroid Embolization in Patients with Scarred Uterus

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - IR DPS

Participants
Saebyol Ma, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the safety and effectiveness of uterine fibroid embolization (UFE) in patients with a scarred uterus caused by a previous myomectomy or cesarean section

METHODS AND MATERIALS

A total of 140 patients who underwent embolization for symptomatic fibroids were included in this retrospective study. The patients were divided into two groups, those with a history of myomectomy and/or cesarean section (scarred uterus group, n = 56), and those without surgical history involving the uterus (no-scar group, n = 84). Demographics, embolization details, outcomes, and complications were analyzed and compared between the two groups.

RESULTS

The overall clinical success rate was 89.28% in the scarred uterus group and 95.24% in the no-scar group. There was no statistical difference in infarction rate or change in fibroid volume in follow-up magnetic resonance imaging (MRI) between the groups. There was one major complication in the no-scar group, but there was no statistical difference in minor and major complications between the groups. The mean follow-up period was 25.9 months. The mean symptom-free time was 27.2 months in the scarred uterus group and 21.9 months in the no-scar group without a significant difference. There were no statistically significant differences in symptom changes, recurrence, and complication rates between the groups. Recurrence seen on imaging or regrowth was more common in the group with myomectomy history (36.8% vs. 15.9%, P = 0.052). However, there was no significant difference in symptom recurrence rates (15.8% vs. 12.5%, P = 0.713).

CONCLUSION

s No statistically significant difference in technical and clinical outcomes was observed between the two groups. There was no significant increase in UFE complication rates in patients with a scarred uterus.

CLINICAL RELEVANCE/APPLICATION

UFE did not increase the risk of complications after myomectomy or cesarean section. Patients with a scarred uterus showed similar technical and clinical outcomes compared to the no-scar group in this study. Although caution should be taken, UFE can be a good option for symptomatic fibroid treatment in patients with a scarred uterus.

T2-SPIR-2

Cost Comparison of Prostatic Artery Embolization Between In-Hospital and Outpatient Lab Settings

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - IR DPS

Participants
Lucas Cusumano, MD, MPH, (*Presenter*) Nothing to Disclose

PURPOSE

To determine the costs associated with prostatic artery embolization (PAE) performed for treatment of benign prostatic hyperplasia (BPH) in hospital and outpatient-based lab (OBL) settings.

METHODS AND MATERIALS

Patients evaluated underwent outpatient PAE between January 2021 and December 2021, utilizing right common femoral artery access. Procedures were performed in similarly-equipped procedure suites located within a tertiary hospital or OBL. Costs were determined utilizing time-driven activity-based costing (TDABC), a micro-costing methodology for calculating procedural costs incurred by the institution. Process maps were created describing personnel, space, equipment, and materials. Time duration of each procedural step was recorded independently by a nurse caring for the patient at the time of the procedure and mean values were included in our model. Costs and capacity cost rates were determined using institutional and publicly available financial data.

RESULTS

37 PAE procedures met inclusion criteria with a mean patient age of 70.4 (+/- 6.7) years and mean prostate gland size of 129.7 (+/-56.4) cc. 26 procedures were performed within the hospital setting and 11 procedures were performed within the OBL. Reduction in International Prostate Symptom Score (IPSS) was not significantly different following hospital and OBL procedures (57.2% vs. 81.8%, P=0.1850). Mean procedural time was not significantly different between the hospital and OBL settings (132.0 vs. 147.4 minutes, P=0.1574). However, duration between admission to discharge was significantly longer for procedures performed in a hospital setting (468.8 vs. 325.4 minutes, P<0.0001). Total costs for hospital-based procedures were marginally higher ($3,858.28 vs. $3,642.67). Personnel and material costs constitute the largest proportion costs of 54.7% and 41.6%, respectively.

CONCLUSION

s Total PAE cost was similar between the hospital and OBL settings. However, longer periprocedural times for hospital-based procedures and differences in reimbursement may favor performance of PAE in an OBL setting.

CLINICAL RELEVANCE/APPLICATION

PAE is a safe and effective treatment for BPH. However, there is a paucity of data regarding costs, especially comparing hospital and OBL settings. The ongoing shift towards value-based incentive models requires accurate assessment of cost drivers and cost inefficiencies.

SpaceOAR Hydrogel Distribution and Early Complications in Patients Undergoing Radiation Therapy for Prostate Cancer

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - IR DPS

Participants
Andrew Yates, MBBCh, BSc, Dublin 7, Ireland (*Presenter*) Nothing to Disclose

PURPOSE

Hydrogel spacers aim to separate the rectum from the prostate before radiation therapy for patients with prostate cancer to decrease the radiation dose to the rectum. The aim of this study was the evaluate the distribution of the hydrogel spacer between the rectum and the prostate, to assess for hydrogel rectal wall infiltration and to assess for immediate complications

METHODS AND MATERIALS

Retrospective study of 161 patients that underwent hydrogel spacer injection was performed. . Symmetry and distribution of the hydrogel were assessed on planning MRI, as was the separation of the rectum and prostate. The MRI was reviewed for rectal wall injection or other malplacement of gel. Immediate post-procedure complications were recorded.

RESULTS

117 (72.7%) patients had a symmetrical distribution of the hydrogel spacer with 44 (27.3%) patients having some asymmetry of the spacer. The mean anteroposterior rectoprostatic separation was 10.2 ± 3.7 mm with a range of 0 - 27 mm. Eight (5.0%) patients had some rectal wall infiltration on the MRI; 7 (4.3%) patients had minimal infiltration and one (0.6%) patient had moderate infiltration. One (0.6%) patient had intraprostatic injection of gel. Two (1.2%) patients required treatment in the emergency department after the procedure; one for urinary retention and one for pain.

CONCLUSION

s Hydrogel injection effectively separates the prostate from the rectum with a symmetrical distribution in the majority of cases prior to radiation therapy with a low rate of rectal wall injection and immediate complications.

CLINICAL RELEVANCE/APPLICATION

This study informs clinicians regarding the technique, outcomes and complications related to hydrogel spacer injection prior to radiation therapy.

T2-SPMK-1 Clinical Evaluation of 3D Elbow Joint MRI with Deep Learning-based Reconstruction: Diagnostic Performance of Tendon and Ligament Injury

Participants
Young Hwa Suh, MD, Busan, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To assess the diagnostic performance of 3D elbow joint MRI with deep learning-based reconstruction (DLR) compared with 2D 1mm slice thickness MRI (1mm MRI) and 3D MRI with conventional reconstruction (CR) to evaluated tendon and ligament injury of elbow joint.

METHODS AND MATERIALS

This retrospective study included 22 patients with 23 elbows (12 men, 8 women; mean age, 53.6 ± 8.9 [SD] years) between October 2021 and February 2022. They underwent 3T elbow MRI with the protocol including T2-weighted fat saturated (T2FS) coronal 1mm MRI with DLR, and 3D proton-density weighted fat saturated (PDFS) coronal MRI with CR and DLR. One musculoskeletal radiologist with 9-year experience assessed three sequences for subjective image quality and artifacts and identified pathologies of the proximal common extensor tendon (CET) and common flexor tendon (CFT), radial collateral ligament (RCL), lateral ulnar collateral ligament (LUCL), and ulnar collateral ligament (UCL). In 10 patients who underwent operation, diagnostic performance was calculated using surgical records as a reference standard.

RESULTS

Mean subjective image quality scores of 2D T2FS 1mm MRI, 3D PDFS MRI with CR and DLR were 2.9 ± 0.4, 2.1 ± 0.6, and 2.9 ± 0.3, respectively. There were significant differences between 2D T2FS 1mm MRI and 3D PDFS MRI with CR, between 3D PDFS MRI with CR and DLR. Mean artifact scores were 3.3 ± 0.6, 3.9 ± 0.3, and 3.9 ± 0.3, respectively. There were significant differences between 2D T2FS 1mm MRI and 3D PDFS MRI with CR, between 2D T2FS 1mm MRI with 3D PDFS MRI with DLR. For three sequences, the diagnostic performance using area under the receiver operating characteristic curve of 2D T2FS 1mm MRI, 3D PDFS MRI with CR and DLR were 0.841, 0.773, and 0.818, respectively. The diagnostic performance of 3D PDFS coronal MRI with adding axial reformation, 3D PDFS coronal MRI with adding axial and sagittal reformation were both 0.886.

CONCLUSION

s By multiplanar reformation, 3D elbow joint MRI with deep learning-based reconstruction showed comparable diagnostic performance than 2D 1mm MRI for the evaluation of tendon and ligament injuries of elbow joint with similar subjective image qualities and artifacts.

CLINICAL RELEVANCE/APPLICATION

3D elbow joint MRI with deep learning-based reconstruction can help detect tendon and ligament pathologies of small joints by multiplanar reformation.

T2-SPMK-2 Operative Management of Advanced Wrist Arthritis: The Current Role of Preoperative Imaging and Intraoperative Inspection

Participants
Shelby Payne, MD, Stanford, CA (*Presenter*) Nothing to Disclose

PURPOSE

Our objectives are to (1) analyze the influence of preoperative imaging (radiography, CT, MRI) on surgical decision-making for wrist arthrodesis and carpectomy procedures, (2) assess the frequency of intraoperative inspection to determine arthritis distribution, and (3) determine the most common surgical procedures for end-stage wrist arthritis.

METHODS AND MATERIALS

A systematic search of peer-reviewed literature on the role of preoperative imaging and intraoperative inspection in the selection of carpal bone fusion and carpectomy procedures was performed in three databases (Pubmed, Embase, Scopus) using established

criteria (PRISMA Extension for Scoping Reviews). Included studies reported at least 3 adult patients with advanced wrist arthritis and were published within the past 11 years (1/1/2011-4/6/2022). Procedures at the trapeziometacarpal and distal radioulnar joints were excluded.

RESULTS

From a total of 307 publications, eligibility criteria were satisfied by 48 articles. A total of 1,823 patients (1,886 wrists) received surgical intervention (age mean 51 [SD 10] yrs; 63% men, 37% women). Of 13 different arthrodesis and carpectomy procedures reported, the four most common were: four-corner fusion with scaphoid excision (845/ 1886, 45%), total wrist arthrodesis (457/1886, 24%), proximal row carpectomy (256/1886, 14%), and scaphocapitate fusion (79/1886, 4%). All articles reported preoperative radiography, but only a small number of articles reported preoperative CT (3/48, 6%) or MRI (2/48, 4%). Only 16 articles (33%) reported intraoperative inspection of the cartilage.

CONCLUSION

s All articles reported that the selection of a surgical procedure was influenced by the radiographic distribution of advanced arthritis in the carpus. Preoperative advanced imaging and intraoperative evaluation was not commonly performed, despite the current widespread availability of CT/MRI and wrist arthroscopy. Of 13 different surgical procedures, the most commonly reported was a 4-corner fusion with scaphoidectomy. Future research should address the unresolved controversy regarding any added value of CT, MRI, and diagnostic arthroscopy for optimizing surgical decision making.

CLINICAL RELEVANCE/APPLICATION

Despite the widespread use of CT, MRI, and diagnostic arthroscopy, radiography is generally the only technique used to assess the distribution of advanced arthritis prior to wrist surgery.

T2-SPMK-3 Chronic Pain After Arthroplasty: Major Contributions of Magnetic Resonance Imaging with Metal Artifact Reduction Sequences.

Participants
Ronald M. Trindade, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To determine the association between resorption at interfaces, using MAVRIC-SL (multiacquisition with variable resonance image combination-selective) sequences in Magnetic Resonance (MR), and the clinical severity of patients undergoing Total Knee Arthroplasties (TKA) and Total Hip Arthroplasties (THA); to describe areas affected by bone resorption in each component of the prostheses; to determine intra and interobserver agreement in the diagnosis of partial loosening of the prosthetic components and to compare fibrous membrane and osteolysis in this context.

METHODS AND MATERIALS

A cross-sectional study was carried out between March 2019 and August 2020, with 47 patients (49 arthroplasties). Postoperative follow-up of knee or hip arthroplasties, with chronic pain 03 months after surgery, who answered the WOMAC questionnaire. The interfaces of the components of arthroplasties were defined as: osseintegration, parcial loosening (fibrous membrane-type reabsorption or osteolysis) or non-diagnostic.

RESULTS

When the loosening criterion is based only on the presence of osteolysis, there is a significant difference in the WOMAC means (p=0.010). When the loosening criteria include osteolysis and fibrous membrane, there are no differences between groups, except in the stiffness subdomain (p=0,026). The images obtained by MAVRIC-SL showed slight correlation between the number of osteolytic zones and clinical severity in most analysis. In the hip, there was a predominance of resorption (osteolysis) in the proximal femoral region (Gruen zones 1, 7, 8, 13 and 14), corresponding to 53.2% of the total. In the knee, the zones most affected by resorption (fibrous membrane) were those related to the tibial plateaus and its stem (zones 1, 2, 3, 4 e 5), corresponding to 64.3% of the total. There was substancial inter-reader reliability for most components (THA: acetabulum with k=0.72 and femur with k=0,77; TKA: tibia with k=0,72). The intraobserver analysis showed moderate and substantial agreement for most components (THA: acetabulum with k=0.57 and femur with k=0,64; TKA: femur with k=0,76 and tibia with k=0.62).

CONCLUSION

s MR with MAVRIC-SL sequences demonstrated that in this sample, consisting of metal-on-metal type prosthesis, the characterization of periprosthetic osteolysis, may play an important role in clinical complaints and loss of joint function, with substancial interobserver and inter-rater reliability. In THA, partial loosening occurs mainly in the proximal part of the femoral component, while in TKA it occurs mainly in the plateau and stem region of the tibial component.

CLINICAL RELEVANCE/APPLICATION

MRI with metal artifact reduction sequences as an additional tool for chronic pain evaluation in patients after arthroplasties.

T2-SPMK-4 Identification of Bone Marrow Edema in Spondylodiscitis of The Dorso-lumbar Spine: Diagnostic Accuracy of Dual-energy CT Versus MRI

Participants
Giovanni Foti, MD, Negrar, Italy (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the diagnostic accuracy values of dual-energy Computed Tomography (DECT) in identifying bone marrow edema (BME) in spondylodiscitis of the dorso-lumbar spine.

METHODS AND MATERIALS

This prospective institutional review board-approved study included 40 consecutive patients (24 males and 16 females; mean age of 66.4, range 22-79 years) studied between January 2020 and January 2022. All patients underwent DECT (80 kV and tin filter 150 kV) and MRI within 7 days. DECT data were post-processed on a dedicated offline workstation (SyngoVia® VB20) by using a three-material decomposition algorithm for generating non-calcium images. Two radiologists (16 and 8 years of experience, respectively),

blinded to clinical data, evaluated the presence of BME on dedicated color-coded maps, endplate erosions and peri-vertebral inflammation. Diagnostic accuracy values of DECT were calculated by using MRI images as standard of reference. DECT numbers were assessed by using a region of interest (quantitative assessment). Receiver operator curves (ROC) and relative area under the curve (AUC) were calculated. Inter-observer and intra-observer agreement were calculated with k-statistics. Continuous and categorical variables were evaluated by using t test and x2 or Fisher exact test, as appropriate. A value of $p<0.05$ was considered statistically significant.

RESULTS

MRI revealed the presence4 of spondylodiscitis in 32/40 patients (80.0%), located at the level of dorsal (n=15) and lumbar spine (n=25), respectively. The sensitivity, specificity, and AUC of DECT were 87.5% (28/32), 75.0 % (6/8) with an AUC of 0.886 (95% CI: 0.771-0.915) for R1, and 75% (24/32) and 100% (8/8) with an AUC of 0.862 (95% CI: 0.748-0.909) for R2. DECT numbers were significantly different between positive (mean -11.4 ± 22.5 HU) and negative cases (mean -77.3 ± 32.3HU) with a p value <0.001. The interobserver and intraobsever agreements were near perfect (k=0.87 and k=0.89, respectively).

CONCLUSION

s DECT is an accurate imaging tool for the diagnosis of spondylodiscitis.

CLINICAL RELEVANCE/APPLICATION

DECT represents a fast and accurate imaging tool for demonstration of BME, erosions and peri-vertebral inflammation in dorso-lumbar spondylodiscitis, virtually free from motion artifacts and with the additional advantage to yield high resolution bone window images.

Clinical Evaluation of 3D Elbow Joint MRI with Deep Learning-based Reconstruction: Diagnostic Performance of Tendon and Ligament Injury

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - MK DPS

Participants
Young Hwa Suh, MD, Busan, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To assess the diagnostic performance of 3D elbow joint MRI with deep learning-based reconstruction (DLR) compared with 2D 1mm slice thickness MRI (1mm MRI) and 3D MRI with conventional reconstruction (CR) to evaluated tendon and ligament injury of elbow joint.

METHODS AND MATERIALS

This retrospective study included 22 patients with 23 elbows (12 men, 8 women; mean age, 53.6 ± 8.9 [SD] years) between October 2021 and February 2022. They underwent 3T elbow MRI with the protocol including T2-weighted fat saturated (T2FS) coronal 1mm MRI with DLR, and 3D proton-density weighted fat saturated (PDFS) coronal MRI with CR and DLR. One musculoskeletal radiologist with 9-year experience assessed three sequences for subjective image quality and artifacts and identified pathologies of the proximal common extensor tendon (CET) and common flexor tendon (CFT), radial collateral ligament (RCL), lateral ulnar collateral ligament (LUCL), and ulnar collateral ligament (UCL). In 10 patients who underwent operation, diagnostic performance was calculated using surgical records as a reference standard.

RESULTS

Mean subjective image quality scores of 2D T2FS 1mm MRI, 3D PDFS MRI with CR and DLR were 2.9 ± 0.4, 2.1 ± 0.6, and 2.9 ± 0.3, respectively. There were significant differences between 2D T2FS 1mm MRI and 3D PDFS MRI with CR, between 3D PDFS MRI with CR and DLR. Mean artifact scores were 3.3 ± 0.6, 3.9 ± 0.3, and 3.9 ± 0.3, respectively. There were significant differences between 2D T2FS 1mm MRI and 3D PDFS MRI with CR, between 2D T2FS 1mm MRI with 3D PDFS MRI with DLR. For three sequences, the diagnostic performance using area under the receiver operating characteristic curve of 2D T2FS 1mm MRI, 3D PDFS MRI with CR and DLR were 0.841, 0.773, and 0.818, respectively. The diagnostic performance of 3D PDFS coronal MRI with adding axial reformation, 3D PDFS coronal MRI with adding axial and sagittal reformation were both 0.886.

CONCLUSION

s By multiplanar reformation, 3D elbow joint MRI with deep learning-based reconstruction showed comparable diagnostic performance than 2D 1mm MRI for the evaluation of tendon and ligament injuries of elbow joint with similar subjective image qualities and artifacts.

CLINICAL RELEVANCE/APPLICATION

3D elbow joint MRI with deep learning-based reconstruction can help detect tendon and ligament pathologies of small joints by multiplanar reformation.

Operative Management of Advanced Wrist Arthritis: The Current Role of Preoperative Imaging and Intraoperative Inspection

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - MK DPS

Participants
Shelby Payne, MD, Stanford, CA (*Presenter*) Nothing to Disclose

PURPOSE

Our objectives are to (1) analyze the influence of preoperative imaging (radiography, CT, MRI) on surgical decision-making for wrist arthrodesis and carpectomy procedures, (2) assess the frequency of intraoperative inspection to determine arthritis distribution, and (3) determine the most common surgical procedures for end-stage wrist arthritis.

METHODS AND MATERIALS

A systematic search of peer-reviewed literature on the role of preoperative imaging and intraoperative inspection in the selection of carpal bone fusion and carpectomy procedures was performed in three databases (Pubmed, Embase, Scopus) using established criteria (PRISMA Extension for Scoping Reviews). Included studies reported at least 3 adult patients with advanced wrist arthritis and were published within the past 11 years (1/1/2011-4/6/2022). Procedures at the trapeziometacarpal and distal radioulnar joints were excluded.

RESULTS

From a total of 307 publications, eligibility criteria were satisfied by 48 articles. A total of 1,823 patients (1,886 wrists) received surgical intervention (age mean 51 [SD 10] yrs; 63% men, 37% women). Of 13 different arthrodesis and carpectomy procedures reported, the four most common were: four-corner fusion with scaphoid excision (845/ 1886, 45%), total wrist arthrodesis (457/1886, 24%), proximal row carpectomy (256/1886, 14%), and scaphocapitate fusion (79/1886, 4%). All articles reported preoperative radiography, but only a small number of articles reported preoperative CT (3/48, 6%) or MRI (2/48, 4%). Only 16 articles (33%) reported intraoperative inspection of the cartilage.

CONCLUSION

s All articles reported that the selection of a surgical procedure was influenced by the radiographic distribution of advanced arthritis in the carpus. Preoperative advanced imaging and intraoperative evaluation was not commonly performed, despite the current widespread availability of CT/MRI and wrist arthroscopy. Of 13 different surgical procedures, the most commonly reported was a 4-corner fusion with scaphoidectomy. Future research should address the unresolved controversy regarding any added value of CT, MRI, and diagnostic arthroscopy for optimizing surgical decision making.

CLINICAL RELEVANCE/APPLICATION

Despite the widespread use of CT, MRI, and diagnostic arthroscopy, radiography is generally the only technique used to assess the distribution of advanced arthritis prior to wrist surgery.

Chronic Pain After Arthroplasty: Major Contributions of Magnetic Resonance Imaging with Metal Artifact Reduction Sequences.

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - MK DPS

Participants
Ronald M. Trindade, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To determine the association between resorption at interfaces, using MAVRIC-SL (multiacquisition with variable resonance image combination-selective) sequences in Magnetic Resonance (MR), and the clinical severity of patients undergoing Total Knee Arthroplasties (TKA) and Total Hip Arthroplasties (THA); to describe areas affected by bone resorption in each component of the prostheses; to determine intra and interobserver agreement in the diagnosis of partial loosening of the prosthetic components and to compare fibrous membrane and osteolysis in this context.

METHODS AND MATERIALS

A cross-sectional study was carried out between March 2019 and August 2020, with 47 patients (49 arthroplasties). Postoperative follow-up of knee or hip arthroplasties, with chronic pain 03 months after surgery, who answered the WOMAC questionnaire. The interfaces of the components of arthroplasties were defined as: osseintegration, parcial loosening (fibrous membrane-type reabsorption or osteolysis) or non-diagnostic.

RESULTS

When the loosening criterion is based only on the presence of osteolysis, there is a significant difference in the WOMAC means (p=0.010). When the loosening criteria include osteolysis and fibrous membrane, there are no differences between groups, except in the stiffness subdomain (p=0,026). The images obtained by MAVRIC-SL showed slight correlation between the number of osteolytic zones and clinical severity in most analysis. In the hip, there was a predominance of resorption (osteolysis) in the proximal femoral region (Gruen zones 1, 7, 8, 13 and 14), corresponding to 53.2% of the total. In the knee, the zones most affected by resorption (fibrous membrane) were those related to the tibial plateaus and its stem (zones 1, 2, 3, 4 e 5), corresponding to 64.3% of the total. There was substancial inter-reader reliability for most components (THA: acetabulum with k=0.72 and femur with k=0,77; TKA: tibia with k=0,72). The intraobserver analysis showed moderate and substantial agreement for most components (THA: acetabulum with k=0.57 and femur with k=0,64; TKA: femur with k=0,76 and tibia with k=0.62).

CONCLUSION

s MR with MAVRIC-SL sequences demonstrated that in this sample, consisting of metal-on-metal type prosthesis, the characterization of periprosthetic osteolysis, may play an important role in clinical complaints and loss of joint function, with substancial interobserver and inter-rater reliability. In THA, partial loosening occurs mainly in the proximal part of the femoral component, while in TKA it occurs mainly in the plateau and stem region of the tibial component.

CLINICAL RELEVANCE/APPLICATION

MRI with metal artifact reduction sequences as an additional tool for chronic pain evaluation in patients after arthroplasties.

Identification of Bone Marrow Edema in Spondylodiscitis of The Dorso-lumbar Spine: Diagnostic Accuracy of Dual-energy CT Versus MRI

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - MK DPS

Participants
Giovanni Foti, MD, Negrar, Italy (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the diagnostic accuracy values of dual-energy Computed Tomography (DECT) in identifying bone marrow edema (BME) in spondylodiscitis of the dorso-lumbar spine.

METHODS AND MATERIALS

This prospective institutional review board-approved study included 40 consecutive patients (24 males and 16 females; mean age of 66.4, range 22-79 years) studied between January 2020 and January 2022. All patients underwent DECT (80 kV and tin filter 150 kV) and MRI within 7 days. DECT data were post-processed on a dedicated offline workstation (SyngoVia® VB20) by using a three-material decomposition algorithm for generating non-calcium images. Two radiologists (16 and 8 years of experience, respectively), blinded to clinical data, evaluated the presence of BME on dedicated color-coded maps, endplate erosions and peri-vertebral inflammation. Diagnostic accuracy values of DECT were calculated by using MRI images as standard of reference. DECT numbers were assessed by using a region of interest (quantitative assessment). Receiver operator curves (ROC) and relative area under the curve (AUC) were calculated. Inter-observer and intra-observer agreement were calculated with k-statistics. Continuous and categorical variables were evaluated by using t test and x2 or Fisher exact test, as appropriate. A value of $p<0.05$ was considered statistically significant.

RESULTS

MRI revealed the presence4 of spondylodiscitis in 32/40 patients (80.0%), located at the level of dorsal (n=15) and lumbar spine (n=25), respectively. The sensitivity, specificity, and AUC of DECT were 87.5% (28/32), 75.0 % (6/8) with an AUC of 0.886 (95% CI: 0.771-0.915) for R1, and 75% (24/32) and 100% (8/8) with an AUC of 0.862 (95% CI: 0.748-0.909) for R2. DECT numbers were significantly different between positive (mean -11.4 ± 22.5 HU) and negative cases (mean -77.3 ± 32.3HU) with a p value <0.001. The interobserver and intraobsever agreements were near perfect (k=0.87 and k=0.89, respectively).

CONCLUSION

s DECT is an accurate imaging tool for the diagnosis of spondylodiscitis.

CLINICAL RELEVANCE/APPLICATION

DECT represents a fast and accurate imaging tool for demonstration of BME, erosions and peri-vertebral inflammation in dorso-lumbar spondylodiscitis, virtually free from motion artifacts and with the additional advantage to yield high resolution bone window images.

T2-SPNMMI-1 Bone Scan versus F-18 Fluciclovine PET/CT at Different PSA Levels: A Single-center Comparison Study

Participants
Hatice Savas, MD, Chicago, IL (*Presenter*) Nothing to Disclose

PURPOSE

To compare the diagnostic performance of bone scintigraphy (BS) and F-18 Fluciclovine PET/CT in detecting bone metastasis in prostate cancer patients at different PSA levels.

METHODS AND MATERIALS

This IRB-approved retrospective study included 267 prostate cancer subjects. We evaluated the detection of bone metastasis using both F-18 Fluciclovine PET/CT and BS. Each scan was performed within less than a three-month period. Subjects with other known malignancies were excluded from this study. Concordance among imaging modalities detecting bone metastasis was assessed at five PSA levels: = 0.5, 0.5-2, 2-5, 5-10, and >10. In addition, positive cases were confirmed with six months follow-up assessments or bone biopsies.

RESULTS

Concordance between both scans was observed in 70% of all cases (203/267). 164 from 203 patients had both scans negative, whereas the remaining 39 from 203 patients had both scans positive. Within the disconcordant group, 26 of 64 patients were positive on F-18 Fluciclovine PET/CT and negative on BS. On the contrary, 38 from 64 scans were positive on BS and negative on F-18 Fluciclovine. The BS had an overall sensitivity of 66.1%, specificity of 81.7%, PPV of 50.6%, and NPV of 89.4%. F-18 Fluciclovine PET/CT had a sensitivity of 93.2%, specificity of 95.1%, PPV of 84.6%, and NPV of 98%.

CONCLUSION

s Our data shows that F-18 Fluciclovine is diagnostically superior to BS in detecting bone metastasis. We found a higher concordance rate between both imaging modalities at lower PSA values.

CLINICAL RELEVANCE/APPLICATION

The literature is scarce when it comes to studies comparing the diagnostic performance of Fluciclovine PET/CT and bone scan evaluating metastatic prostate cancer. The largest available study only assessed 106 patients. They did not report the concordance between scans at various PSA levels or even the correlation with other sites of recurrence.

T2-SPNMMI-2 The Impact of PSMA PET on the Treatment and Outcomes of Men with Biochemical Recurrence of Prostate Cancer: a Systematic Review and Meta-Analysis

Participants
Alex Pozdnyakov, MD, Hamilton, ON (*Presenter*) Nothing to Disclose

PURPOSE

Prostate-specific membrane antigen (PSMA) PET is highly sensitive in identifying disease recurrence in men with biochemical recurrence of prostate cancer (BCR) after primary therapy and is rapidly being adopted in clinical practice. The purpose of this systematic review and meta-analysis was to assess the documented impact of PSMA-PET on patient management and outcomes, including prostate-specific antigen (PSA) response, and intermediate and long-term outcome measures.

METHODS AND MATERIALS

MBASE, PubMed, Web of Science, Cochrane and OVID databases were searched for studies reporting on the impact of PSMA-PET on the management and outcomes of patients with BCR after definitive primary therapy. Outcome measures assessed included biochemical response to therapy after PET and BCR-free survival (BRFS). The proportions of patients in whom management changed, and the proportion of patients in whom each outcome measure was obtained were tabulated and pooled into meta-analysis using DerSimonian-Laird method.

RESULTS

A total of 34 studies with 3680 men reported change in management after PSMA-PET and 27 studies with 2639 men reported on at

least one outcome measure and had follow-up data. PSMA-PET was positive in 2508/3680 (68.2%). The pooled proportion of change in management after PSMA-PET was 56.4% (95% CI, 48.0-63.9%). A decrease in serum PSA was documented in 72.4% of men (95% CI, 63.4-81.5%), and complete biochemical response in 23.3% (95% CI, 14.6-32.0%) at a median follow-up of 8.1 and 11 months, respectively. The pooled BRFS rate was 60.2% (95% CI, 49.1-71.4%) at a median follow-up of 20 months.

CONCLUSION

s In conclusion, PSMA PET is positive in more than 2/3 of men with BCR and impacts patient management in more than half of the men. BRFS after PET-directed management is 60% at a median of 20 months after salvage therapy, and complete biochemical response may be achieved in up to a quarter of men.

CLINICAL RELEVANCE/APPLICATION

The findings of this meta-analysis further confirm the crucial role of PSMA PET in biochemical recurrence of prostate cancer and highlight the clinical implications of this molecular imaging technique.

T2-SPNMMI-3 A Pilot Study of68Ga-PSMA11 and68Ga-RM2 PET/MRI for Biopsy Guidance in Patients with Suspected Prostate Cancer

Participants
Heying Duan, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Targeting of lesions seen on multiparametric MRI (mpMRI) improves prostate cancer (PC) detection at biopsy. However, 20-65% of highly suspicious lesions on mpMRI (PI-RADS 4 or 5) are false positives (FP), while 5-10% of clinically significant PC (csPC) are missed. Prostate specific membrane antigen (PSMA) and gastrin-releasing peptide receptors (GRPR) are both overexpressed in PC. We therefore aimed to evaluate the potential utility of 68Ga-PSMA11 and 68Ga-RM2 PET/MRI for biopsy guidance in patients with suspected PC.

METHODS AND MATERIALS

Thirteen men, aged 58.00±7.13 years, with suspected PC were prospectively enrolled to undergo 68Ga-PSMA11 and 68Ga-RM2 PET/MRI. PET/MRI included whole-body and dedicated delayed pelvic imaging. All patients had standard 12-core biopsy, and additional targeted biopsy of any lesions seen on PET. Maximum and peak standardized uptake values (SUVmax and SUVpeak) of suspected PC lesions were collected and compared to gold standard biopsy.

RESULTS

PSA and PSA density at enrollment were 9.80±5.97 (range 1.50-25.46) ng/mL and 0.20±0.18 (range 0.06-0.68) ng/mL2, respectively. Biopsy revealed a total of 14 PC in 8 participants: 6 were csPC and 8 were non-clinically significant PC (ncsPC). 68Ga-PSMA11 identified 25 lesions, of which 11 (44%) were true positive (TP) (5 csPC). 68Ga-RM2 showed 27 lesions, of which 14 (52%) were TP, identifying all 6 csPC and 8 ncsPC. There were 17 concordant lesions in 11 patients vs. 14 discordant lesions in 7 patients between PSMA and RM2. Incongruent lesions had the highest rate of FP (12 FP vs. 2 TP). PET/MRI guided biopsy led to the additional finding of 8 cancers of which 5 were csPC. Median SUVmax was significantly higher for TP than FP lesions in delayed pelvic imaging for 68Ga-PSMA11 (6.49±4.14 vs. 4.05±1.55, P=0.023) but not for whole body images, nor for 68Ga-RM2. Sensitivity and specificity were 83% and 67% for 68Ga-RM2 63% and 86% for 68Ga-PSMA11, and 30% and 95% for mpMRI, respectively.

CONCLUSION

s Our results show that both 68Ga-PSMA11 and 68Ga-RM2 PET/MRI are feasible for biopsy guidance in suspected PC. Both radiopharmaceuticals detected additional clinically significant cancers not seen on mpMRI, 68Ga-RM2 PET/MRI identified all csPC confirmed at biopsy.

CLINICAL RELEVANCE/APPLICATION

68Ga-PSMA11 and 68Ga-RM2 guided prostate biopsy help detecting csPC and might therefore avoid unnecessary biopsies and associated risks.

To study recent trends in total charges of 20 common interventional radiology procedures by Medicare from 2012 to 2020.

METHODS AND MATERIALS

A list of common interventional radiology procedures was elicited from the Society for Interventional Radiology, similar to the methodology in Schwartz and Young 2021.The Medicare Part B Physician/Supplier Procedure Summary (PSPS) Master Files from 2012 through 2020 were used to extract reimbursement data. Compound annual growth rates (CAGRs) for three segments were compared: 2012-2016, 2016-2019, 2019-2020. The overall time interval was divided into segments based on significant events that would affect physician practice patterns, such as the MACRA act of 2015 and the COVID-19 pandemic beginning in 2020.

RESULTS

The average CAGR of total charges from 2012-2016 was 11.4% [-8.9% to 31.7%], from 2016-2019 was -3.2% [-8.2% to 1.8%], and from 2019-2020 was -13.2% [-20.4% to -6.0%]. The top three individual procedure CAGRs in 2012-2016 were for percutaneous catheter placement, visceral (194.3%), retrieval of IVC filter (36.3%), and radiofrequency ablation of hepatic tumor (22.4%). The three lowest individual procedure CAGRs for 2012-2016 were vascular embolization, tumors or ischemia (-18.5%), carotid artery stent placement (-16.3%), and external biliary drain placement (-15.2%). The top three individual procedure CAGRs in 2016-2019 were for carotid artery stent placement (30.1%), radiofrequency ablation renal tumor (11.0%), and radiofrequency ablation of hepatic tumor (5.7%). The three lowest individual procedure CAGRs for 2016-2019 were venous mechanical thrombectomy (-21.9%), insertion of IVC filter (-16.7%), and non-tunneled central venous line (-16.3%). The COVID-19 pandemic significantly decreased the total charges for IR procedures performed, as all procedures analyzed in this study exhibited significant decreases except for vascular embolization, tumors or ischemia (+29.9%) and venous mechanical thrombectomy (+19.0%).

CONCLUSION

s Since 2016, the total charges for IR procedures have been cut by Medicare considerably. There continues to be steady decline in total charges for the most IR procedures, including those with relatively high complication rates, rate of revision, and prolonged operative time. The COVID-19 pandemic has negatively impacted reimbursement for IR procedures.

CLINICAL RELEVANCE/APPLICATION

Knowledge of these trends in total charges for interventional radiology procedures are important when formulating future reimbursement plans to facilitate and sustain the growth of interventional radiology.

T2-SPNPM-2 Inaugural Pan-Canadian RADGames: Results from a Successful Approach to Radiology Education for Medical Students

Participants
Aidan Canil, Kingston, ON (*Presenter*) Nothing to Disclose

PURPOSE

A goal in radiology recruitment is to improve medical student exposure to the field through activities such as networking and medical education events. Numerous studies have looked at gamification and game-based approaches to increase attendance at such events. In 2022, the Canadian Association of Radiologists' Medical Student Network hosted for the first time "RADGames", an interactive image interpretation contest for medical students across Canada. This program was aimed to spark medical student interest in radiology and improve their image interpretation skills with expert guidance. An evaluation from participants is presented.

METHODS AND MATERIALS

Volunteers from radiology interest groups in Canadian medical schools worked in team to set up a virtual session using breakout rooms and an interactive quiz platform for the competition. Recruitment was through social media and advertisement by medical student associations. Participants were surveyed anonymously for feedback following the event. Data about previous exposure to and knowledge of radiology and an evaluation of the event including self-perceived impact on participants' understanding of the field were collected.

RESULTS

87 medical students from 15 of Canada’s 17 medical schools competed against one another virtually. 47 (54%) responded to the post-event evaluation survey. All respondents responded favourably about the event itself. Respondents overwhelmingly indicated that the RADGames event increased their interest in radiology (38, 81%) and their understanding of the work of a radiologist (31, 66%), increased their knowledge about imaging principles (46, 98%), and improved their confidence in basic imaging interpretation (36, 77%).

CONCLUSION

s The Canadian Association of Radiologists’ Medical Student Network hosted Canada’s first national image interpretation competition for medical students, RADGames. Feedback was overwhelmingly positive, with perceived benefits to participants on their understanding of and interest in radiology.

CLINICAL RELEVANCE/APPLICATION

While medical students are underexposed to radiology, we present a new initiative using gamification and a game-based approach to promote radiology for medical students on a pan-Canadian scale.

Recent Cuts in Reimbursement by Medicare for Interventional Radiology Procedures

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - NPM DPS

Participants
Kenneth Huynh, BS, Orange, CA (*Presenter*) Nothing to Disclose

PURPOSE

To study recent trends in total charges of 20 common interventional radiology procedures by Medicare from 2012 to 2020.

METHODS AND MATERIALS

A list of common interventional radiology procedures was elicited from the Society for Interventional Radiology, similar to the methodology in Schwartz and Young 2021.The Medicare Part B Physician/Supplier Procedure Summary (PSPS) Master Files from 2012 through 2020 were used to extract reimbursement data. Compound annual growth rates (CAGRs) for three segments were compared: 2012-2016, 2016-2019, 2019-2020. The overall time interval was divided into segments based on significant events that would affect physician practice patterns, such as the MACRA act of 2015 and the COVID-19 pandemic beginning in 2020.

RESULTS

The average CAGR of total charges from 2012-2016 was 11.4% [-8.9% to 31.7%], from 2016-2019 was -3.2% [-8.2% to 1.8%], and from 2019-2020 was -13.2% [-20.4% to -6.0%]. The top three individual procedure CAGRs in 2012-2016 were for percutaneous catheter placement, visceral (194.3%), retrieval of IVC filter (36.3%), and radiofrequency ablation of hepatic tumor (22.4%). T2-SPNR

Neuroradiology Tuesday Poster Discussions

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - NR DPS

Sub-Events

T2-SPNR-1 Deep Learning-based Infarct Core And Penumbra Quantification In Perfusion CT Data: Comparison with DWI Final Infarct Volume and RAPID

Participants
Peter Chang, MD, Irvine, CA (*Presenter*) Co-founder, Avicenna.ai;Stockholder, Avicenna.ai;Research Grant, Canon Medical Systems Corporation;Speakers Bureau, Canon Medical Systems Corporation;Research Grant, General Electric Company

PURPOSE

The primary objective of this study was to evaluate the accuracy of deep learning-based CT perfusion (CTP) core volume estimation when compared with diffusion-weighted imaging (DWI). The secondary objective of this study was to evaluate deep learning-based (DL) core and penumbra volume values with those obtained with a commercially-available threshold-based CTP analysis.

METHODS AND MATERIALS

A total of 38 consecutive adult patients for suspected acute ischemic stroke were retrospectively identified between 12/2020 - 06/2021 for whom CTP and 24-48 hour follow-up DWI MRI were obtained as part of the clinical workflow. Images of non-diagnostic quality or with missing data required for the DL analysis were excluded. The core volume was manually segmented on DWI images by a neuroradiologist with 5 years of experience. CTP images were analyzed for core and penumbra volumes with: (1) standard RAPID processing; (2) a DL-based method as part of Arterys Neuro AI (Arterys Inc.). Data normality distribution was checked using the Shapiro-Wilk test. Descriptive statistics were reported as median and interquartile range (IQR) values. Spearman correlation coefficients were used to compare core volumes. Two-sided Wilcoxon tests were used to compare automatically derived core and penumbra volumes. A P-value of 0.05 was deemed as statistically significant.

RESULTS

A total of 33 patients met all inclusion criteria for final analysis. Median (IQR) core volume from DWI images was 3.1 (0.1 - 15.2) ml. Median (IQR) difference between DWI and CTP core volumes was 3.0 (0.08 - 7.1) and 0.64 (0 - 6.5) ml for RAPID and Arterys software, respectively. Spearman correlation with DWI core volumes were 0.51 ($p<0.05$) and 0.61 ($p<0.001$) for RAPID and Arterys, respectively. A statistically significant difference was found between automatically derived core volumes ($p=0.023$) but not for penumbra.

CONCLUSION

s Deep learning-based CTP analysis showed higher correlation with DWI-defined core values than traditional threshold-based CTP analysis. The presence of patients with embolic infarcts, which are too small to cause perfusion changes, might have contributed to the discrepancies between software packages. Further studies on a larger and heterogeneous patient cohort are needed to confirm these preliminary findings.

CLINICAL RELEVANCE/APPLICATION

Deep learning CTP may provide a more accurate estimate of DWI-defined core infarct volume than traditional threshold-based CTP analysis.

T2-SPNR-11 COVID-19 Effect on Mortality of Patients with Pulmonary Embolism

Participants
Miranda Rougelot, BS, (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this research was to determine if COVID-19 diagnosis within the past ninety days increased severity of PE. COVID diagnosis does not take into consideration specific strain.

METHODS AND MATERIALS

In this retrospective study 903 patients with pulmonary embolism and had tested positive for COVID in the last ninety days were observed. Risk was analyzed and patients were given PESI scores. PESI scores are a point system based on risk factors such as age, gender, medical history, symptoms, etc. Points categorize into Classes I-V with Class V being the highest risk. Class IV and V PESI scores were eligible for thrombectomy.

RESULTS

PE patient PESI scores increased by one class with COVID-19 diagnoses. Of the 903 patients, 1.9% had a standard PESI of Class I

while PESI + COVID was 1.4%. Class II jumped from a standard score of 4.9% to 10.9% with the inclusion of COVID diagnoses. Class III had 8.0% standard and 14.2% with COVID. Class IV had 14.2% standard and 22.4% with COVID. Finally class V had 23.6% standard and 27.2% with COVID diagnoses. These results are a significant difference from standard risk stratification (p=0.03).

CONCLUSION

s COVID-19 diagnosis significantly increases mortality in patients with Pulmonary Embolism in regards to PESI Score.

CLINICAL RELEVANCE/APPLICATION

COVID- 19 exposure increases thirty day mortality in patients with pulmonary embolism (PE). A Pulmonary Embolism Severity Index (PESI) score is given to patients based on age and predictors present. A patient's PESI score increases in class with the diagnosis of COVID-19 within 90 days of admission.

T2-SPNR-12 Association of White Matter Hyperintensity Burden and Ischemic Core Growth in Large-Vessel Occlusion Stroke

Participants
Jia-Ying Zhou, (*Presenter*) Nothing to Disclose

PURPOSE

To assess whether heavier white matter hyperintensity (WMH) burden is associated with faster ischemic core growth in acute stroke patients with large vessel occlusion.

METHODS AND MATERIALS

In this retrospective study, we reviewed anterior circulation large-vessel-involved acute stroke patients who had baseline CT perfusion within 24 hours after symptom onset and had an MRI scan five days after admission from October 1, 2018, to October 31, 2021 at two stroke center. Core growth rate was calculated by the following equation: The core growth rate = Acute core volume on CT perfusion / Time from stroke onset to CT perfusion. The WMH volumes were assessed with semiautomated volumetric analysis at fluid-attenuated inversion recovery MRI by readers who were blinded to clinical data. The WMH index was calculated by the ratio of WMH volume within whole brain tissue volume and then categorized into tertiles: for each tertile, the core growth rate was summarized as median and inter-quartile range. Simple linear regressions were then performed to measure the predictive power of WMH volume and WMH index in core growth rate.

RESULTS

A total of 154 patients in center 1 and 46 patients in center 2were included (mean age, 69 years ± 19 [standard deviation]; 121 women [57.6%]). For patients allocated to slight WMH burden (tertile 1 of WMH index), moderate WMH burden (tertile 2), and heavy WMH burden (tertile 3), the median core growth rate was 3.15 ml/hour (1.05-6.24), 8.21 ml/hour (5.33-16.27), and 22.67 ml /hour (10.82-39.89) respectively. Increments in the WMH index by 1% resulted in an increase of core growth by 0.49 ml/hour (coefficient=0.49, 95% confidence interval=[0.41, 0.57], p<0.001). The relationship of core growth and WMH index was validated in center 2. An increment in WMH index by 1% resulted in an increase of core growth by 0.54 ml/hour (coefficient=0.54 [0.42, 0.67], p<0.001) in center 2.

CONCLUSION

s WMH burden was associated with ischemic core growth for large-vessel occlusion stroke. Acute ischemic stroke patients with heavier white matter hyperintensity burden have faster ischemic core growth.

CLINICAL RELEVANCE/APPLICATION

Acute ischemic stroke patients with heavier white matter hyperintensity burden have faster ischemic core growth. This study recommends considering WMH burden when making treatment decisions for acute ischemic stroke patients on the tissue-based level.

T2-SPNR-13 Development of a Nomogram Based on DWI and Clinical Information to Predict DEACMP

Participants
Wenxuan Han, XI'AN, China (*Presenter*) Nothing to Disclose

PURPOSE

Prevention of delayed encephalopathy after carbon monoxide poisoning (DEACMP), one of the most serious complications of acute carbon monoxide poisoning (ACOP), remains challenging. Hence, the purpose of this study was to identify the independent risk factors for DEACMP and to establish a nomogram to predict the probability of DEACMP.

METHODS AND MATERIALS

Data of patients diagnosed with ACOP between September 2015 and June 2021 were retrospectively analyzed. According to the prognosis results, they were divided into the DEACMP group and the non-DEACMP group. Univariate analysis and multivariate logistic regression analysis were used to assess the risk factors of DEACMP, and a nomogram was constructed to predict the risk of DEACMP. The receiver operating characteristic curve (ROC) and calibration curves were used to evaluate the performance of this model.

RESULTS

A total of 122 patients were enrolled in this study, of whom 30(24.6%) developed DEACMP. Multivariate logistic regression analysis showed that acute high-signal lesions on DWI, CO exposure time, and GCS score were independent risk factors for DEACMP (Odds Ratio=6.230,1.323,0.714, P<0.05). The predictive nomogram was established according to the above indicators. The model reached an area under the curve (AUC) of the according receiver operating characteristic (ROC) curve of 0.959. The calibration curve of a nomogram showed a satisfactory consistency between prediction and observation.

CONCLUSION

s In this study, a nomogram to predict DEACMP based on high-signal lesions on DWI and clinical indicators was constructed, which

may be a reliable tool to distinguish high-risk patients and then provide them with personalized treatment to reduce the incidence of DEACMP.

CLINICAL RELEVANCE/APPLICATION

We believe the nomogram may be a potential tool for identifying high-risk patients of DEACMP.

T2-SPNR-14 3D Chemical Exchange Saturation Transfer (CEST) Imaging: Differentiating Capability of Malignant from Benign Intracranial Meningiomas

Participants
Kazuhiro Murayama, MD, Toyoake, Japan (*Presenter*) Research Grant, Canon Medical Systems Corporation

PURPOSE

To determine the capability of 3D chemical exchange saturation transfer (CEST) imaging at 3.5 ppm, which provides amide proton transfer (APT) weighted information in the entire brain, for differentiating malignant from benign intracranial meningiomas.

METHODS AND MATERIALS

36 patients with pathologically diagnosed intracranial meningiomas (mean age, 61.1 years) underwent CEST imaging using 3D gradient-echo based sequences at a 3T MR system. According to pathological and follow-up examination results, all tumors were divided into benign (grade 1, n = 24) and malignant (grade 2 or 3, n = 12) meningioma groups. In each lesion, magnetization transfer ratio asymmetry (MTRasym) at 3.5 ppm was computationally calculated from z spectra from each CEST data, and the MTRasym map was generated by pixel-by-pixel analysis. Then, MTRasym in the solid component of a tumor was determined by ROI measurements. To evaluate cell proliferation in each meningioma, MIB-1 index was also pathologically evaluated. To compare MTRasym between malignant and benign meningiomas, Student’s t-test was performed. To evaluate the relationship between amide proton transfer and cell proliferation within each tumor, Spearman's correlations was performed between MTRasym and MIB-1 index. To assess the capability of MTRasym for distinguishing malignant from benign meningiomas, a ROC-based positive test was performed for determine the feasible threshold value. Finally, sensitivity, specificity and accuracy were assessed.

RESULTS

MTRasym of malignant meningiomas was significantly higher than that of benign meningiomas (malignant: 2.61±0.79%, benign: 1.19±0.58, p<0.0001). MTRasym was significantly and positively correlated with MIB-1 index (?=0.51, p<0.05). When applied feasible threshold value of MTRasym in this setting, sensitivity (SE), specificity (SP) and accuracy (AC) were determined as follows: SE, 91.7 (11/12) %; SP, 95.8 (23/24) %; AC, 94.4 (34/36) %, respectively.

CONCLUSION

s 3D CEST imaging has a good potential for differentiatiing malignant from benign meningiomas. APT-weighted imaging may provide regional cell proliferation difference within meningioma in routine clinical practice.

CLINICAL RELEVANCE/APPLICATION

3D CEST imaging has a good potential for differentiatiing malignant from benign meningiomas. APT-weighted imaging may provide regional cell proliferation difference within meningioma in routine clinical practice.

T2-SPNR-15 Association Between Auditory fMRI And Clinical Outcomes in Mild Traumatic Brain Injury

Participants
Priya Santhanam, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

This study assesses the relationship between auditory functional magnetic resonance imaging (fMRI) findings and clinical outcomes of patients diagnosed with mild traumatic brain injury (mTBI).

METHODS AND MATERIALS

Civilian patients (n=221) diagnosed with mTBI underwent auditory fMRI with separate auditory tasks performed on the right ear, the left ear, and bilaterally. Quantification of blood-oxygen-level dependent (BOLD) signal activation was performed, and a laterality index was calculated for each series. Clinical data relating to presentation and resolution of post-concussive symptoms were obtained via retrospective chart review. To account for inherent variability and uncertainty in symptom onset and resolution, data were right-censored and interval-censored. Clinical data were compared to the fMRI laterality index, overall asymmetry, and total activation.

RESULTS

Intensity and laterality of auditory fMRI activation were not significantly associated (p>0.05) with incidence of any surveyed post-concussive symptoms. Post-concussive headaches persisted significantly (p=0.038) longer in patients with a right-biased laterality during bilateral auditory stimulation. For left-sided auditory stimulation, longevity of post-concussive anxiety (p=0.043) and depression (p<0.001) were found to associate with activation signal intensity for subjects in the bottom 10th percentile of overall activation. For the right-sided auditory stimulation, longevity of post-concussive anxiety (p<0.001) and depression (p<0.001) were found to associate with activation signal intensity for subjects in bottom and top 10th percentiles of overall activation as well as asymmetry for those subjects in the top 10th percentile of activation asymmetry.

CONCLUSION

s Our results suggest that auditory fMRI may be a viable quantitative predictor of mTBI symptom persistence for the clinical assessment and management of mTBI. Further studies more explicitly assessing the relationship between fMRI activation and post-concussive headache, anxiety, and depression are warranted.

CLINICAL RELEVANCE/APPLICATION

Auditory functional magnetic resonance imaging could serve as a predictor of symptom persistence and recovery in patients with mild traumatic brain injury.

T2-SPNR-16 Follow-up Imaging of Clipped Intracranial Aneurysms With 3-T MRI: Comparison Between 3D Time-Of-Flight Mrangiography and Pointwise Encoding Time Reduction Withradial Acquisition Subtraction-Based MR Angiography

Participants
Inyoung Kim, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Metallic susceptibility artifact due to implanted clips is a major limitation of using 3D time-of-flight magnetic resonance angiography (TOF-MRA) for follow-up imaging of clipped aneurysms (CAs). The purpose of this study was tocompare pointwise encoding time reduction with radial acquisition (PETRA) subtraction-based MRA with TOF-MRA in terms of imaging quality and visibility of clip-adjacent arteries for use in follow-up imaging of CAs.

METHODS AND MATERIALS

Sixty-two patients with 73 CAs were included retrospectively in this comparative study. All patients underwent PETRA-MRA after TOF-MRA performed simultaneously with 3-T MRI between September 2019 and March 2020.Two neuroradiologists independently compared images obtained with both MRA modalities to evaluate overall image quality using a 4-point scale and visibility of the parent artery and branching vessels near the clips using a 3-point scale.Subgroup analysis was performed according to the number of clips (less-clipped [1-2 clips] vs more-clipped [= 3 clips] aneurysms). The ability to detect aneurysm recurrence was also assessed.

RESULTS

Compared with TOF-MRA, PETRA-MRA showed acceptable image quality (score of 3.97 ± 0.18 for TOFMRA vs 3.73 ± 0.53 for PETRA-MRA) and had greater visibility of the adjacent vessels near the CAs (score of 1.25 ± 0.59 for TOF-MRA vs 2.27 ± 0.75 for PETRA-MRA, $p < 0.0001$). PETRA-MRA had greater visibility of vessels adjacent to less-clipped aneurysms (score of 2.39 ± 0.75 for less-clipped aneurysms vs 2.09 ± 0.72 for more-clipped aneurysms, $p = 0.014$). Of 73 CAs, aneurysm recurrence in 4 cases was detected using PETRA-MRA.

CONCLUSION

s This study demonstrated that PETRA-MRA is superior to TOF-MRA for visualizing adjacent vessels near clips and can be an advantageous alternative to TOF-MRA for follow-up imaging of CAs.

CLINICAL RELEVANCE/APPLICATION

PETRA-MRA may be an effective alternative for follow-up imaging of CAs.

T2-SPNR-18 Characterization of Thalamic Subregions Over 1-2 Years in Small Vessel Disease Using MR-Based Quantitative Susceptibility Mapping and Free-Water Mapping

Participants
Yawen Sun, Shanghai, China (*Presenter*) Nothing to Disclose

PURPOSE

The aim of this study was to evaluate the characteristics of the thalamic subregions using quantitative susceptibility mapping and free-water (FW) mapping in small vessel disease (SVD) over 1-2 years.

METHODS AND MATERIALS

Fifty-one SVD patients underwent brain MRI scans and neuropsychological evaluations both at baseline and at follow-up, composed of 28 SVD patients with mild cognitive impairment (VaMCI) and 23 with no cognitive impairment (NCI). Quantitative susceptibility (QS) values, FW values, and volumes within thalamic subregions, i.e., the anterior nuclei, the median nuclei, the lateral nuclei (TL-LT), the pulvinar (TL-PLV) and the internal medullary lamina (TL-IML), were calculated for each individual. Temporal (baseline vs. follow-up) and cross-sectional (VaMCI vs. NCI) differences were studied using mixed factorial ANOVA analysis and appropriate t-tests. Partial correlations were used to assess the relationship between the MRI indices changes (i.e., ?FWfollowup-baseline/FWbaseline) and cognitive function changes (i.e., ?MoCAfollowup-baseline/MoCAbaseline).

RESULTS

The Group effect resulted in greater mean FW values (index of neuroinflammation) in the left TL-PLV, bilateral TL-LT, and bilateral TL-IML for VaMCI compared with NCI, as well as resulted in higher mean QS values (index of iron deposition) in the left TL-PL and lower volumes in the left TL-IML ($p < 0.05$). The Group×Time interaction identified increased mean QS values in the left TL-PLV for VaMCI over time. In addition, there were no significant effects for the FW values across Time. Furthermore, we observed significant negative associations between the FW values changes in the left TL-PLV and the right TL-LT and MoCA scores changes in VaMCI group over 1-2 years.

CONCLUSION

s Our results demonstrate that elevated FW and QS values in the thalamic subregions have the potential to be used as an indicator in the progression of SVD. The FW values changes in the TL-PLV and the TL-LT might be the biomarkers for the mechanism of cognitive decline in the evolution of SVD.

CLINICAL RELEVANCE/APPLICATION

QSM and FW mapping when combined, can be considered as a specific and sensitive tool for the monitoring of the complex pathologies such as neuroinflammation and iron deposition in SVD. Our results might contribute to understanding the pathogenesis and progression of SVD.

T2-SPNR-19 Multiparametric Quantitative Evaluation Using Synthetic MRI in Normal-Appearing Brain Parenchyma in Adult Moyamoya Disease

Participants

Kazufumi Kikuchi, MD, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

Moyamoya disease (MMD) is a progressive, steno-occlusive cerebrovascular disease affecting the arteries of the circle of the Willis. Few studies have examined the correlation between brain volume and function in patients with MMD. The purpose of this study was to investigate whether multiparametric brain volumes measured by synthetic MRI (SyMRI) correlate with cerebral blood flow (CBF) and brain function (BF) in MMD.

METHODS AND MATERIALS

This retrospective study was approved by our institutional review boards and conducted on 18 MMD patients (3 men, 15 women; median age, 43 years; range, 20-72 years). SyMRI was performed using the 3D-QALAS sequence by a 3T scanner. Quantification map acquisition and raw data processing were performed with SyMRI software (Version 21.4; SyMRI, Linköping, Sweden). CBF was measured using 123I-IMP SPECT, including the acetazolamide challenge. BFs were measured using WAIS-III/IV and WMS-R tests. Quantitative evaluations, including grey matter (GM), white matter (WM), and myelin correlated volume (MyC), were measured and corrected with total brain volume in normal-appearing brain parenchyma in six areas (bilateral anterior, middle, posterior cerebral arterial [ACA/MCA/PCA] territories). These three parameters and their correlations with corrected CBF and BF were evaluated by Spearman's rank-order correlation test.

RESULTS

Resting CBFs were correlated with GM fractions in the right ACA/MCA territories (r=0.524, 0.632; P=0.039, 0.018, respectively). Cerebrovascular reactivity to an acetazolamide challenge was correlated with GM fraction in the left PCA territory (r=0.574, P=0.018). FSIQ/VCI derived from WAIS were correlated with GM fraction in the left PCA territory (r=0.625, 0.615; P=0.009, 0.001, respectively). PSI derived from WAIS was correlated with GM fraction in the right MCA territory (r=0.665, P=0.011). There was no correlation between brain volume fractions and WMS-R indices.

CONCLUSION

s Synthetic MRI could noninvasively evaluate multiparametric brain volumes that correlate with CBF and BF in MMD.

CLINICAL RELEVANCE/APPLICATION

Synthetic MRI can quantitatively assess brain volume loss in patients with Moyamoya disease, which correlates with cerebral blood flow and brain function, and may help determine the disease severity.

T2-SPNR-2 NCCT Image-based Automated Intracranial Hemorrhage Classification Using A Deep Learning Model: Is the Intracranial Hemorrhage Classification of Very Small Volume Hematoma Cases Reliable?

Participants
Myeong Jin Kim, MD, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

Intracranial hemorrhage (ICH) is a fatal disease that significantly affects the patient's life and prognosis over time. Patients with small-volume ICH (SICH) with small hematoma are more likely to have a benign clinical course and tend to experience hematoma expansion and have worse outcomes. In this study, we evaluate the classification performance for SICH cases using AI software(cHS-Heuron) for ICH diagnosis.

METHODS AND MATERIALS

We evaluated the SICH classification performance by testing the target group SICH data and the control group non-small volume ICH (Non-SICH) data using cHS-Heuron. As the evaluation data, RSNA ICH Challenge 2019 test dataset and clinical data from single institute were used. The number of data was 397 patients in ICH (250 SICH, 147 non-SICH) and 130 patients in the control group (Non-ICH). The gold standard was generated by a stroke expert by evaluating the hematoma volume of each slice. SICH data were defined as hematoma volume less than 0.65ml and diameter of 2mm or more and 5mm or less. The classifying performance was evaluated through the sensitivity and specificity compared to gold standard.

RESULTS

As the classifying performance of ICH patients, the sensitivity and specificity were 0.9748 and 0.9692, respectively. Among ICH patients, the true positive rate of SICH was 0.9600 in patient-wise classification. However, in slice-wise classification, the sensitivity and specificity were 0.8801 and 0.9890 for SICH group, and, in Non-SICH group, it was 0.9600 and 0.9867, respectively.

CONCLUSION

s As a result of the ICH classification study using cHS-Heuron, the SICH group showed slightly lower sensitivity than the Non-SICH group, but in the patient-wise and slice-wise tests, the SICH group, the Non-SICH group all showed very high ICH classification performance.

CLINICAL RELEVANCE/APPLICATION

In the diagnosis of patients with ICH containing a very small volume hematoma area of ??less than 5 mm in diameter on NCCT images, cHS-Heuron can be utilized as a reliable pre-diagnosis tool for clinicians to quickly and accurately diagnose and make treatment decisions.

T2-SPNR-3 Diagnostic Yield of CTA Head After Stroke Protocol Standardization: A Retrospective Study

Participants
Dane Weinert, MD, (*Presenter*) Nothing to Disclose

PURPOSE

CT Angiography (CTA) of the head and neck is useful in the imaging of suspected stroke for identifying patients eligible for endovascular therapies. Acute stroke protocols may vary by when CTA is performed in the imaging algorithm. At our institution, a protocol was implemented which standardized CTA imaging to be obtained only as indicated after an initial non-contrast CT (NCCT)

head per American Heart Association stroke guidelines. The objective of our study is to investigate how often relevant diagnostic findings were found in CTA imaging as part of the acute stroke protocol when obtained only after NCCT head imaging and an appropriate neurological exam raised high clinical suspicion for acute ischemia, compared to when CTA head was obtained along with NCCT head imaging immediately upon activation of the stroke protocol and without a neurological exam.

METHODS AND MATERIALS

CTA head reports were reviewed from April 2021 to Jan 2022. Patients with stroke-related indications in the image-requisition were included. A study was classified as "positive" if a large vessel occlusion was identified on imaging. Studies were then divided into "pre-intervention" (April through Aug 2021) and "post-intervention" (Sept 2021 through Jan 2022) groups to demarcate before and after the acute stroke protocol standardization to obtain CTA imaging after NCCT head imaging and an appropriate neurological exam raised high clinical suspicion for acute ischemia.

RESULTS

Results identified 428 studies in the pre-intervention group and 280 in the post-intervention group. There were 21 positive CTA exams in the pre-intervention group (4.9%) and 23 positive exams in the post-intervention group (8.2%) ($p<0.05$). Additionally, the number of studies ordered for stroke-related reasons decreased by 34.6% compared to the pre-intervention period.

CONCLUSION

s The diagnostic yield of CTA was significantly improved after standardizing the acute stroke protocol to obtain CTA only after ischemic stroke was confirmed on NCCT. Adherence to standard practice guidelines in conjunction with judicious decision making when ordering imaging for stroke diagnosis is critical for limiting unnecessary radiation exposure and efficacious CT utilization.

CLINICAL RELEVANCE/APPLICATION

This study supports guideline-directed imaging protocol for stroke diagnosis vis a vis higher diagnostic yield, limiting unnecessary radiation exposure, and efficient resource utilization.

T2-SPNR-4 The Application of Proton Exchange rate (kex) MRI in Ischemic Stroke Patients

Participants
Yiran Zhou, (*Presenter*) Nothing to Disclose

PURPOSE

Proton exchange rate (kex) MRI has recently been developed and preliminarily shown its potential value for evaluating reactive oxygen species of tissues in vivo. This study aimed to investigate the change of kex in different stroke stages and its correlation with stroke severity and prognosis.

METHODS AND MATERIALS

96 ischemic stroke patients were divided into 3 groups (acute, subacute and chronic) based on the stroke phases. A spin-echo echo-planar imaging sequence with pre-saturation chemical exchange saturation power of 1.5, 2.5, and 3.5 μT was implemented to obtain Z-spectra which were fitted to remove the water direct saturation (DS) effect. kex maps were constructed from DS-removed omega plots. Relative kex (rkex) and relative apparent diffusion coefficient (rADC) were calculated by taking the ratio of kex or ADC in the infarcts over that of the mirrored contralateral tissue, respectively. Pearson's correlation analysis was implemented to evaluate the correlations between kex rkex and the National Institute of Health Stroke Scale (NIHSS). The predictive performance of kex, rkex, rADC, and lesion volume for acute stroke outcome was evaluated through receiver operating characteristic curve.

RESULTS

The kex of ischemic lesions was significantly higher compared to the mirrored contralateral tissue at the three stages (acute: ischemic lesion 935.08 s-1 vs contralateral tissue 777.26 s-1, $P < 0.001$; subacute: ischemic lesion 881.42 s-1 vs contralateral tissue 762.17 s-1, $P < 0.001$; chronic: ischemic lesion 866.93 s-1 vs contralateral tissue 756.34 s-1, $P < 0.001$). Besides, the kex of acute lesions was significantly higher than subacute and chronic lesions ($P < 0.05$, $P < 0.01$, respectively). However, the difference between the subacute and chronic lesions was not significant. Lesion's kex and rkex significantly correlated with the NIHSS score only for the acute cases ($r = 0.406$, $P = 0.016$; $r = 0.531$, $P = 0.001$). Acute patients with poor prognosis had significantly higher kex rkex of lesion compared to patients with good prognosis (991.08 vs. 893.08 s-1, $P < 0.001$; 1.28 vs. 1.15, $P < 0.001$). These measures showed favorable predictive performance for acute stroke outcome with area under the curve (AUC) of 0.837 and 0.880, slightly while not significantly higher than lesion volume (AUC: 0.730) and rADC (AUC: 0.673).

CONCLUSION

s kex-MRI could identify ischemic lesions at different stages with markedly elevated intensity on the kex maps. It showed potential capability to reflect the stroke severity and predict the prognosis for acute stroke patients.

CLINICAL RELEVANCE/APPLICATION

kex-MRI is promising for ischemic stroke diagnosis and management as it may reflect oxidative stress of stroke lesions at different stages and predict the acute stroke outcome.

T2-SPNR-5 Clinical, Imaging Correlates and Prognostic Implications of Asymmetric Perivascular Spaces in Acute Ischemic Stroke

Participants
Jinhao Lyu, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

Perivascular spaces (PVSs) have been considered a key element of the glymphatic system of the central nervous system and played a role in the mechanism of small vessel disease. Asymmetric PVSs is reported to be correlated with post-stroke depression and seizure. The incidence, mechanism, and prognostic implication of asymmetric PVSs have yet to be determined. We aimed to determine the associations of asymmetric PVSs with stroke presentations, cerebral hemodynamics and functional independence in acute ischemic stroke (AIS).

METHODS AND MATERIALS

We included 26 AIS patients with unilateral internal carotid artery and middle cerebral artery occlusion, who had undergone baseline routine head MRI and dynamic susceptibility contrast (DSC). Collateral circulation was graded 0-3 based on DSC source imaging (a higher value indicated better collaterals). The burden of PVSs was assessed by using a semi-quantitative scale. The scale selected 3 representative locations (midbrain [MB], basal ganglia [BG], and centrum semiovale [CS]) based on axial T2-weighted imaging slices and scored based on the number of PVSs (details please see Fig 1). The total score of PVSs in each hemisphere was calculated as: Stotal = SBG+ SCS+ SMB. Lesion side dominant asymmetry PVSs were defined as: Stotal of the infarct hemisphere - Stotal of the contralateral hemisphere > 0. The full baseline clinical and imaging features were listed in Table 1 in Fig 1. Binary logistic regression was used to identify predictors of lesion side dominant asymmetry PVSs and poor outcome defined as 3-month modified Rankin Scale > 2.

RESULTS

In them, 17/26 presented lesion side dominant asymmetry PVSs, 9/26 presented symmetry distribution of PVSs, and 0/26 presented contralateral side dominant asymmetry PVSs. Collateral circulation grade was significantly associated with the presence of lesion side dominant asymmetry PVSs (unadjusted odds ratio [OR], 0.07; 95% confidence interval [CI], 0.01-0.53; P=0.01). In binary logistic regression, lesion side dominant asymmetry PVSs (OR, 12.06; 95% CI, 1.16-125.91; P=0.038) was independent predictors of stroke outcomes after adjusted for age. The total burden of PVSs showed no significant association with stroke outcomes.

CONCLUSION

s In acute large vessel occlusion stroke, lesion side dominant asymmetry PVSs suggest the rapid impairments of the glymphatic system after ischemia, and hypoperfusion due to collateral circulation insufficiency may be one critical mechanism in the process.

CLINICAL RELEVANCE/APPLICATION

Lesion side dominant asymmetry PVSs negatively associated with stroke outcomes in acute ischemic stroke. Global estimation of PVSs is feasible and the asymmetry appearance may provide helpful and insightful information.

T2-SPNR-1

Deep Learning-based Infarct Core And Penumbra Quantification In Perfusion CT Data: Comparison with DWI Final Infarct Volume and RAPID

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Peter Chang, MD, Irvine, CA (*Presenter*) Co-founder, Avicenna.ai;Stockholder, Avicenna.ai;Research Grant, Canon Medical Systems Corporation;Speakers Bureau, Canon Medical Systems Corporation;Research Grant, General Electric Company

PURPOSE

The primary objective of this study was to evaluate the accuracy of deep learning-based CT perfusion (CTP) core volume estimation when compared with diffusion-weighted imaging (DWI). The secondary objective of this study was to evaluate deep learning-based (DL) core and penumbra volume values with those obtained with a commercially-available threshold-based CTP analysis.

METHODS AND MATERIALS

A total of 38 consecutive adult patients for suspected acute ischemic stroke were retrospectively identified between 12/2020 - 06/2021 for whom CTP and 24-48 hour follow-up DWI MRI were obtained as part of the clinical workflow. Images of non-diagnostic quality or with missing data required for the DL analysis were excluded. The core volume was manually segmented on DWI images by a neuroradiologist with 5 years of experience. CTP images were analyzed for core and penumbra volumes with: (1) standard RAPID processing; (2) a DL-based method as part of Arterys Neuro AI (Arterys Inc.). Data normality distribution was checked using the Shapiro-Wilk test. Descriptive statistics were reported as median and interquartile range (IQR) values. Spearman correlation coefficients were used to compare core volumes. Two-sided Wilcoxon tests were used to compare automatically derived core and penumbra volumes. A P-value of 0.05 was deemed as statistically significant.

RESULTS

A total of 33 patients met all inclusion criteria for final analysis. Median (IQR) core volume from DWI images was 3.1 (0.1 - 15.2) ml. Median (IQR) difference between DWI and CTP core volumes was 3.0 (0.08 - 7.1) and 0.64 (0 - 6.5) ml for RAPID and Arterys software, respectively. Spearman correlation with DWI core volumes were 0.51 ($p<0.05$) and 0.61 ($p<0.001$) for RAPID and Arterys, respectively. A statistically significant difference was found between automatically derived core volumes ($p=0.023$) but not for penumbra.

CONCLUSION

s Deep learning-based CTP analysis showed higher correlation with DWI-defined core values than traditional threshold-based CTP analysis. The presence of patients with embolic infarcts, which are too small to cause perfusion changes, might have contributed to the discrepancies between software packages. Further studies on a larger and heterogeneous patient cohort are needed to confirm these preliminary findings.

CLINICAL RELEVANCE/APPLICATION

Deep learning CTP may provide a more accurate estimate of DWI-defined core infarct volume than traditional threshold-based CTP analysis.

T2-SPNR-11

COVID-19 Effect on Mortality of Patients with Pulmonary Embolism

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Miranda Rougelot, BS, (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this research was to determine if COVID-19 diagnosis within the past ninety days increased severity of PE. COVID diagnosis does not take into consideration specific strain.

METHODS AND MATERIALS

In this retrospective study 903 patients with pulmonary embolism and had tested positive for COVID in the last ninety days were observed. Risk was analyzed and patients were given PESI scores. PESI scores are a point system based on risk factors such as age, gender, medical history, symptoms, etc. Points categorize into Classes I-V with Class V being the highest risk. Class IV and V PESI scores were eligible for thrombectomy.

RESULTS

PE patient PESI scores increased by one class with COVID-19 diagnoses. Of the 903 patients, 1.9% had a standard PESI of Class I while PESI + COVID was 1.4%. Class II jumped from a standard score of 4.9% to 10.9% with the inclusion of COVID diagnoses. Class III had 8.0% standard and 14.2% with COVID. Class IV had 14.2% standard and 22.4% with COVID. Finally class V had 23.6% standard and 27.2% with COVID diagnoses. These results are a significant difference from standard risk stratification (p=0.03).

CONCLUSION

s COVID-19 diagnosis significantly increases mortality in patients with Pulmonary Embolism in regards to PESI Score.

CLINICAL RELEVANCE/APPLICATION

COVID- 19 exposure increases thirty day mortality in patients with pulmonary embolism (PE). A Pulmonary Embolism Severity Index (PESI) score is given to patients based on age and predictors present. A patient's PESI score increases in class with the diagnosis of COVID-19 within 90 days of admission.

T2-SPNR-12

Association of White Matter Hyperintensity Burden and Ischemic Core Growth in Large-Vessel Occlusion Stroke

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Jia-Ying Zhou, (*Presenter*) Nothing to Disclose

PURPOSE

To assess whether heavier white matter hyperintensity (WMH) burden is associated with faster ischemic core growth in acute stroke patients with large vessel occlusion.

METHODS AND MATERIALS

In this retrospective study, we reviewed anterior circulation large-vessel-involved acute stroke patients who had baseline CT perfusion within 24 hours after symptom onset and had an MRI scan five days after admission from October 1, 2018, to October 31, 2021 at two stroke center. Core growth rate was calculated by the following equation: The core growth rate = Acute core volume on CT perfusion / Time from stroke onset to CT perfusion. The WMH volumes were assessed with semiautomated volumetric analysis at fluid-attenuated inversion recovery MRI by readers who were blinded to clinical data. The WMH index was calculated by the ratio of WMH volume within whole brain tissue volume and then categorized into tertiles: for each tertile, the core growth rate was summarized as median and inter-quartile range. Simple linear regressions were then performed to measure the predictive power of WMH volume and WMH index in core growth rate.

RESULTS

A total of 154 patients in center 1 and 46 patients in center 2were included (mean age, 69 years ± 19 [standard deviation]; 121 women [57.6%]). For patients allocated to slight WMH burden (tertile 1 of WMH index), moderate WMH burden (tertile 2), and heavy WMH burden (tertile 3), the median core growth rate was 3.15 ml/hour (1.05-6.24), 8.21 ml/hour (5.33-16.27), and 22.67 ml /hour (10.82-39.89) respectively. Increments in the WMH index by 1% resulted in an increase of core growth by 0.49 ml/hour (coefficient=0.49, 95% confidence interval=[0.41, 0.57], p<0.001). The relationship of core growth and WMH index was validated in center 2. An increment in WMH index by 1% resulted in an increase of core growth by 0.54 ml/hour (coefficient=0.54 [0.42, 0.67], p<0.001) in center 2.

CONCLUSION

s WMH burden was associated with ischemic core growth for large-vessel occlusion stroke. Acute ischemic stroke patients with heavier white matter hyperintensity burden have faster ischemic core growth.

CLINICAL RELEVANCE/APPLICATION

Acute ischemic stroke patients with heavier white matter hyperintensity burden have faster ischemic core growth. This study recommends considering WMH burden when making treatment decisions for acute ischemic stroke patients on the tissue-based level.

T2-SPNR-13

Development of a Nomogram Based on DWI and Clinical Information to Predict DEACMP

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Wenxuan Han, XI'AN, China (*Presenter*) Nothing to Disclose

PURPOSE

Prevention of delayed encephalopathy after carbon monoxide poisoning (DEACMP), one of the most serious complications of acute carbon monoxide poisoning (ACOP), remains challenging. Hence, the purpose of this study was to identify the independent risk factors for DEACMP and to establish a nomogram to predict the probability of DEACMP.

METHODS AND MATERIALS

Data of patients diagnosed with ACOP between September 2015 and June 2021 were retrospectively analyzed. According to the prognosis results, they were divided into the DEACMP group and the non-DEACMP group. Univariate analysis and multivariate logistic regression analysis were used to assess the risk factors of DEACMP, and a nomogram was constructed to predict the risk of DEACMP. The receiver operating characteristic curve (ROC) and calibration curves were used to evaluate the performance of this model.

RESULTS

A total of 122 patients were enrolled in this study, of whom 30(24.6%) developed DEACMP. Multivariate logistic regression analysis showed that acute high-signal lesions on DWI, CO exposure time, and GCS score were independent risk factors for DEACMP (Odds Ratio=6.230,1.323,0.714, P<0.05). The predictive nomogram was established according to the above indicators. The model reached an area under the curve (AUC) of the according receiver operating characteristic (ROC) curve of 0.959. The calibration curve of a nomogram showed a satisfactory consistency between prediction and observation.

CONCLUSION

s In this study, a nomogram to predict DEACMP based on high-signal lesions on DWI and clinical indicators was constructed, which may be a reliable tool to distinguish high-risk patients and then provide them with personalized treatment to reduce the incidence of DEACMP.

CLINICAL RELEVANCE/APPLICATION

We believe the nomogram may be a potential tool for identifying high-risk patients of DEACMP.

3D Chemical Exchange Saturation Transfer (CEST) Imaging: Differentiating Capability of Malignant from Benign Intracranial Meningiomas

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Kazuhiro Murayama, MD, Toyoake, Japan (*Presenter*) Research Grant, Canon Medical Systems Corporation

PURPOSE

To determine the capability of 3D chemical exchange saturation transfer (CEST) imaging at 3.5 ppm, which provides amide proton transfer (APT) weighted information in the entire brain, for differentiating malignant from benign intracranial meningiomas.

METHODS AND MATERIALS

36 patients with pathologically diagnosed intracranial meningiomas (mean age, 61.1 years) underwent CEST imaging using 3D gradient-echo based sequences at a 3T MR system. According to pathological and follow-up examination results, all tumors were divided into benign (grade 1, n = 24) and malignant (grade 2 or 3, n = 12) meningioma groups. In each lesion, magnetization transfer ratio asymmetry (MTRasym) at 3.5 ppm was computationally calculated from z spectra from each CEST data, and the MTRasym map was generated by pixel-by-pixel analysis. Then, MTRasym in the solid component of a tumor was determined by ROI measurements. To evaluate cell proliferation in each meningioma, MIB-1 index was also pathologically evaluated. To compare MTRasym between malignant and benign meningiomas, Student’s t-test was performed. To evaluate the relationship between amide proton transfer and cell proliferation within each tumor, Spearman's correlations was performed between MTRasym and MIB-1 index. To assess the capability of MTRasym for distinguishing malignant from benign meningiomas, a ROC-based positive test was performed for determine the feasible threshold value. Finally, sensitivity, specificity and accuracy were assessed.

RESULTS

MTRasym of malignant meningiomas was significantly higher than that of benign meningiomas (malignant: 2.61±0.79%, benign: 1.19±0.58, p<0.0001). MTRasym was significantly and positively correlated with MIB-1 index (?=0.51, p<0.05). When applied feasible threshold value of MTRasym in this setting, sensitivity (SE), specificity (SP) and accuracy (AC) were determined as follows: SE, 91.7 (11/12) %; SP, 95.8 (23/24) %; AC, 94.4 (34/36) %, respectively.

CONCLUSION

s 3D CEST imaging has a good potential for differentiatiing malignant from benign meningiomas. APT-weighted imaging may provide regional cell proliferation difference within meningioma in routine clinical practice.

CLINICAL RELEVANCE/APPLICATION

3D CEST imaging has a good potential for differentiatiing malignant from benign meningiomas. APT-weighted imaging may provide regional cell proliferation difference within meningioma in routine clinical practice.

T2-SPNR-15

Association Between Auditory fMRI And Clinical Outcomes in Mild Traumatic Brain Injury

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Priya Santhanam, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

This study assesses the relationship between auditory functional magnetic resonance imaging (fMRI) findings and clinical outcomes of patients diagnosed with mild traumatic brain injury (mTBI).

METHODS AND MATERIALS

Civilian patients (n=221) diagnosed with mTBI underwent auditory fMRI with separate auditory tasks performed on the right ear, the left ear, and bilaterally. Quantification of blood-oxygen-level dependent (BOLD) signal activation was performed, and a laterality index was calculated for each series. Clinical data relating to presentation and resolution of post-concussive symptoms were obtained via retrospective chart review. To account for inherent variability and uncertainty in symptom onset and resolution, data were right-censored and interval-censored. Clinical data were compared to the fMRI laterality index, overall asymmetry, and total activation.

RESULTS

Intensity and laterality of auditory fMRI activation were not significantly associated ($p>0.05$) with incidence of any surveyed post-concussive symptoms. Post-concussive headaches persisted significantly ($p=0.038$) longer in patients with a right-biased laterality during bilateral auditory stimulation. For left-sided auditory stimulation, longevity of post-concussive anxiety ($p=0.043$) and depression ($p<0.001$) were found to associate with activation signal intensity for subjects in the bottom 10th percentile of overall activation. For the right-sided auditory stimulation, longevity of post-concussive anxiety ($p<0.001$) and depression ($p<0.001$) were found to associate with activation signal intensity for subjects in bottom and top 10th percentiles of overall activation as well as asymmetry for those subjects in the top 10th percentile of activation asymmetry.

CONCLUSION

s Our results suggest that auditory fMRI may be a viable quantitative predictor of mTBI symptom persistence for the clinical assessment and management of mTBI. Further studies more explicitly assessing the relationship between fMRI activation and post-concussive headache, anxiety, and depression are warranted.

CLINICAL RELEVANCE/APPLICATION

Auditory functional magnetic resonance imaging could serve as a predictor of symptom persistence and recovery in patients with mild traumatic brain injury.

T2-SPNR-16

Follow-up Imaging of Clipped Intracranial Aneurysms With 3-T MRI: Comparison Between 3D Time-Of-Flight Mrangiography and Pointwise Encoding Time Reduction Withradial Acquisition Subtraction-Based MR Angiography

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Inyoung Kim, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Metallic susceptibility artifact due to implanted clips is a major limitation of using 3D time-of-flight magnetic resonance angiography (TOF-MRA) for follow-up imaging of clipped aneurysms (CAs). The purpose of this study was tocompare pointwise encoding time reduction with radial acquisition (PETRA) subtraction-based MRA with TOF-MRA in terms of imaging quality and visibility of clip-adjacent arteries for use in follow-up imaging of CAs.

METHODS AND MATERIALS

Sixty-two patients with 73 CAs were included retrospectively in this comparative study. All patients underwent PETRA-MRA after TOF-MRA performed simultaneously with 3-T MRI between September 2019 and March 2020.Two neuroradiologists independently compared images obtained with both MRA modalities to evaluate overall image quality using a 4-point scale and visibility of the parent artery and branching vessels near the clips using a 3-point scale.Subgroup analysis was performed according to the number of clips (less-clipped [1-2 clips] vs more-clipped [= 3 clips] aneurysms). The ability to detect aneurysm recurrence was also assessed.

RESULTS

Compared with TOF-MRA, PETRA-MRA showed acceptable image quality (score of 3.97 ± 0.18 for TOFMRA vs 3.73 ± 0.53 for PETRA-MRA) and had greater visibility of the adjacent vessels near the CAs (score of 1.25 ± 0.59 for TOF-MRA vs 2.27 ± 0.75 for PETRA-MRA, $p < 0.0001$). PETRA-MRA had greater visibility of vessels adjacent to less-clipped aneurysms (score of 2.39 ± 0.75 for less-clipped aneurysms vs 2.09 ± 0.72 for more-clipped aneurysms, $p = 0.014$). Of 73 CAs, aneurysm recurrence in 4 cases was detected using PETRA-MRA.

CONCLUSION

s This study demonstrated that PETRA-MRA is superior to TOF-MRA for visualizing adjacent vessels near clips and can be an advantageous alternative to TOF-MRA for follow-up imaging of CAs.

CLINICAL RELEVANCE/APPLICATION

PETRA-MRA may be an effective alternative for follow-up imaging of CAs.

Characterization of Thalamic Subregions Over 1-2 Years in Small Vessel Disease Using MR-Based Quantitative Susceptibility Mapping and Free-Water Mapping

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Yawen Sun, Shanghai, China (*Presenter*) Nothing to Disclose

PURPOSE

The aim of this study was to evaluate the characteristics of the thalamic subregions using quantitative susceptibility mapping and free-water (FW) mapping in small vessel disease (SVD) over 1-2 years.

METHODS AND MATERIALS

Fifty-one SVD patients underwent brain MRI scans and neuropsychological evaluations both at baseline and at follow-up, composed of 28 SVD patients with mild cognitive impairment (VaMCI) and 23 with no cognitive impairment (NCI). Quantitative susceptibility (QS) values, FW values, and volumes within thalamic subregions, i.e., the anterior nuclei, the median nuclei, the lateral nuclei (TL-LT), the pulvinar (TL-PLV) and the internal medullary lamina (TL-IML), were calculated for each individual. Temporal (baseline vs. follow-up) and cross-sectional (VaMCI vs. NCI) differences were studied using mixed factorial ANOVA analysis and appropriate t-tests. Partial correlations were used to assess the relationship between the MRI indices changes (i.e., ?FWfollowup-baseline/FWbaseline) and cognitive function changes (i.e., ?MoCAfollowup-baseline/MoCAbaseline).

RESULTS

The Group effect resulted in greater mean FW values (index of neuroinflammation) in the left TL-PLV, bilateral TL-LT, and bilateral TL-IML for VaMCI compared with NCI, as well as resulted in higher mean QS values (index of iron deposition) in the left TL-PL and lower volumes in the left TL-IML ($p < 0.05$). The Group×Time interaction identified increased mean QS values in the left TL-PLV for VaMCI over time. In addition, there were no significant effects for the FW values across Time. Furthermore, we observed significant negative associations between the FW values changes in the left TL-PLV and the right TL-LT and MoCA scores changes in VaMCI group over 1-2 years.

CONCLUSION

s Our results demonstrate that elevated FW and QS values in the thalamic subregions have the potential to be used as an indicator in the progression of SVD. The FW values changes in the TL-PLV and the TL-LT might be the biomarkers for the mechanism of cognitive decline in the evolution of SVD.

CLINICAL RELEVANCE/APPLICATION

QSM and FW mapping when combined, can be considered as a specific and sensitive tool for the monitoring of the complex pathologies such as neuroinflammation and iron deposition in SVD. Our results might contribute to understanding the pathogenesis and progression of SVD.

Multiparametric Quantitative Evaluation Using Synthetic MRI in Normal-Appearing Brain Parenchyma in Adult Moyamoya Disease

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Kazufumi Kikuchi, MD, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

Moyamoya disease (MMD) is a progressive, steno-occlusive cerebrovascular disease affecting the arteries of the circle of the Willis. Few studies have examined the correlation between brain volume and function in patients with MMD. The purpose of this study was to investigate whether multiparametric brain volumes measured by synthetic MRI (SyMRI) correlate with cerebral blood flow (CBF) and brain function (BF) in MMD.

METHODS AND MATERIALS

This retrospective study was approved by our institutional review boards and conducted on 18 MMD patients (3 men, 15 women; median age, 43 years; range, 20-72 years). SyMRI was performed using the 3D-QALAS sequence by a 3T scanner. Quantification map acquisition and raw data processing were performed with SyMRI software (Version 21.4; SyMRI, Linköping, Sweden). CBF was measured using 123I-IMP SPECT, including the acetazolamide challenge. BFs were measured using WAIS-III/IV and WMS-R tests. Quantitative evaluations, including grey matter (GM), white matter (WM), and myelin correlated volume (MyC), were measured and corrected with total brain volume in normal-appearing brain parenchyma in six areas (bilateral anterior, middle, posterior cerebral arterial [ACA/MCA/PCA] territories). These three parameters and their correlations with corrected CBF and BF were evaluated by Spearman's rank-order correlation test.

RESULTS

Resting CBFs were correlated with GM fractions in the right ACA/MCA territories (r=0.524, 0.632; P=0.039, 0.018, respectively). Cerebrovascular reactivity to an acetazolamide challenge was correlated with GM fraction in the left PCA territory (r=0.574, P=0.018). FSIQ/VCI derived from WAIS were correlated with GM fraction in the left PCA territory (r=0.625, 0.615; P=0.009, 0.001, respectively). PSI derived from WAIS was correlated with GM fraction in the right MCA territory (r=0.665, P=0.011). There was no correlation between brain volume fractions and WMS-R indices.

CONCLUSION

s Synthetic MRI could noninvasively evaluate multiparametric brain volumes that correlate with CBF and BF in MMD.

CLINICAL RELEVANCE/APPLICATION

Synthetic MRI can quantitatively assess brain volume loss in patients with Moyamoya disease, which correlates with cerebral blood flow and brain function, and may help determine the disease severity.

NCCT Image-based Automated Intracranial Hemorrhage Classification Using A Deep Learning Model: Is the Intracranial Hemorrhage Classification of Very Small Volume Hematoma Cases Reliable?

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Myeong Jin Kim, MD, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

Intracranial hemorrhage (ICH) is a fatal disease that significantly affects the patient's life and prognosis over time. Patients with small-volume ICH (SICH) with small hematoma are more likely to have a benign clinical course and tend to experience hematoma expansion and have worse outcomes. In this study, we evaluate the classification performance for SICH cases using AI software(cHS-Heuron) for ICH diagnosis.

METHODS AND MATERIALS

We evaluated the SICH classification performance by testing the target group SICH data and the control group non-small volume ICH (Non-SICH) data using cHS-Heuron. As the evaluation data, RSNA ICH Challenge 2019 test dataset and clinical data from single institute were used. The number of data was 397 patients in ICH (250 SICH, 147 non-SICH) and 130 patients in the control group (Non-ICH). The gold standard was generated by a stroke expert by evaluating the hematoma volume of each slice. SICH data were defined as hematoma volume less than 0.65ml and diameter of 2mm or more and 5mm or less. The classifying performance was evaluated through the sensitivity and specificity compared to gold standard.

RESULTS

As the classifying performance of ICH patients, the sensitivity and specificity were 0.9748 and 0.9692, respectively. Among ICH patients, the true positive rate of SICH was 0.9600 in patient-wise classification. However, in slice-wise classification, the sensitivity and specificity were 0.8801 and 0.9890 for SICH group, and, in Non-SICH group, it was 0.9600 and 0.9867, respectively.

CONCLUSION

s As a result of the ICH classification study using cHS-Heuron, the SICH group showed slightly lower sensitivity than the Non-SICH group, but in the patient-wise and slice-wise tests, the SICH group, the Non-SICH group all showed very high ICH classification performance.

CLINICAL RELEVANCE/APPLICATION

In the diagnosis of patients with ICH containing a very small volume hematoma area of ??less than 5 mm in diameter on NCCT images, cHS-Heuron can be utilized as a reliable pre-diagnosis tool for clinicians to quickly and accurately diagnose and make treatment decisions.

Diagnostic Yield of CTA Head After Stroke Protocol Standardization: A Retrospective Study

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Dane Weinert, MD, (*Presenter*) Nothing to Disclose

PURPOSE

CT Angiography (CTA) of the head and neck is useful in the imaging of suspected stroke for identifying patients eligible for endovascular therapies. Acute stroke protocols may vary by when CTA is performed in the imaging algorithm. At our institution, a protocol was implemented which standardized CTA imaging to be obtained only as indicated after an initial non-contrast CT (NCCT) head per American Heart Association stroke guidelines. The objective of our study is to investigate how often relevant diagnostic findings were found in CTA imaging as part of the acute stroke protocol when obtained only after NCCT head imaging and an appropriate neurological exam raised high clinical suspicion for acute ischemia, compared to when CTA head was obtained along with NCCT head imaging immediately upon activation of the stroke protocol and without a neurological exam.

METHODS AND MATERIALS

CTA head reports were reviewed from April 2021 to Jan 2022. Patients with stroke-related indications in the image-requisition were included. A study was classified as "positive" if a large vessel occlusion was identified on imaging. Studies were then divided into "pre-intervention" (April through Aug 2021) and "post-intervention" (Sept 2021 through Jan 2022) groups to demarcate before and after the acute stroke protocol standardization to obtain CTA imaging after NCCT head imaging and an appropriate neurological exam raised high clinical suspicion for acute ischemia.

RESULTS

Results identified 428 studies in the pre-intervention group and 280 in the post-intervention group. There were 21 positive CTA exams in the pre-intervention group (4.9%) and 23 positive exams in the post-intervention group (8.2%) ($p<0.05$). Additionally, the number of studies ordered for stroke-related reasons decreased by 34.6% compared to the pre-intervention period.

CONCLUSION

s The diagnostic yield of CTA was significantly improved after standardizing the acute stroke protocol to obtain CTA only after ischemic stroke was confirmed on NCCT. Adherence to standard practice guidelines in conjunction with judicious decision making when ordering imaging for stroke diagnosis is critical for limiting unnecessary radiation exposure and efficacious CT utilization.

CLINICAL RELEVANCE/APPLICATION

This study supports guideline-directed imaging protocol for stroke diagnosis vis a vis higher diagnostic yield, limiting unnecessary radiation exposure, and efficient resource utilization.

The Application of Proton Exchange rate (kex) MRI in Ischemic Stroke Patients

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Yiran Zhou, (*Presenter*) Nothing to Disclose

PURPOSE

Proton exchange rate (kex) MRI has recently been developed and preliminarily shown its potential value for evaluating reactive oxygen species of tissues in vivo. This study aimed to investigate the change of kex in different stroke stages and its correlation with stroke severity and prognosis.

METHODS AND MATERIALS

96 ischemic stroke patients were divided into 3 groups (acute, subacute and chronic) based on the stroke phases. A spin-echo echo-planar imaging sequence with pre-saturation chemical exchange saturation power of 1.5, 2.5, and 3.5 μT was implemented to obtain Z-spectra which were fitted to remove the water direct saturation (DS) effect. kex maps were constructed from DS-removed omega plots. Relative kex (rkex) and relative apparent diffusion coefficient (rADC) were calculated by taking the ratio of kex or ADC in the infarcts over that of the mirrored contralateral tissue, respectively. Pearson's correlation analysis was implemented to evaluate the correlations between kex rkex and the National Institute of Health Stroke Scale (NIHSS). The predictive performance of kex, rkex, rADC, and lesion volume for acute stroke outcome was evaluated through receiver operating characteristic curve.

RESULTS

The kex of ischemic lesions was significantly higher compared to the mirrored contralateral tissue at the three stages (acute: ischemic lesion 935.08 s-1 vs contralateral tissue 777.26 s-1, $P < 0.001$; subacute: ischemic lesion 881.42 s-1 vs contralateral tissue 762.17 s-1, $P < 0.001$; chronic: ischemic lesion 866.93 s-1 vs contralateral tissue 756.34 s-1, $P < 0.001$). Besides, the kex of acute lesions was significantly higher than subacute and chronic lesions ($P < 0.05$, $P < 0.01$, respectively). However, the difference between the subacute and chronic lesions was not significant. Lesion's kex and rkex significantly correlated with the NIHSS score only for the acute cases ($r = 0.406$, $P = 0.016$; $r = 0.531$, $P = 0.001$). Acute patients with poor prognosis had significantly higher kex rkex of lesion compared to patients with good prognosis (991.08 vs. 893.08 s-1, $P < 0.001$; 1.28 vs. 1.15, $P < 0.001$). These measures showed favorable predictive performance for acute stroke outcome with area under the curve (AUC) of 0.837 and 0.880, slightly while not significantly higher than lesion volume (AUC: 0.730) and rADC (AUC: 0.673).

CONCLUSION

s kex-MRI could identify ischemic lesions at different stages with markedly elevated intensity on the kex maps. It showed potential capability to reflect the stroke severity and predict the prognosis for acute stroke patients.

CLINICAL RELEVANCE/APPLICATION

kex-MRI is promising for ischemic stroke diagnosis and management as it may reflect oxidative stress of stroke lesions at different stages and predict the acute stroke outcome.

T2-SPNR-5

Clinical, Imaging Correlates and Prognostic Implications of Asymmetric Perivascular Spaces in Acute Ischemic Stroke

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Jinhao Lyu, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

Perivascular spaces (PVSs) have been considered a key element of the glymphatic system of the central nervous system and played a role in the mechanism of small vessel disease. Asymmetric PVSs is reported to be correlated with post-stroke depression and seizure. The incidence, mechanism, and prognostic implication of asymmetric PVSs have yet to be determined. We aimed to determine the associations of asymmetric PVSs with stroke presentations, cerebral hemodynamics and functional independence in acute ischemic stroke (AIS).

METHODS AND MATERIALS

We included 26 AIS patients with unilateral internal carotid artery and middle cerebral artery occlusion, who had undergone baseline routine head MRI and dynamic susceptibility contrast (DSC). Collateral circulation was graded 0-3 based on DSC source imaging (a higher value indicated better collaterals). The burden of PVSs was assessed by using a semi-quantitative scale. The scale selected 3 representative locations (midbrain [MB], basal ganglia [BG], and centrum semiovale [CS]) based on axial T2-weighted imaging slices and scored based on the number of PVSs (details please see Fig 1). The total score of PVSs in each hemisphere was calculated as: Stotal = SBG+ SCS+ SMB. Lesion side dominant asymmetry PVSs were defined as: Stotal of the infarct hemisphere - Stotal of the contralateral hemisphere > 0. The full baseline clinical and imaging features were listed in Table 1 in Fig 1. Binary logistic regression was used to identify predictors of lesion side dominant asymmetry PVSs and poor outcome defined as 3-month modified Rankin Scale > 2.

RESULTS

In them, 17/26 presented lesion side dominant asymmetry PVSs, 9/26 presented symmetry distribution of PVSs, and 0/26 presented contralateral side dominant asymmetry PVSs. Collateral circulation grade was significantly associated with the presence of lesion side dominant asymmetry PVSs (unadjusted odds ratio [OR], 0.07; 95% confidence interval [CI], 0.01-0.53; P=0.01). In binary logistic regression, lesion side dominant asymmetry PVSs (OR, 12.06; 95% CI, 1.16-125.91; P=0.038) was independent predictors of stroke outcomes after adjusted for age. The total burden of PVSs showed no significant association with stroke outcomes.

CONCLUSION

s In acute large vessel occlusion stroke, lesion side dominant asymmetry PVSs suggest the rapid impairments of the glymphatic system after ischemia, and hypoperfusion due to collateral circulation insufficiency may be one critical mechanism in the process.

CLINICAL RELEVANCE/APPLICATION

Lesion side dominant asymmetry PVSs negatively associated with stroke outcomes in acute ischemic stroke. Global estimation of PVSs is feasible and the asymmetry appearance may provide helpful and insightful information.

T2-SPOB-1 Pregnancy Following Hysterosalpingography: From Research to Reality

Participants
Anne P. Hemingway, MBBS, (*Presenter*) Consultant, Guerbet SA

PURPOSE

An RCT published in the NEJM in 2017 concluded that women under the age of 39 with unexplained subfertility had an improved spontaneous conception and live birth rate following hysteosalpingography (HSG)and that this benefit was greater when the HSG was undertaken with Oil-soluble contrast media(OSCM) compared to Water soluble contrast media (WSCM).Studies have shown that patients who participate in RCTs,whether in the intervention or control group, have a better outcome that those who do not.We wished to determine if the conception rates following HSG with either WSCM or OSCM in routine clinical practice mirrored those reported in the published RCT.

METHODS AND MATERIALS

The imaging and medical records relating to 667 consecutive HSGs undertaken between January 2020 and December 2021 were retrospectively reviewed. Research Ethics committee approval was granted for this study. Demographic, medical, imaging and reproductive data was collected. Pregnancy outcomes, mode of conception (spontaneous or assisted reproductive therapy (ART), time to conception from HSG and type of contrast used was recorded.

RESULTS

667 consecutive hysterosalpingograms (HSG) in women aged between 19 and 51 years, mean 35.5 years were reviewed.133 (23.6%) conceptions occurred following HSG with WSCM, 92(69%) spontaneous, 36 (27%) following ART. 13 of the spontaneous pregnancies and 8 of the ART pregnancies occurred in women aged 39 or over. 77 of the pregnancies (57 spontaneous and 18 ART, 2 unspecified) occurred in HSGs reported as normal, 56 (35 spontaneous, 18 ART, 3 unspecified) in HSGs reported as abnormal. 31(30%) conceptions followed an HSG with OSCM, 25 (81%) spontaneous, 6 (19%) following ART. 24 pregnancies followed an HSG reported as normal, 6 in HSGs reported as abnormal. 4 spontaneous pregnancies occurred in women aged 39 years or over.

CONCLUSION

s The study remains ongoing, women continue to be followed up. Preliminary data however fully supports the hypothesis that in everyday routine HSG practice the procedure is associated with an enhanced conception rate and that OSCM is superior to WSCM in this respect.Research does indeed translate to reality.

CLINICAL RELEVANCE/APPLICATION

The management of subfertility is complex. Detailed investigation to determine cause is critical to appropriate management. Assisted reproductive therapies (ART) are demanding of the patients involved physically, emotionally and often financially. Any safe intervention that improves the chances of successful spontaneous conception is desirable. From both published RCTs, meta analyses and observational studies such was this, it is clear that an HSG with either WSCM or OSCM is advantageous in this respect and that OSCM has a significant advantage over WSCM.

T2-SPPD-1 Neuroradiological Imaging in Newborns: A Standardized Brain MRI Protocol With Non-invasive Sedation Using a Melatonin-Based Solution

Participants
Simone Marziali, MD, Rome, Italy (*Presenter*) Nothing to Disclose

PURPOSE

MRI is the best technique to investigate newborn neurological pathologies, particularly affecting preterm infants, in both acute setting and follow-up of late sequelae. Given the increasing use of neonatal brain MRI, great interest is developing in obtaining diagnostic images without profound sedation, which requires logistic accommodations and trained personnel in neonatal anesthesia, often difficult to achieve.Melatonin is known as a sleep inducer in children and used in neurophysiological and neuroimaging procedures.Our aim was to assess the efficacy of a melatonin-based solution for non-invasive sedation in a standardized neonatal brain MRI protocol.

METHODS AND MATERIALS

110 newborns (37 term and 73 preterm) which underwent brain MRI between 2017 and 2019 were enrolled in this study.Sedation was induced with one, two or three administrations of an oral solution of melatonin, tryptophan, and vitamin B6 (Melamil Tripto©). 30 minutes before the exam, 2 mg of melatonin was administered. If the neonate was still awake after 20 minutes, and additional 1 mg was administered. Additional 1 mg was administered if the baby was not sleeping after further 15 minutes.A neonatologist was present at each examination and both heart rate and oxygen saturation were monitored. We used a vacuum mattress to contain the little patients and mini muffs to reduce the noise.MRI was performed on a 1.5T scanner and basic protocol included multi-planar spin-echo (SE) T1-weighted, turbo-spin-echo (TSE) T2-weighted sequences, T2* gradient echo sequences (GRE), diffusion weighted imaging (DWI) and susceptivity weighted imaging (SWI).Evaluation was performed by two different neuroradiologists experienced in neonatal neuroimaging.

RESULTS

In 106 patients we obtained sufficient sedation to perform an adequate quality MRI, with a median time of 25min to reach sleeping. In 3 patients MRI could not be performed due to complete wakefulness. One patient was excluded for consent withdrawn.Higher melatonin dose was necessary in patients with higher weight and in all the patients who took 3 shots of the solution, difficulty in performing the MRI was reported. However, this did not significantly affect the total length of the acquisition and no side effects have been reported up to 4 mg.

CONCLUSION

s In patients with higher tendency to wakefulness, the acquisition of high resolution sequences was not possible due to longer acquisition time leading to increasing motion artifacts.However, in most cases our method was able to achieve sufficient sedation to perform MRI, avoiding the use of anesthetics and obtaining good quality images.

CLINICAL RELEVANCE/APPLICATION

These initial results may be helpful for future development of non-invasive neuroimaging protocols in neonates.

T2-SPPH-1 Soft Tissue Image Quality in Computed Tomography Using an Anthropomorphic Phantom: Model Observer Comparison Between Dual-Energy and Photon-Counting Scanners

Participants
Dimitar Petrov, Leuven, Belgium (*Presenter*) Nothing to Disclose

PURPOSE

Study the soft tissue image quality (IQ) using an anthropomorphic phantom on a dual-energy CT scanner (DE-CT) and a newly installed photon-counting CT scanner (PC-CT). Investigate the differences in monoenergetic reconstructions and compare the performance between the two scanners.

METHODS AND MATERIALS

An anthropomorphic abdomen phantom producing clinically relevant soft tissue Hounsfield units (HU) was scanned 12 times on both a Siemens DE-CT and PC-CT scanners with CTDIvol=8mGy. A custom insert containing 45 low-contrast (-20HU) spheres grouped into 3 sizes of 4, 6, and 8mm diameter was placed in the phantom for task-based IQ estimation. The acquisitions were reconstructed for 7 ascending monoenergetic X-ray spectra ranging between 60keV and 85keV, each of them reconstructed with iterative (IR) and filtered-back projection (FBP) reconstruction algorithms. The conventional polychromatic reconstructions were also added to the comparison.For each condition, 30 signal present and 90 signal absent regions of interest (ROI) were extracted from the phantom images. The image quality analysis was performed using a two-layer channelized Hoteling observer (CHO) performing a four-alternative forced-choice (4AFC) reading. The percentage correct (PC) values for each sphere size and condition were fitted with a psychometric fit and the sphere threshold detectability diameter (Dtr) at 62.5 PC was used as a final IQ figure of merit.

RESULTS

The Dtr for each system was compared against the corresponding scanner type and reconstruction algorithm type (figure). The analysis showed that there is no significant difference between FBP and IR ($p>0.11$). The performance of the DE-CT compared to the PC-CT for the polychromatic settings was, for both reconstruction algorithms, not significantly different ($p=0.44$). For the two scanners, optimal low-contrast detectability occurred at different keV settings, for the PC-CT, at 67keV, and for DE-CT at 80keV. The PC-CT reached a monoenergetic threshold detectability diameter of 5.3±0.12 mm, and the DE-CT a significantly higher value of 5.5±0.10 mm ($p=0.57$). Both scanners reach similar monoenergetic performance at 74kev ($p>0.32$).

CONCLUSION

s The CHO results show that the two scanners perform similarly for the standard polychromatic settings. The PC-CT outperforms the DE-CT for the lower monoenergetic reconstructions.

CLINICAL RELEVANCE/APPLICATION

The soft tissue image quality of PC-CT was optimal at 67keV. As most abdominal CT exams use contrast agents that also benefit from low keV values, the PC-CT may clinically outperform conventional DE-CTs.

T2-SPPH-2 Human Observer Detection of Liver Metastases in Patients vs. Model Observer Detection (D') In a Liver Phantom

Participants
Emma Thingstad, MSc, Oslo, Norway (*Presenter*) Research collaboration, The Phantom Laboratory

PURPOSE

Detection and characterization of liver lesions is essential in oncological imaging, with decisive implication on patient care. Quantitative methods to evaluate diagnostic performance are aspired in clinical practice to tailor protocols. This study compares the detectability of liver metastasis by radiologists in a clinical setting (human observer) to performance of a tailored software applied to CT images of a liver phantom containing lesions (model observer).

METHODS AND MATERIALS

20 patients were scanned with standard abdominal CT protocol for detection of liver metastases (median CTDIvol = 12.2 mGy). 11 of these were additionally scanned with 60% and 40% dose and 9 were scanned with 50% and 30% dose. Images were reconstructed with ASiR-V (AV) 50% and True-Fidelity - high (TF). Detectability of liver metastases was assessed by two

radiologists and compared to a gold standard (evaluation using high dose and clinical information of the patient). CT scans of a liver phantom (The Phantom Laboratory) containing inserts with various iodine concentrations and diameters at corresponding conditions were analyzed using the ImQuest software (Duke University), and a detectability index (d') was calculated for each configuration. Results from the human observer method were compared to those of the model observer method.

RESULTS

The model observer d' followed the same trend as lesions detected by human observers in patient images when changing dose level. When changing reconstruction algorithm TF improved d' compared to AV. In the patient group with 30/50% dose, results show that AV may be beneficial compared to TF, while in the patient group with 40/60% dose, this trend is not as clear. This may be because of different lesion sizes in the two groups. Dependence of lesion size and contrast is work in progress.

CONCLUSION

s The behavior of the detectability in patient vs. d' in the phantom coincides at different dose levels. However, when changing reconstruction algorithm the tests do not correlate to the same degree. Dependence on lesion size and contrast may be the reason for this.

CLINICAL RELEVANCE/APPLICATION

Quality assessment of CT protocols is time consuming. Model observers in imaging phantoms could save radiologists both time and cost. But does the model observer correlate well with lesion detection?

T2-SPPH-3 Comparison of Low-Contrast Object Detectability in Deep Learning and Conventional Reconstructions: AAPM TG-233 Phantom Evaluation

Participants
Chang Yong Heo, BS, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To measure the detectability of low-contrast objects on CT according to AAPM TG-233 report and examine if deep learning-based technique could improve the detectability of low-contrast objects over conventional reconstructions in low-dose CT imaging.

METHODS AND MATERIALS

ACR phantom was scanned at 120kV with SD (100mAs) and LD (25mAs) settings and reconstructed with two different scanners (GE: Discovery 750 HD, FBP and ASiR-V 30%; Siemens: Somatom Force, FBP and ADMIRE 2). A deep learning-based CT denoising model (DLM; ClariCT.AI ™, ClariPi) was applied to all FBP images. Low-contrast detectability was measured according to AAPM TG-233 report using imQuest soft (Duke University) and compared for the different scan and reconstruction settings. Noise power spectrum (NPS) was measured on uniform section of module 3, and task-based transfer function (TTF) was analyzed on acrylic disk of module 1. Detectability index (d') was computed for a 5 mm low contrast disk object with 7 HU.

RESULTS

Detectability index (d') improved markedly with DLM (GE, 1.90; Siemens, 2.17) from that of FBP (GE, 0.99; Siemens, 1.11), and was comparable with IR (GE, 1.03; Siemens, 1.22) in LD scans of both scanners. The detectability indices with DLM in LD scans were superior to those with FBP in HD scans (GE, 1.77; Siemens, 2.08) which translated to the dose reduction potential more than 75%.

CONCLUSION

s Measurement of low-contrast detectability on ACR phantom provided an objective comparison of image quality in conventional and DL reconstructions. Deep learning-based denoising model was shown to improve detectability of low-contrast objects while conventional IR was not.

CLINICAL RELEVANCE/APPLICATION

Detectability measurement according to AAPM TG-233 report can be an objective way of examining image quality with newly developed reconstruction techniques in comparison with conventional reconstructions.

T2-SPPH-4 Impact of an Artificial Intelligence Deep-Learning Reconstruction Algorithm for CT on Image Quality and Potential Dose Reduction: A Phantom Study

Participants
Joel Greffier, PhD, Nimes, France (*Presenter*) Nothing to Disclose

PURPOSE

To assess the impact of a artificial intelligence deep-learning reconstruction (AI-DLR) algorithm on image quality and dose reduction compared with a hybrid IR algorithm in chest CT for different clinical indications.

METHODS AND MATERIALS

Acquisitions on the CT ACR 464 and CT Torso CTU-41 phantoms were performed at five dose levels (CTDIvol: 9.5/7.5/6/2.5/0.4mGy) used for chest CT conditions. Raw data were reconstructed using filtered back projection (FBP), two levels of IR (iDose4 levels 4 (i4) and 7 (i7)), and five levels of AI-DLR (Precise Image; Smoother, Smooth, Standard, Sharp, Sharper). Noise power spectrum (NPS), task-based transfer function (TTF) and detectability index (d') were computed: d' modelled detection of a soft tissue mediastinal nodule, ground-glass opacity, or high-contrast pulmonary lesion. Subjective image quality of chest anthropomorphic phantom images was independently evaluated by two radiologists. They have assessed image noise, image smoothing, contrast between the vessels and fat in the mediastinum for mediastinal images, visual border detection between bronchus and lung parenchyma for parenchymal images and overall image quality using a commonly-used four or five-point scale.

RESULTS

From Standard to Smoother levels, the noise magnitude decreased, the average NPS spatial frequency decreased and the detectability (d') of the three lesions increased. The opposite pattern was found from Standard to Sharper levels. From Smoother to Sharper levels, the spatial resolution increased for the low contrast polyethylene insert and the opposite for the high contrast air

insert. Compared to the i4 used in clinical practice, d' values were higher using Smoother, Smooth and Standard levels for mediastinal images and Smoother and Smooth levels for parenchymal images. Radiologists considered the images satisfactory for clinical use at these levels, but adaptation to the dose level of the protocol is required.

CONCLUSION

s With AI-DLR, the smoothest levels reduced the noise and improved the detectability of chest lesions but increased the image smoothing. The opposite was found with the sharpest levels. The choice of level depends on the dose level and type of image: mediastinal or parenchymal.

CLINICAL RELEVANCE/APPLICATION

For the first time, we assessed the impact of the new artificial intelligence deep-learning reconstruction algorithm developped by Philips Healthcare and called Precise Image, compared to a standard clinical protocol using either FBP or IR reconstruction algorithms.

T2-SPPH-5 A Novel Detector Geometry for Third Generation CT

Participants
Jiang Hsieh, PhD, (*Presenter*) Former Employee, General Electric Company

PURPOSE

State-of-the-art CT scanners employ conventional detector geometry that forms an arc concentric to the x-ray source. The collected projection samples form an equiangular dataset, but their distance to the isocenter is nonuniformly spaced. When CT scanners employ steps to convert cone-beam datasets to parallel-beam datasets prior to the reconstruction, both channel- and view-wise rebinning are required. Such approach potentially leads to a degraded spatial resolution and an increased aliasing artifact.

METHODS AND MATERIALS

We propose a novel detector geometry that acquires projection samples with an evenly spaced distance to the isocenter. To ensure that the detector cell size is independent of the cell position, the source-to-detector distance varies as a function of the detector fan-angle. To guarantee detector surface being normal to the x-ray beam, each detector module (16 channels) is tilted relative to each other. This design requires only view-rebinning to form a parallel dataset. In addition, the detector surface area (arc-length) is reduced compared to the conventional design and a smaller cell size can be employed.

RESULTS

Extensive computer simulations were used to demonstrate the efficacy of our design, utilizing a wire phantom, water phantom, Shepp-Logan head phantom, and a specially designed aliasing phantom. Spatial resolution was measured with modulation transfer function (MTF) and the proposed design offers 12.6% increase compared to the conventional design, resulting from the smaller detector cell and removal of the channel-wise interpolation. In addition, aliasing artifact is significantly improved at locations away from the isocenter. At matched spatial resolution (by modifying the reconstruction kernel for the conventional design), image noise for the proposed system is 8.8% lower.

CONCLUSION

s Compared to the conventional geometry, the proposed detector geometry offers improved performance in spatial resolution and artifact reduction, and exhibits better noise performance at a matching resolution. Further research on this design is warranted to fully explore other systems parameters such as the compactness of the gantry design.

CLINICAL RELEVANCE/APPLICATION

This research is relevant to improve the clinical performance of a CT system.

T2-SPPH-6 Robust High Precision Nonlinear CT Reconstruction Two Orders of Magnitude Faster than Competing Iterative Reconstruction

Participants
Wolfram Jarisch, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

A new method for Tomographic reconstructions potentially makes highest quality diagnostic CT imaging available to all patients. The new method continues to evolve in competition to existing nonlinear iterative and deep learning methods that are overly sensitive to small data changes (Vegard Antuna,et al., 2020). Here we focus on a new iterative approach combining filtered backprojection (FBP), logarithmic and exponential transformations (LET), matching linearizations, and voxel state expansion. The nonlinear iterative approach provides highstability, accuracy, and computational speed. The method surpasses performanceof other methods in terms of accuracy with two orders of magnitude higherspeed.

METHODS AND MATERIALS

The method was first implemented in a high level program language at an NIH laboratory using publicly available program components for projection and backprojection. Accuracy and speed exceeded results over a state-of-the art OS-SART implementation (Ander Biguri, 2017, GitHub).

RESULTS

On a 3D skull model, development of new Python code, showed half the residual-sum-of squares on central slices and between 80 and 150 fold higher speed than OS-SART (Figure). Both algorithms used the same array processor.

CONCLUSION

s The high imaging quality and speed of the new algorithm allows to compute 3D angiographic images from a sequence of 6 moving projections. Similarly, movie-like 3D tomograms may by estimated motion parameters during the reconstruction process (Levenber-Marquardt; 1944, 1963; not shown). The high imaging quality of the new algorithm follows from its relation to minimum variance

estimation and structural similarity to Maximum Entropy estimation.

CLINICAL RELEVANCE/APPLICATION

The combined noise resilience, high imaging quality, modeling of movement, and speed, can reduce several barriers to the effective use of CT: cost per procedures, radiation, procedure time, and movement of patients.

T2-SPPH-7 CT Number Stability in Clinical Photon-Counting Virtual Monoenergetic Imaging

Participants
Jessica Flores, MS, (*Presenter*) Nothing to Disclose

PURPOSE

In the quantitative assessment of pathology in sequential and inter-patient studies, robust attenuation estimation of materials is essential for clinical applications of computed tomography (CT). Current standards in CT technology rely on energy-integrating detectors in single-energy CT (SECT) and dual-energy CT (DECT). With the introduction of photon-counting CT (PCCT) into clinical practice, there is the potential to improve HU stability. Therefore, this work aimed to study CT number stability to elucidate differences in CT systems and to highlight the strengths of clinical PCCT.

METHODS AND MATERIALS

Data was acquired on a clinical PCCT scanner, Siemens NAEOTOM Alpha, and a SECT/DECT scanner, Siemens SOMATOM Drive. HU variation was investigated in the CIRS 662 phantom with material-equivalent inserts, like iodine in water (15.0 mg/mL), adipose, bone (200 mg/mL) and muscle. Two factory protocols and phantom size configurations were used to demonstrate stability across CTDIvol and size. Protocols were adjusted to sweep across kVp and define a constant CTDIvol. Standard IR strengths and a single reconstruction kernel were used to create volume images. Virtual monoenergetic images in the PCCT scanner were produced at 70 keV, corresponding closest to the mean energy of a 120 kVp spectrum. Circular ROI masks were applied over regions containing inserts in volume images and used to determine mean HU per material. Percent relative standard deviation is reported as a metric to quantity HU variation in each material.

RESULTS

Preliminary studies show that the clinical PCCT scanner produces more consistent measurements than the SECT/DECT scanner in SECT mode for the same material across phantom size, CTDIvol and kVp. For all material inserts, percent relative standard deviation varied between 4.6% and 26.2% in the SECT scanner and between 0.7% and 2.6% in the PCCT scanner. Differences in performance between scanners are particularly apparent in higher HU materials such as bone and iodine inserts, where measurements from the PCCT scanner show less variation. For 15.0 mg/mL iodine in water, HU estimations showed 26.2% and 0.7% relative standard deviation in the SECT and PCCT scanners, respectively.

CONCLUSION

s Compared to SECT, clinical PCCT produces more stable and consistent CT number measurements.

CLINICAL RELEVANCE/APPLICATION

Comparing a new clinical PCCT scanner to other scanners that are already familiar, this work highlights the strength of PCCT in the clinic to facilitate the quantitative assessment of pathology.

T2-SPPH-8 Quality Comparison of Single-Energy CT at Low Tube Voltages and Virtual Monochromatic Imaging at Low Energies by Dual-Energy CT With Deep Learning Reconstruction

Participants
Shingo Harashima, Tokyo, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To compare quality of single-energy CT (SECT) at low tube voltages and virtual monochromatic imaging (VMI) at low energies by dual-energy CT (DECT) with deep learning reconstruction (DLR) in phantom experiments to simulate routine abdominal contrast-enhanced CT (CECT).

METHODS AND MATERIALS

We performed SECT and DECT scanning of a water phantom (GE), a phantom to assess beam-hardening artifact (BHA) (QSP-1 phantom; FUYO, Tokyo), and our original phantom to measure task-based modulation transfer function (TTF) using a state-of-the-art 256-gemstone-detector CT scanner (Revolution Apex, GE) at the similar volume CT dose index of approximately 10 mGy. For SECT scanning, tube voltage/current was 70 kVp/750 mA and 80 kVp/470 mA. For DECT scanning, tube voltage was rapidly switched from 80 to 140 kVp and tube current was 200 mA. SECT at 70 and 80 kVp and VMI at 40 and 50 keV were reconstructed using thickness of 1.25 mm and DLR (TrueFidelity, GE). We measured standard deviation of CT value as image noise and noise power spectrum (NPS) using the water phantom; CT value using the QSP-1 phantom with and without surrounding 350-mg iodine contrast media (CM), iohexol (Omnipaque 350, GE), at dilution factor of 10 for simulating bone attenuation to calculate its absolute difference as an index of BHA; contrast-noise ratio (CNR) and TTF using the TTF phantom with the CM at dilution factors of 30 and 60 for simulating arterial and hepatic attenuations, respectively; and thus compared these results among SECT at 70 and 80 kVp and VMI at 40 and 50 keV using one-way ANOVA and Tukey tests.

RESULTS

Whereas image noise significantly decreased from 40 keV to 50 keV to SECT ($P < 0.05$), CNR significantly increased from SECT to 50 keV to 40 keV ($P < 0.05$). NPS peaked at lower frequency by DECT than by SECT. BHA was significantly less by DECT than by SECT ($P < 0.05$). TTF was lower by DECT than by SECT by approximately 12%.

CONCLUSION

s Using DLR at the similar radiation dose, VMI at the low energies degrade noise characteristics and decrease spatial resolution by approximately 12% but increase CNR and reduce BHA compared with SECT at the low tube voltages in routine abdominal CECT.

CLINICAL RELEVANCE/APPLICATION

When decreased spatial resolution by approximately 12% is acceptable, combined with DLR, VMI at 40-50 keV by DECT are clinically more beneficial than SECT at 70-80 kVp in routine abdominal CECT.

T2-SPPH-9 Evaluation of Pulse Pileup on a Clinical Photon-Counting CT Scanner

Participants
Mridul Bhattarai, MS, BS, Durham, NC (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the significance of pulse pileup on clinical photon-counting CT (PCCT) in terms of task-generic image quality metrics.

METHODS AND MATERIALS

An ACR phantom was scanned on a commercial PCCT (NAEOTOM Alpha, Siemens). Tube current was varied from 240 - 980 mA to study the effects of the flux to the detector on pulse pileup. Helical scans were done at 120 kV without tube current modulation (TCM) under eleven tube currents (240 - 980 mA), rotation time of 0.5 s, and pitch of 1. The dose levels corresponded to CTDIvol (32 cm phantom) of 9.5 - 38.7 mGy. Images were reconstructed using QIR-off mode (FBP) with Br44 kernel and voxel size of 0.4102 x 0.4102 x 3 mm3. imQuest, an open-source MATLAB-based software package, was used to calculate noise power spectrum (NPS), modulation transfer function (MTF), contrast-to-noise ratio (CNR), and CT number according to AAPM task group 233.

RESULTS

The shape of MTF did not change with mA. The relationship between noise magnitude and mA, noise proportional to mA-1/2, deviated up to 24.5% at the higher dose levels. The average frequency of NPS decreased from 0.31 (at 240 mA) to 0.27 mm-1 (at 980 mA), insignificant compared to the increase in dose. CNR increased monotonically up to 880 mA, then it decreased to 980 mA, demonstrating detector saturation due to high flux. CT numbers were consistent across all tube currents with ranges of +-0.8, +-1.1, +-3.4, +-4.6, +-1.0 HU for water, polyethylene, bone, air, and acrylic inserts, respectively.

CONCLUSION

s Results demonstrate that the pulse pileup does not affect the spatial resolution, noise texture, and CT number accuracy, but has a modest influence on the noise magnitude and CNR. The significant effects were seen for only extremely high tube currents (> 880 mA = CTDIvol of 34.7 mGy) when used to scan a 20-cm ACR phantom, which is not clinically applicable. In addition, generally, in clinical practices, TCM is used to control the exposure level decreasing the variation of flux on the detector and alleviating the chance of detector saturation due to high count rates. Thus, pulse pileup does not affect the image quality of commercial PCCT when clinically relevant tube currents are used.

CLINICAL RELEVANCE/APPLICATION

High tube current causes high flux to the photon-counting detectors resulting in piling up of pulses formed by concurrent photons. Theoretically, pulse pileup causes count loss and energy resolution degradation, affecting image quality and HU number accuracy in PCCT. Several studies have been done previously to study the effects of pulse pileup through simulations or use of non-clinical detectors. In the tests perfomed, pulse pileup proved to be inconsequential in clinical PCCT as implemented.

Soft Tissue Image Quality in Computed Tomography Using an Anthropomorphic Phantom: Model Observer Comparison Between Dual-Energy and Photon-Counting Scanners

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - PH DPS

Participants
Dimitar Petrov, Leuven, Belgium (*Presenter*) Nothing to Disclose

PURPOSE

Study the soft tissue image quality (IQ) using an anthropomorphic phantom on a dual-energy CT scanner (DE-CT) and a newly installed photon-counting CT scanner (PC-CT). Investigate the differences in monoenergetic reconstructions and compare the performance between the two scanners.

METHODS AND MATERIALS

An anthropomorphic abdomen phantom producing clinically relevant soft tissue Hounsfield units (HU) was scanned 12 times on both a Siemens DE-CT and PC-CT scanners with CTDIvol=8mGy. A custom insert containing 45 low-contrast (-20HU) spheres grouped into 3 sizes of 4, 6, and 8mm diameter was placed in the phantom for task-based IQ estimation. The acquisitions were reconstructed for 7 ascending monoenergetic X-ray spectra ranging between 60keV and 85keV, each of them reconstructed with iterative (IR) and filtered-back projection (FBP) reconstruction algorithms. The conventional polychromatic reconstructions were also added to the comparison.For each condition, 30 signal present and 90 signal absent regions of interest (ROI) were extracted from the phantom images. The image quality analysis was performed using a two-layer channelized Hoteling observer (CHO) performing a four-alternative forced-choice (4AFC) reading. The percentage correct (PC) values for each sphere size and condition were fitted with a psychometric fit and the sphere threshold detectability diameter (Dtr) at 62.5 PC was used as a final IQ figure of merit.

RESULTS

The Dtr for each system was compared against the corresponding scanner type and reconstruction algorithm type (figure). The analysis showed that there is no significant difference between FBP and IR ($p>0.11$). The performance of the DE-CT compared to the PC-CT for the polychromatic settings was, for both reconstruction algorithms, not significantly different ($p=0.44$). For the two scanners, optimal low-contrast detectability occurred at different keV settings, for the PC-CT, at 67keV, and for DE-CT at 80keV. The PC-CT reached a monoenergetic threshold detectability diameter of 5.3±0.12 mm, and the DE-CT a significantly higher value of 5.5±0.10 mm ($p=0.57$). Both scanners reach similar monoenergetic performance at 74kev ($p>0.32$).

CONCLUSION

s The CHO results show that the two scanners perform similarly for the standard polychromatic settings. The PC-CT outperforms the DE-CT for the lower monoenergetic reconstructions.

CLINICAL RELEVANCE/APPLICATION

The soft tissue image quality of PC-CT was optimal at 67keV. As most abdominal CT exams use contrast agents that also benefit from low keV values, the PC-CT may clinically outperform conventional DE-CTs.

T2-SPPH-2

Human Observer Detection of Liver Metastases in Patients vs. Model Observer Detection (D') In a Liver Phantom

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - PH DPS

Participants
Emma Thingstad, MSc, Oslo, Norway (*Presenter*) Research collaboration, The Phantom Laboratory

PURPOSE

Detection and characterization of liver lesions is essential in oncological imaging, with decisive implication on patient care. Quantitative methods to evaluate diagnostic performance are aspired in clinical practice to tailor protocols. This study compares the detectability of liver metastasis by radiologists in a clinical setting (human observer) to performance of a tailored software applied to CT images of a liver phantom containing lesions (model observer).

METHODS AND MATERIALS

20 patients were scanned with standard abdominal CT protocol for detection of liver metastases (median CTDIvol = 12.2 mGy). 11 of these were additionally scanned with 60% and 40% dose and 9 were scanned with 50% and 30% dose. Images were reconstructed with ASiR-V (AV) 50% and True-Fidelity - high (TF). Detectability of liver metastases was assessed by two radiologists and compared to a gold standard (evaluation using high dose and clinical information of the patient). CT scans of a liver phantom (The Phantom Laboratory) containing inserts with various iodine concentrations and diameters at corresponding conditions were analyzed using the ImQuest software (Duke University), and a detectability index (d') was calculated for each configuration. Results from the human observer method were compared to those of the model observer method.

RESULTS

The model observer d' followed the same trend as lesions detected by human observers in patient images when changing dose level. When changing reconstruction algorithm TF improved d' compared to AV. In the patient group with 30/50% dose, results show that AV may be beneficial compared to TF, while in the patient group with 40/60% dose, this trend is not as clear. This may be because of different lesion sizes in the two groups. Dependence of lesion size and contrast is work in progress.

CONCLUSION

s The behavior of the detectability in patient vs. d' in the phantom coincides at different dose levels. However, when changing reconstruction algorithm the tests do not correlate to the same degree. Dependence on lesion size and contrast may be the reason for this.

CLINICAL RELEVANCE/APPLICATION

Quality assessment of CT protocols is time consuming. Model observers in imaging phantoms could save radiologists both time and cost. But does the model observer correlate well with lesion detection?

Comparison of Low-Contrast Object Detectability in Deep Learning and Conventional Reconstructions: AAPM TG-233 Phantom Evaluation

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - PH DPS

Participants
Chang Yong Heo, BS, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To measure the detectability of low-contrast objects on CT according to AAPM TG-233 report and examine if deep learning-based technique could improve the detectability of low-contrast objects over conventional reconstructions in low-dose CT imaging.

METHODS AND MATERIALS

ACR phantom was scanned at 120kV with SD (100mAs) and LD (25mAs) settings and reconstructed with two different scanners (GE: Discovery 750 HD, FBP and ASiR-V 30%; Siemens: Somatom Force, FBP and ADMIRE 2). A deep learning-based CT denoising model (DLM; ClariCT.AI ™, ClariPi) was applied to all FBP images. Low-contrast detectability was measured according to AAPM TG-233 report using imQuest soft (Duke University) and compared for the different scan and reconstruction settings. Noise power spectrum (NPS) was measured on uniform section of module 3, and task-based transfer function (TTF) was analyzed on acrylic disk of module 1. Detectability index (d') was computed for a 5 mm low contrast disk object with 7 HU.

RESULTS

Detectability index (d') improved markedly with DLM (GE, 1.90; Siemens, 2.17) from that of FBP (GE, 0.99; Siemens, 1.11), and was comparable with IR (GE, 1.03; Siemens, 1.22) in LD scans of both scanners. The detectability indices with DLM in LD scans were superior to those with FBP in HD scans (GE, 1.77; Siemens, 2.08) which translated to the dose reduction potential more than 75%.

CONCLUSION

s Measurement of low-contrast detectability on ACR phantom provided an objective comparison of image quality in conventional and DL reconstructions. Deep learning-based denoising model was shown to improve detectability of low-contrast objects while conventional IR was not.

CLINICAL RELEVANCE/APPLICATION

Detectability measurement according to AAPM TG-233 report can be an objective way of examining image quality with newly developed reconstruction techniques in comparison with conventional reconstructions.

Jessica Flores, MS, (*Presenter*) Nothing to Disclose

PURPOSE

In the quantitative assessment of pathology in sequential and inter-patient studies, robust attenuation estimation of materials is essential for clinical applications of computed tomography (CT). Current standards in CT technology rely on energy-integrating detectors in single-energy CT (SECT) and dual-energy CT (DECT). With the introduction of photon-counting CT (PCCT) into clinical practice, there is the potential to improve HU stability. Therefore, this work aimed to study CT number stability to elucidate differences in CT systems and to highlight the strengths of clinical PCCT.

METHODS AND MATERIALS

Data was acquired on a clinical PCCT scanner, Siemens NAEOTOM Alpha, and a SECT/DECT scanner, Siemens SOMATOM Drive. HU variation was investigated in the CIRS 662 phantom with material-equivalent inserts, like iodine in water (15.0 mg/mL), adipose, bone (200 mg/mL) and muscle. Two factory protocols and phantom size configurations were used to demonstrate stability across CTDIvol and size. Protocols were adjusted to sweep across kVp and define a constant CTDIvol. Standard IR strengths and a single reconstruction kernel were used to create volume images. Virtual monoenergetic images in the PCCT scanner were produced at 70 keV, corresponding closest to the mean energy of a 120 kVp spectrum. Circular ROI masks were applied over regions containing inserts in volume images and used to determine mean HU per material. Percent relative standard deviation is reported as a metric to quantity HU variation in each material.

RESULTS

Preliminary studies show that the clinical PCCT scanner produces more consistent measurements than the SECT/DECT scanner in SECT mode for the same material across phantom size, CTDIvol and kVp. For all material inserts, percent relative standard deviation varied between 4.6% and 26.2% in the SECT scanner and between 0.7% and 2.6% in the PCCT scanner. Differences in performance between scanners are particularly apparent in higher HU materials such as bone and iodine inserts, where measurements from the PCCT scanner show less variation. For 15.0 mg/mL iodine in water, HU estimations showed 26.2% and 0.7% relative standard deviation in the SECT and PCCT scanners, respectively.

CONCLUSION

s Compared to SECT, clinical PCCT produces more stable and consistent CT number measurements.

CLINICAL RELEVANCE/APPLICATION

Comparing a new clinical PCCT scanner to other scanners that are already familiar, this work highlights the strength of PCCT in the clinic to facilitate the quantitative assessment of pathology.

Quality Comparison of Single-Energy CT at Low Tube Voltages and Virtual Monochromatic Imaging at Low Energies by Dual-Energy CT With Deep Learning Reconstruction

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - PH DPS

Participants
Shingo Harashima, Tokyo, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To compare quality of single-energy CT (SECT) at low tube voltages and virtual monochromatic imaging (VMI) at low energies by dual-energy CT (DECT) with deep learning reconstruction (DLR) in phantom experiments to simulate routine abdominal contrast-enhanced CT (CECT).

METHODS AND MATERIALS

We performed SECT and DECT scanning of a water phantom (GE), a phantom to assess beam-hardening artifact (BHA) (QSP-1 phantom; FUYO, Tokyo), and our original phantom to measure task-based modulation transfer function (TTF) using a state-of-the-art 256-gemstone-detector CT scanner (Revolution Apex, GE) at the similar volume CT dose index of approximately 10 mGy. For SECT scanning, tube voltage/current was 70 kVp/750 mA and 80 kVp/470 mA. For DECT scanning, tube voltage was rapidly switched from 80 to 140 kVp and tube current was 200 mA. SECT at 70 and 80 kVp and VMI at 40 and 50 keV were reconstructed using thickness of 1.25 mm and DLR (TrueFidelity, GE). We measured standard deviation of CT value as image noise and noise power spectrum (NPS) using the water phantom; CT value using the QSP-1 phantom with and without surrounding 350-mg iodine contrast media (CM), iohexol (Omnipaque 350, GE), at dilution factor of 10 for simulating bone attenuation to calculate its absolute difference as an index of BHA; contrast-noise ratio (CNR) and TTF using the TTF phantom with the CM at dilution factors of 30 and 60 for simulating arterial and hepatic attenuations, respectively; and thus compared these results among SECT at 70 and 80 kVp and VMI at 40 and 50 keV using one-way ANOVA and Tukey tests.

RESULTS

Whereas image noise significantly decreased from 40 keV to 50 keV to SECT ($P < 0.05$), CNR significantly increased from SECT to 50 keV to 40 keV ($P < 0.05$). NPS peaked at lower frequency by DECT than by SECT. BHA was significantly less by DECT than by SECT ($P < 0.05$). TTF was lower by DECT than by SECT by approximately 12%.

CONCLUSION

s Using DLR at the similar radiation dose, VMI at the low energies degrade noise characteristics and decrease spatial resolution by approximately 12% but increase CNR and reduce BHA compared with SECT at the low tube voltages in routine abdominal CECT.

CLINICAL RELEVANCE/APPLICATION

When decreased spatial resolution by approximately 12% is acceptable, combined with DLR, VMI at 40-50 keV by DECT are clinically more beneficial than SECT at 70-80 kVp in routine abdominal CECT.

T2-SPPH-9

Evaluation of Pulse Pileup on a Clinical Photon-Counting CT Scanner

Tuesday, Nov. 29 9:00AM - 9:30AM Room: Learning Center - PH DPS

Participants
Mridul Bhattarai, MS, BS, Durham, NC (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the significance of pulse pileup on clinical photon-counting CT (PCCT) in terms of task-generic image quality metrics.

METHODS AND MATERIALS

An ACR phantom was scanned on a commercial PCCT (NAEOTOM Alpha, Siemens). Tube current was varied from 240 - 980 mA to study the effects of the flux to the detector on pulse pileup. Helical scans were done at 120 kV without tube current modulation (TCM) under eleven tube currents (240 - 980 mA), rotation time of 0.5 s, and pitch of 1. The dose levels corresponded to CTDIvol (32 cm phantom) of 9.5 - 38.7 mGy. Images were reconstructed using QIR-off mode (FBP) with Br44 kernel and voxel size of 0.4102 x 0.4102 x 3 mm3. imQuest, an open-source MATLAB-based software package, was used to calculate noise power spectrum (NPS), modulation transfer function (MTF), contrast-to-noise ratio (CNR), and CT number according to AAPM task group 233.

RESULTS

The shape of MTF did not change with mA. The relationship between noise magnitude and mA, noise proportional to mA-1/2, deviated up to 24.5% at the higher dose levels. The average frequency of NPS decreased from 0.31 (at 240 mA) to 0.27 mm-1 (at 980 mA), insignificant compared to the increase in dose. CNR increased monotonically up to 880 mA, then it decreased to 980 mA, demonstrating detector saturation due to high flux. CT numbers were consistent across all tube currents with ranges of +-0.8, +-1.1, +-3.4, +-4.6, +-1.0 HU for water, polyethylene, bone, air, and acrylic inserts, respectively.

CONCLUSION

s Results demonstrate that the pulse pileup does not affect the spatial resolution, noise texture, and CT number accuracy, but has a modest influence on the noise magnitude and CNR. The significant effects were seen for only extremely high tube currents (> 880 mA = CTDIvol of 34.7 mGy) when used to scan a 20-cm ACR phantom, which is not clinically applicable. In addition, generally, in clinical practices, TCM is used to control the exposure level decreasing the variation of flux on the detector and alleviating the chance of detector saturation due to high count rates. Thus, pulse pileup does not affect the image quality of commercial PCCT when clinically relevant tube currents are used.

CLINICAL RELEVANCE/APPLICATION

High tube current causes high flux to the photon-counting detectors resulting in piling up of pulses formed by concurrent photons. Theoretically, pulse pileup causes count loss and energy resolution degradation, affecting image quality and HU number accuracy in PCCT. Several studies have been done previously to study the effects of pulse pileup through simulations or use of non-clinical detectors. In the tests perfomed, pulse pileup proved to be inconsequential in clinical PCCT as implemented.

T5A-SPBR-1 Racial Disparities Associated with Suboptimal Preoperative Breast MRI Use in Recently Diagnosed Breast Cancer Patients

Participants
Sarah Eskreis-Winkler, MD, New York, NY (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate racial disparities in preoperative breast MRI utilization among recently diagnosed breast cancer patients.

METHODS AND MATERIALS

Breast cancer patients presenting to our institution between 2008 and 2020, and who underwent breast surgery (either total or partial mastectomy) as part of their cancer treatment and self-identified as either non-Hispanic white or non-Hispanic Black, were included in this IRB approved, HIPAA-compliant retrospective study. Patients were divided into two cohorts: those who received an MRI before surgery (MRI cohort), and those who did not (No MRI cohort). Rates of MRI use were calculated for all patients, as well as for white and black racial subgroups, which were compared using a Chi-square test. For patients who underwent partial mastectomy, the rate of positive surgical margins (ink on tumor) was calculated for all patients, for those in the MRI cohort, for those in the No MRI cohort, as well as for white and black racial subgroups in the MRI and No MRI cohorts.

RESULTS

Of 28,384 eligible breast cancer patients (90% white, 10% Black), 9,305 (33%) received an MRI and 19,079 (67%) did not. White patients had a higher MRI use rate than Black patients (33% v. 30%, $p < 0.001$). Patients in the MRI cohort had lower rates of positive surgical margins than those in the No MRI cohort (2.9% v. 4.8%, $p = .029$). Black patients in the No MRI cohort had a higher positive margin rate compared to white patients in the No MRI cohort (6.2% v. 4.6%, $p = .028$), however, this difference was not observed within the MRI cohort, with Black patients having a similar positive margin rate to white patients (3.2% v. 2.9%, $p = 0.9$).

CONCLUSION

s Compared to white patients, Black breast cancer patients were less likely to receive a breast MRI prior to breast surgery. Black patients who received a breast MRI had similar rates of positive surgical margins compared to white patients, while Black patients who did not receive an MRI had higher rates of positive surgical margins. This suggests that racial disparities exist in the utilization of preoperative breast MRI, which warrants further investigation to improve surgical outcomes for Black patients.

CLINICAL RELEVANCE/APPLICATION

Racial disparities exist in preoperative breast MRI use, which may be caused by a variety of factors, potentially leading to poor surgical outcomes for minority patients, representing an urgent need for unbiased data-driven triaging of MRI prior to breast surgery.

T5A-SPBR-2 A Study on The Utility of Minimum ADC in Decreasing Unnecessary Biopsy Rate of Suspected Breast MRI Lesions

Participants
Fang Wu, MMedSc, (*Presenter*) Nothing to Disclose

PURPOSE

This study aimed to evaluate the ability of minimum apparent diffusion coefficient (ADCmin) in decreasing the unnecessary biopsy rate of breast suspected lesions, to determine the ADCmin threshold to facilitate clinical implementation, and to compare the results with the utility of mean ADC (ADCmean).

METHODS AND MATERIALS

Totally, 523 female patients with 548 MRI-detected BI-RADS 3, 4, or 5 lesions confirmed by surgical pathology were recruited in

this retrospective study. A traning set (344 lesions) and a validation set (204 lesions) were determined according to the time sequence of collection. Variations including lesion size, morphology (mass, non-mass),minimum ADC (ADCmin) and mean ADC(ADCmean) of each lesion were collected for analysis. The diagnostic performance indices were calculated by Receiver Operating Characteristics (ROC) analysis, and the Hanley and McNeil test was used for further performance comparison. Under the negative likelihood ratio (-LR)of 0.1, the ADC threshold with the highest specificity was selected as the clinical ADC threshold (ADCnl) . The ability to decrease the biopsy rate of suspected lesions were compared by contingency table analysis.

RESULTS

ADCmin and ADCmean of malignant lesions were significantly lower than that of benign ones. ADCmin showed comparable performance with ADCmean in the diagnosis of benign and malignant breast leisons (P>0.05 for all comparisons). According to the results of training set, the value of 1.39×10-3 mm2/s and the value of 1.52×10-3 mm2/s were determined as the cut-off for ADCmin (ADCnl-min) and ADCmean (ADCnl-mean) in the diagnosis of benign and malignant breast lesions. Application of ADCnl to the validation set, -LR< 0.1, resulted in 26.2% (95%CL: 20.2~33.9%) and 26.7% (95%CL: 19.7~35.1%) reduction of the biopsy rate to BI-RADS 4 and 5 lesions. Compared with ADCnl-min and ADCnl-mean, there was no significant difference among all subsets in reduction of the biopsy rate of BI-RADS 4 and 5 lesions (P>0.05 for all comparisons).

CONCLUSION

s Almost 1/4 unnecessary biopsies classified as BI-RADS 4 and BI-RADS 5 could be avoided by using an ADCnl-min of 1.39×10-3 mm2/s or an ADCnl-mean of 1.52×10-3 mm2/s.

CLINICAL RELEVANCE/APPLICATION

Using the ADCmin of 1.39 × 10-3mm2/s can avoid 1/4 unnecessary biopsies, the result was favorably compared with ADCmean by using a threshold of 1.52×10-3mm2/s, and obtained a high sensitivity, so as to improve the overall accuracy of breast MRI.

T5A-SPBR-4 Image Quality and Diagnostic Performance of A Next-generation Low-field MRI Scanner in The Clinical Setting: First Experience in Breast Imaging at 0.55T

Participants
Sabine Ohlmeyer, PhD, MD, Erlangen, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Breast-MRI is essential for state-of-the-art breast imaging. However, broader clinical use is limited due to high procedural costs, technical complexity, limited availability and substantial requirements on local-infrastructure. Low-field breast-MRI may compensate for some of these disadvantages. We optimized sequence parameters for a dedicated breast imaging protocol on a next-generation 0.55T scanner and report on our first ten patients in clinical routine examination settings.

METHODS AND MATERIALS

We examined 5 healthy woman and 10 patients with indication for breast MRI (5 with breast Cup size A/B, 5 with Cup size = C) on a low-field MRI unit (MAGNETOM Free.Max, Siemens Healthcare, Erlangen/Germany; multichannel breast-coil, Noras, Höchberg/Germany). An adapted protocol including the following standard sequences was used: diffusion weighted imaging (DWI), T2w TSE, T2w Dixon and T1w VIBE with dynamic contrast enhancement (CE). Three independent MRI experts rated all sequences for signal-to-noise (SNR), contrast, resolution and overall diagnostic impression using a 5-point Likert scale (1 = very good to 5 = very bad). One expert in breast imaging blinded to further patients' history and MRI indication categorized a BI-RADS score to each breast.

RESULTS

Diagnostic image quality, SNR, contrast and resolution were rated as very good to moderate (Likert score 1-3) by the 3 readers for almost all individual sequences. Only in one woman, DWI was rated to be poor (Likert Score 4) by one reader. The mean Likert scores were as follows: DWI 1.92, T2w TSE 1.67, T2w TSE Dixon 1.77, T1w VIBE 1.82. The study doctor (not blinded to patients' history) was able to reproduce all findings in the low-field MRI known from conventional breast diagnostics (mammography and ultrasound) and evaluated all datasets with a mean Likert Score of 1.23, regardless of breast size. Patient reports were as follows: 8 × BI-RADS 1, 6 × BI-RADS 2 (fibroadenomas, cystic lesions, intramammary lymph node), 6 × BI-RADS 6 (breast cancer under NAC). The blinded breast expert correctly categorized all benign reports. Three breast cancers were reported correctly, one as BI-RADS 4, two were missed and categorized as benign because of only residual DWI signal alterations and completely regressive CE of the breast cancer under NAC.

CONCLUSION

s The image quality with a next-generation low-field breast-MRI system with tailored sequences was diagnostic in the clinical setting in our first patients.

CLINICAL RELEVANCE/APPLICATION

Breast imaging with a 0.55T MRI is possible. Our datasets showed diagnostic image quality that resulted in high sensitivity in our study group. This, together with the easier availability of a low-field scanner, could be an interesting aspect for MRI-based breast screening.

T5A-SPBR-5 The Association Between the Ultrafast and Conventional Dynamic Contrast-enhanced MRI Parameters of Breast Cancer and the Histologic Prognostic Markers

Participants
Seong Gwang Kim, MD, Seongnam, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To compare the ultrafast and conventional dynamic contrast-enhanced MRI (DCE-MRI) parameters of breast cancer with their histologic characteristics.

METHODS AND MATERIALS

This retrospective study included 102 patients who were diagnosed with breast cancer between Mar 2021 and Mar 2022 (98

patients with unilateral cancer and 4 patients with bilateral cancer, a total of 106 cancer lesions). The kinetic and morphologic features on ultrafast and conventional DCE-MRI were compared with histologic prognostic markers.

RESULTS

Ninety-seven tumors were invasive cancer and 9 tumors were in situ cancers. 80 tumors were luminal cancer, 9 were HER2-enriched, and 11 were triple-negative. ER positivity was associated with a lower percentage of delayed washout (p=0.022), smaller tumor size (p=0.043), multiplicity (p=0.039), and negative lymph node metastasis (p=0.007). HER2 positivity and high histologic grade were associated with lymph node metastasis (p=0.018 and p=0.002). Ki-67 positivity (>14%) was associated with higher maximum enhancement (ME) on ultrafast imaging. Non-luminal cancers showed a higher percentage of delayed washout (p=0.047), lymph node metastasis (p=0.04), and single lesion (p=0.024). Ultrafast imaging kinetic parameters were not significantly different according to molecular subtype of breast cancer. Invasive breast cancer showed higher ME (p<0.001), slope (p=0.007), maximum slope (p=0.013), and area under the kinetic curve (p=0.014) on ultrafast imaging, and delayed washout kinetics (p=0.01) on conventional kinetic curve, and lesion type-mass (p=0.035). In regression analysis using lesion type, delayed kinetics, and slope on ultrafast kinetics, delayed washout kinetics and slope higher than 4.5%/s were independent predictors of invasive breast cancer.

CONCLUSION

s Ki-67 positivity was associated with a higher ME on ultrafast imaging, but there was no significant difference on ultrafast imaging parameters according to other histologic markers and molecular subtype. Histologic invasiveness of breast cancer was associated with a higher and faster enhancement on ultrafast imaging, delayed washout kinetics on conventional dynamic imaging, and lesion type-mass.

CLINICAL RELEVANCE/APPLICATION

A higher and faster enhancement of breast cancer on ultrafast MR imaging can predict Ki-67 positivity and histologic invasiveness.

T5A-SPBR-6 Not Detected Breast Malignancy in Dynamic Contrast-enhanced MRI: Frequency and Causes

Participants
Dong-Hun Song, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the frequency and main causes of malignant lesions not-detected in dynamic contrast-enhanced (DCE) breast MRI

METHODS AND MATERIALS

A total 1707 cases of preoperative breast MR performed between 2020 and 2021 were included in this study. Of these 1707 cases, the final 13 malignancy cases not-detected in DCE MR were selected, based on the consensus between three radiologists. They also reviewed the final pathology reports to estimate the frequency, and evaluated the imaging findings including DCE MR with diffusion weighted image (DWI), ultrasound, mammography, and if available contrast enhanced chest CT. Then, each cases were classified into three main causes; rare but known non-enhancing pathological feature (n = 7), peripherally located tumor (n = 3), and underlying background parenchymal enhancement (BPE) (n = 3).

RESULTS

The final pathology and frequency of 13 cases were as follows; invasive ductal carcinoma (IDC) (4/1253, 0.3%), invasive lobular carcinoma (ILC) (3/58, 5.2%), mucinous carcinoma (3/50, 6%), ductal carcinoma in situ (DCIS) (1/233, 0.4%), metaplastic carcinoma (1/10, 10%), and primary breast lymphoma (1/2, 50%). Seven cases were not-detected due to non-enhancing pathological feature; mucinous carcinoma (n = 3), ILC (n = 2), metaplastic carcinoma (n = 1) and lymphoma (n = 1). In three cases, tumors were located in the breast periphery. They showed non-enhancement in MR due to compression, but showed homogeneous enhancement at corresponding lesion in chest CT. In the remaining three cases, malignant lesions were not identified due to underlying marked level of BPE. Although these cases were not-detected in DCE-MR, 7 cases were visible in mammography, 10 cases in DWI, 12 cases in ultrasound, and all 13 cases in ultrasound and DWI combination.

CONCLUSION

s The frequency of not-detected malignancy in DCE-MR is very rare (13/1707, 0.76%). Knowing the causes of each case and correlating it with other imaging modalities could be helpful in diagnosis of breast malignancy.

CLINICAL RELEVANCE/APPLICATION

MR is known to have the highest sensitivity in diagnosing breast malignancy among various imaging modalities, but some lesions are not-detected in DCE-MR. In this retrospective study, we evaluated the frequency and causes of these cases.

T5A-SPBR-7 Impact of Pre-operative Breast MRI in Patient with N2 or N3 Stage Breast Cancer Using Propensity Score Matching

Participants
Minah Lee, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the association between preoperative breast magnetic resonance (MR) imaging and surgical nodal outcomes in patients with invasive breast carcinoma by using propensity score matching to decide whether MR examination is beneficial in avoiding unexpected N2 or N3 stage and the number of axillary lymph node dissection.

METHODS AND MATERIALS

Patients diagnosed with invasive breast cancer cancer and clinically N0 stage between 2006 and 2011 who had or had not undergone preoperative MRI and sentinel lymph node biopsy during breast surgery were retrospectively identified. We used propensity score matching using 17 variables and created matched groups with MRI and without MRI. Surgical outcomes of axillary nodes were compared by using chi-square and McNemar's test.

RESULTS

Among 2054 Patients (mean age ± standard deviation, 50 years±10), 1402 had undergone preoperative MRI(mean age, 49±10) and

Among 2054 Patients (mean age ± standard deviation, 50 years±10), 1402 had undergone preoperative MRI(mean age, 49±10) and 652(mean age, 52 years ±11) had not. Any stage Npositive disease was found in 303 in the MRI group, and 204 of the 652 patients in the non-MRI group (21.6% vs 31.3%, P <0.001). Stage N2 or N3 disease was found in 52 patients in the MRI group, and 45 patients in the non-MRI group (3.7% vs 6.9% in any N stage, P =0.002). The rate of axillary lymph node dissection was higher in non-MRI group (n=391) than MRI group (n=402; 60.4% vs 28.7%, P <0.001). After PS matching, Stage N2 or N3 disease was found in 14 of 363 patients in the MRI group, and 26 of 363 patients in the non-MRI group (3.9% vs 7.2% in any N stage, P =0.072). The axillary dissection rate was 104 patents in the MRI group and 217 patient in the non-MRI group (28.7% vs. 59.8 %, P <0.001).

CONCLUSION

s Preoperative MRI in patients with breast cancer is a useful method to predict the high tumor burden of axillary lymph nodes prior to sentinel biopsy and to decrease the axillary lymph node dissection surgery due to unexpected lymph node metastasis.

CLINICAL RELEVANCE/APPLICATION

Preoperative MRI is useful method for avoiding the axillary lymph node dissection surgery due to unexpected lymph node metastasis.

T5A-SPBR-2

A Study on The Utility of Minimum ADC in Decreasing Unnecessary Biopsy Rate of Suspected Breast MRI Lesions

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - BR DPS

Participants
Fang Wu, MMedSc, (*Presenter*) Nothing to Disclose

PURPOSE

This study aimed to evaluate the ability of minimum apparent diffusion coefficient (ADCmin) in decreasing the unnecessary biopsy rate of breast suspected lesions, to determine the ADCmin threshold to facilitate clinical implementation, and to compare the results with the utility of mean ADC (ADCmean).

METHODS AND MATERIALS

Totally, 523 female patients with 548 MRI-detected BI-RADS 3, 4, or 5 lesions confirmed by surgical pathology were recruited in this retrospective study. A traning set (344 lesions) and a validation set (204 lesions) were determined according to the time sequence of collection. Variations including lesion size, morphology (mass, non-mass),minimum ADC (ADCmin) and mean ADC(ADCmean) of each lesion were collected for analysis. The diagnostic performance indices were calculated by Receiver Operating Characteristics (ROC) analysis, and the Hanley and McNeil test was used for further performance comparison. Under the negative likelihood ratio (-LR)of 0.1, the ADC threshold with the highest specificity was selected as the clinical ADC threshold (ADCnl) . The ability to decrease the biopsy rate of suspected lesions were compared by contingency table analysis.

RESULTS

ADCmin and ADCmean of malignant lesions were significantly lower than that of benign ones. ADCmin showed comparable performance with ADCmean in the diagnosis of benign and malignant breast leisons (P>0.05 for all comparisons). According to the results of training set, the value of 1.39×10-3 mm2/s and the value of 1.52×10-3 mm2/s were determined as the cut-off for ADCmin (ADCnl-min) and ADCmean (ADCnl-mean) in the diagnosis of benign and malignant breast lesions. Application of ADCnl to the validation set, -LR< 0.1, resulted in 26.2% (95%CL: 20.2~33.9%) and 26.7% (95%CL: 19.7~35.1%) reduction of the biopsy rate to BI-RADS 4 and 5 lesions. Compared with ADCnl-min and ADCnl-mean, there was no significant difference among all subsets in reduction of the biopsy rate of BI-RADS 4 and 5 lesions (P>0.05 for all comparisons).

CONCLUSION

s Almost 1/4 unnecessary biopsies classified as BI-RADS 4 and BI-RADS 5 could be avoided by using an ADCnl-min of 1.39×10-3 mm2/s or an ADCnl-mean of 1.52×10-3 mm2/s.

CLINICAL RELEVANCE/APPLICATION

Using the ADCmin of 1.39 × 10-3mm2/s can avoid 1/4 unnecessary biopsies, the result was favorably compared with ADCmean by using a threshold of 1.52×10-3mm2/s, and obtained a high sensitivity, so as to improve the overall accuracy of breast MRI.

Image Quality and Diagnostic Performance of A Next-generation Low-field MRI Scanner in The Clinical Setting: First Experience in Breast Imaging at 0.55T

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - BR DPS

Participants
Sabine Ohlmeyer, PhD, MD, Erlangen, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Breast-MRI is essential for state-of-the-art breast imaging. However, broader clinical use is limited due to high procedural costs, technical complexity, limited availability and substantial requirements on local-infrastructure. Low-field breast-MRI may compensate for some of these disadvantages. We optimized sequence parameters for a dedicated breast imaging protocol on a next-generation 0.55T scanner and report on our first ten patients in clinical routine examination settings.

METHODS AND MATERIALS

We examined 5 healthy woman and 10 patients with indication for breast MRI (5 with breast Cup size A/B, 5 with Cup size = C) on a low-field MRI unit (MAGNETOM Free.Max, Siemens Healthcare, Erlangen/Germany; multichannel breast-coil, Noras, Höchberg/Germany). An adapted protocol including the following standard sequences was used: diffusion weighted imaging (DWI), T2w TSE, T2w Dixon and T1w VIBE with dynamic contrast enhancement (CE). Three independent MRI experts rated all sequences for signal-to-noise (SNR), contrast, resolution and overall diagnostic impression using a 5-point Likert scale (1 = very good to 5 = very bad). One expert in breast imaging blinded to further patients' history and MRI indication categorized a BI-RADS score to each breast.

RESULTS

Diagnostic image quality, SNR, contrast and resolution were rated as very good to moderate (Likert score 1-3) by the 3 readers for almost all individual sequences. Only in one woman, DWI was rated to be poor (Likert Score 4) by one reader. The mean Likert scores were as follows: DWI 1.92, T2w TSE 1.67, T2w TSE Dixon 1.77, T1w VIBE 1.82. The study doctor (not blinded to patients' history) was able to reproduce all findings in the low-field MRI known from conventional breast diagnostics (mammography and ultrasound) and evaluated all datasets with a mean Likert Score of 1.23, regardless of breast size. Patient reports were as follows: 8 × BI-RADS 1, 6 × BI-RADS 2 (fibroadenomas, cystic lesions, intramammary lymph node), 6 × BI-RADS 6 (breast cancer under NAC). The blinded breast expert correctly categorized all benign reports. Three breast cancers were reported correctly, one as BI-RADS 4, two were missed and categorized as benign because of only residual DWI signal alterations and completely regressive CE of the breast cancer under NAC.

CONCLUSION

s The image quality with a next-generation low-field breast-MRI system with tailored sequences was diagnostic in the clinical setting in our first patients.

CLINICAL RELEVANCE/APPLICATION

Breast imaging with a 0.55T MRI is possible. Our datasets showed diagnostic image quality that resulted in high sensitivity in our study group. This, together with the easier availability of a low-field scanner, could be an interesting aspect for MRI-based breast screening.

T5A-SPBR-5

The Association Between the Ultrafast and Conventional Dynamic Contrast-enhanced MRI Parameters of Breast Cancer and the Histologic Prognostic Markers

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - BR DPS

Participants
Seong Gwang Kim, MD, Seongnam, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To compare the ultrafast and conventional dynamic contrast-enhanced MRI (DCE-MRI) parameters of breast cancer with their histologic characteristics.

METHODS AND MATERIALS

This retrospective study included 102 patients who were diagnosed with breast cancer between Mar 2021 and Mar 2022 (98 patients with unilateral cancer and 4 patients with bilateral cancer, a total of 106 cancer lesions). The kinetic and morphologic features on ultrafast and conventional DCE-MRI were compared with histologic prognostic markers.

RESULTS

Ninety-seven tumors were invasive cancer and 9 tumors were in situ cancers. 80 tumors were luminal cancer, 9 were HER2-enriched, and 11 were triple-negative. ER positivity was associated with a lower percentage of delayed washout (p=0.022), smaller tumor size (p=0.043), multiplicity (p=0.039), and negative lymph node metastasis (p=0.007). HER2 positivity and high histologic grade were associated with lymph node metastasis (p=0.018 and p=0.002). Ki-67 positivity (>14%) was associated with higher maximum enhancement (ME) on ultrafast imaging. Non-luminal cancers showed a higher percentage of delayed washout (p=0.047), lymph node metastasis (p=0.04), and single lesion (p=0.024). Ultrafast imaging kinetic parameters were not significantly different according to molecular subtype of breast cancer. Invasive breast cancer showed higher ME (p<0.001), slope (p=0.007), maximum slope (p=0.013), and area under the kinetic curve (p=0.014) on ultrafast imaging, and delayed washout kinetics (p=0.01) on conventional kinetic curve, and lesion type-mass (p=0.035). In regression analysis using lesion type, delayed kinetics, and slope on ultrafast kinetics, delayed washout kinetics and slope higher than 4.5%/s were independent predictors of invasive breast cancer.

CONCLUSION

s Ki-67 positivity was associated with a higher ME on ultrafast imaging, but there was no significant difference on ultrafast imaging parameters according to other histologic markers and molecular subtype. Histologic invasiveness of breast cancer was associated with a higher and faster enhancement on ultrafast imaging, delayed washout kinetics on conventional dynamic imaging, and lesion type-mass.

CLINICAL RELEVANCE/APPLICATION

A higher and faster enhancement of breast cancer on ultrafast MR imaging can predict Ki-67 positivity and histologic invasiveness.

T5A-SPBR-6

Not Detected Breast Malignancy in Dynamic Contrast-enhanced MRI: Frequency and Causes

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - BR DPS

Participants
Dong-Hun Song, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the frequency and main causes of malignant lesions not-detected in dynamic contrast-enhanced (DCE) breast MRI

METHODS AND MATERIALS

A total 1707 cases of preoperative breast MR performed between 2020 and 2021 were included in this study. Of these 1707 cases, the final 13 malignancy cases not-detected in DCE MR were selected, based on the consensus between three radiologists. They also reviewed the final pathology reports to estimate the frequency, and evaluated the imaging findings including DCE MR with diffusion weighted image (DWI), ultrasound, mammography, and if available contrast enhanced chest CT. Then, each cases were classified into three main causes; rare but known non-enhancing pathological feature (n = 7), peripherally located tumor (n = 3), and underlying background parenchymal enhancement (BPE) (n = 3).

RESULTS

The final pathology and frequency of 13 cases were as follows; invasive ductal carcinoma (IDC) (4/1253, 0.3%), invasive lobular carcinoma (ILC) (3/58, 5.2%), mucinous carcinoma (3/50, 6%), ductal carcinoma in situ (DCIS) (1/233, 0.4%), metaplastic carcinoma (1/10, 10%), and primary breast lymphoma (1/2, 50%). Seven cases were not-detected due to non-enhancing pathological feature; mucinous carcinoma (n = 3), ILC (n = 2), metaplastic carcinoma (n = 1) and lymphoma (n = 1). In three cases, tumors were located in the breast periphery. They showed non-enhancement in MR due to compression, but showed homogeneous enhancement at corresponding lesion in chest CT. In the remaining three cases, malignant lesions were not identified due to underlying marked level of BPE. Although these cases were not-detected in DCE-MR, 7 cases were visible in mammography, 10 cases in DWI, 12 cases in ultrasound, and all 13 cases in ultrasound and DWI combination.

CONCLUSION

s The frequency of not-detected malignancy in DCE-MR is very rare (13/1707, 0.76%). Knowing the causes of each case and correlating it with other imaging modalities could be helpful in diagnosis of breast malignancy.

CLINICAL RELEVANCE/APPLICATION

MR is known to have the highest sensitivity in diagnosing breast malignancy among various imaging modalities, but some lesions are not-detected in DCE-MR. In this retrospective study, we evaluated the frequency and causes of these cases.

T5A-SPBR-7

Impact of Pre-operative Breast MRI in Patient with N2 or N3 Stage Breast Cancer Using Propensity Score Matching

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - BR DPS

Participants
Minah Lee, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the association between preoperative breast magnetic resonance (MR) imaging and surgical nodal outcomes in patients with invasive breast carcinoma by using propensity score matching to decide whether MR examination is beneficial in avoiding unexpected N2 or N3 stage and the number of axillary lymph node dissection.

METHODS AND MATERIALS

Patients diagnosed with invasive breast cancer cancer and clinically N0 stage between 2006 and 2011 who had or had not undergone preoperative MRI and sentinel lymph node biopsy during breast surgery were retrospectively identified. We used propensity score matching using 17 variables and created matched groups with MRI and without MRI. Surgical outcomes of axillary nodes were compared by using chi-square and McNemar's test.

RESULTS

Among 2054 Patients (mean age ± standard deviation, 50 years±10), 1402 had undergone preoperative MRI(mean age, 49±10) and 652(mean age, 52 years ±11) had not. Any stage Npositive disease was found in 303 in the MRI group, and 204 of the 652 patients in the non-MRI group (21.6% vs 31.3%, P <0.001). Stage N2 or N3 disease was found in 52 patients in the MRI group, and 45 patients in the non-MRI group (3.7% vs 6.9% in any N stage, P =0.002). The rate of axillary lymph node dissection was higher in non-MRI group (n=391) than MRI group (n=402; 60.4% vs 28.7%, P <0.001). After PS matching, Stage N2 or N3 disease was found in 14 of 363 patients in the MRI group, and 26 of 363 patients in the non-MRI group (3.9% vs 7.2% in any N stage, P =0.072). The axillary dissection rate was 104 patents in the MRI group and 217 patient in the non-MRI group (28.7% vs. 59.8 %, P <0.001).

CONCLUSION

s Preoperative MRI in patients with breast cancer is a useful method to predict the high tumor burden of axillary lymph nodes prior to sentinel biopsy and to decrease the axillary lymph node dissection surgery due to unexpected lymph node metastasis.

CLINICAL RELEVANCE/APPLICATION

Preoperative MRI is useful method for avoiding the axillary lymph node dissection surgery due to unexpected lymph node metastasis.

Cardiac Tuesday Poster Discussions - A

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - CA DPS

Sub-Events

T5A-SPCA-1 Non-contrast-enhanced High-resolution REACT MR Angiography of The Great Vessels in Young Children with Complex Congenital Heart Disease

Participants
Alexander Isaak, MD, Bonn, Germany (*Presenter*) Nothing to Disclose

PURPOSE

High-resolution MR angiography (MRA) in small children with congenital heart disease (CHD) is challenging and generally requires contrast agent administration. This study aimed to evaluate the great vessels in young children with complex CHD using native 3D Relaxation-Enhanced Angiography without ContrasT (REACT) in comparison to high-resolution contrast-enhanced MRA.

METHODS AND MATERIALS

In this retrospective study from April to July 2021, respiratory- and electrocardiogram-gated REACT MRA was compared to contrast-enhanced single-phase MRA in young children with CHD (<10 years) that underwent cardiac MRI at 3T for pre- or postsurgical follow-up. Vascular assessment at predefined landmarks of the great vessels and proximal coronary arteries included (i) image quality (1=non-diagnostic, 5=excellent), (ii) vessel size, (iii) artifact burden, and (iv) diagnostic findings. For statistical analysis, paired t-test, Pearson correlation, Bland-Altman analysis, Wilcoxon test, and intraclass correlation coefficients (ICC) were applied.

RESULTS

36 children with complex CHD (median age, 4 years, interquartile range, 2-5; 20 males) who had undergone cardiac MRI under deep sedation were included. Native REACT MRA (mean scan time: 4:22±1:44min) demonstrated comparable overall image quality to contrast-enhanced MRA (3.9±1.0 vs 3.8±0.9, P=0.018). REACT MRA achieved better image quality at the ascending aorta (4.8±0.5 vs 4.3±0.8, P<0.001), proximal coronary arteries (e.g., left: 4.1±1.0 vs 3.3±1.1, P=0.001), and inferior vena cava (4.6±0.5 vs 3.2±0.8, P<0.001). Overall vessel diameters correlated strongly between both MRA methods (Pearson r=0.99; bias=0.04±0.61mm) with high interobserver reproducibility (ICCs: 0.99). Six new vascular findings were detected equally with native REACT MRA and the contrast-enhanced reference standard.

CONCLUSION

s In young children with complex CHD undergoing preoperative or postoperative follow-up, non-contrasted enhanced REACT MRA provides high image quality, accurate vascular measurements, and equivalent diagnostic quality of the great vessels and proximal coronary arteries compared to standard contrast-enhanced MRA.

CLINICAL RELEVANCE/APPLICATION

The use of REACT MRA can provide gadolinium-free vascular assessment in young children with CHD, eliminating potential risks of contrast-associated complications, reducing examination costs, and expediting clinical workflow.

T5A-SPCA-2 Doppler Ultrasound-gated Fetal Cardiac MRI in Complex Congenital Heart Disease: Clinical Feasibility and Comparison to Echocardiography

Participants
Thomas Vollbrecht, Bonn, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the feasibility of fetal cardiac MRI using recently introduced Doppler ultrasound (DUS)-based direct gating in clinical routine and to investigate its diagnostic performance in complex congenital heart disease (CHD) compared to fetal echocardiography.

METHODS AND MATERIALS

In this prospective study (ClinicalTrials.gov identifier: NCT05066399) from May 2021 to March 2022, female participants with CHD of the fetus underwent fetal echocardiography and DUS-gated fetal cardiac MRI on the same day. For fetal cardiac MRI, balanced steady-state free precession cine images were acquired in continous axial and optional saggital and/or coronal orientation (slice thickness: 4 mm). Overall image quality and cardiovascular structure delineability for cine MRI were assessed (4-point Likert scale; 1=non-diagnostic image quality - 4=good image quality). Abnormalities of 20 fetal cardiovascular features previously defined in a study evaluation form were independently assessed for both modalities (abnormality present: yes or no). The reference standard was the result of postnatal examinations. Differences in sensitivities and specificities were calculated with McNemar's test.

RESULTS

23 participants (mean gestational age, 36 weeks ± 1) were included. Fetal cardiac MRI could be completed in all participants. Median overall image quality of DUS-gated cine images was 3 (interquartile range, 2.5-4). In 21 of 23 participants (91%) the underlying CHD was correctly assumed by fetal cardiac MRI. One case with situs inversus but levocardia and congenitally corrected transposition of the great arteries was correctly diagnosed only with MRI. No differences were found regarding sensitivities (88.2%, 95% confidence interval [CI]: 81.4%-92.7% vs. 90.6%, 95% CI: 84.2%-94.5%; P=0.581) and specificities (99.1%, 95% CI: 97.4%-99.7% vs. 99.4%, 95% CI: 97.8%-99.8%; P=0.999) for the detection of abnormal fetal cardiovascular features between echocardiography and MRI.

CONCLUSION

s DUS-gated fetal cine cardiac MRI can reliably diagnose even complex forms of CHD and might be implemented as an adjunct diagnostic tool for prenatal assessment of congenital heart disease.

CLINICAL RELEVANCE/APPLICATION

As echocardiography may be limited especially in late gestation, DUS-gated fetal cardiac MRI could become a diagnostic tool for CHD assessment and further expand the applications of cardiac MRI.

T5A-SPCA-3 Microvascular Dysfunction Predicts Outcomes in Hypertrophic Cardiomyopathy: Insights from the Intravoxel Incoherent Motion MRI

Participants
Xiaorui Xiang, MD, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

Although intravoxel incoherent motion (IVIM) magnetic resonance imaging (MRI) has emerged as an in vivo marker of microvascular dysfunction, its role in predicting outcomes of patients with hypertrophic cardiomyopathy (HCM) remains unclear. This study aimed to investigate the prognostic value of IVIM-MRI in patients with HCM.

METHODS AND MATERIALS

A total of 112 consecutive patients with HCM underwent cardiac MRI were enrolled in this study. The imaging protocol consisted of cine, IVIM, and late gadolinium enhancement (LGE). IVIM derived parameters (D, D* and f) were quantitively analyzed to assess microvascular dysfunction, and the relationship of IVIM derived parameters and LGE extent were analyzed based on 16 American Heart Association segments. All patients were followed up prospectively, the endpoint was set as major adverse cardiac events (MACEs) including cardiac death, aborted sudden death, heart transplantation, and unplanned rehospitalization for heart failure. The MACEs were examined with univariable and multivariable Cox proportional hazards models. Log-rank test and Kaplan-Meier survival analysis were performed to identify the association between variables and outcomes.

RESULTS

During an average follow-up of 40.84±10.47 months, 19 patients (16.9%) reached endpoints. Patients with MACEs showed a trend towards impaired D* value (43.02 ± 14.24μm2/ms, p = 0.01), lower f value (10.57 ± 1.72%, p=0.02), and more extensive LGE (19.95 ± 8.99%, p <0.001) than those without events, while D value (4.75 ± 1.63μm2/ms, p = 0.285) was preserved. Significant correlations were demonstrated between D* value, f value and LGE extent. In the stepwise multivariate Cox regression analysis, D* value (HR 0.93, 95% CI 0.88-0.98, p = 0.001) and f value (HR 0.65, 95% CI 0.45-0.92, p = 0.002) emerged as independent predictors of MACEs, even after adjustment for other relevant disease variables. In the Kaplan-Meier survival analysis, the incidence of MACEs was significantly higher in patients with decreased D* value and f value (all, p < 0.001).

CONCLUSION

s Microvascular dysfunction accessed by IVIM is associated with adverse clinical outcomes in patients with HCM, D* value and f value are independent predictors in addition to LGE.

CLINICAL RELEVANCE/APPLICATION

This is the &7;rst study to apply IVIM-MRI to predict clinical outcomes in HCM patients, providing real world evidence for the use of non-contrast IVIM-MRI to aid in assessing microvascular dysfunction in routine practice.

T5A-SPCA-4 Cardiac Magnetic Resonance Native T1 mapping for Risk Stratification in Pulmonary Arterial Hypertension

Participants
Yue Wang, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the value of cardiac magnetic resonance (CMR) native T1 mapping for risk stratification in patients with pulmonary arterial hypertension (PAH)

METHODS AND MATERIALS

A total of 59 patients with diagnosed PAH who received CMR examination at our institution was retrospectively included. Patients were subdivided into two groups based on the clinically-assessed risk status: low-risk group and intermediate- or high-risk group. Thirty healthy individuals were included as normal controls. Anterior right ventricular insertion point (ARVIP), interventricular septum (IVS) and inferior right ventricular insertion point (IRVIP) native T1 times were evaluated manually. CMR-based cardiac functional parameters such as ejection fraction (EF), end diastolic ventricular volume index (EDV-index) and end systolic ventricular volume index (ESV index) of left ventricular (LV) and right ventricular (RF) were also measured and recorded. Native T1 times at ARVIP, IVS and IRVIP as well as CMR-based functional parameters were compared between groups. Receiver operating characteristics (ROC) curves and area under the curves (AUC) were calculated.

RESULTS

ARVIP, IVS and IRVIP native T1 times were significantly higher in PAH patients as compared with normal controls. Patients in intermediate- or high-risk status showed higher native T1 times in ARVIP and IRVIP. The AUC for ARVIP and IRVIP native T1 times

for discriminating patients with different risk status were 0.741 and 0.702, respectively. LV EDV index, LV ESV index, RVEF, RV EDV index, RV ESV index were also obviously differed between patients with different risk status,with AUC ranged between 0.701 to 0.801. The combining model which integrated ARVIP and IRVIP native T1 times as well as CMR-based cardiac functional parameters showed an AUC of 0.846 for discriminating patients with intermediate- or high-risk status.

CONCLUSION

s ARVIP, and IRVIP native T1 times hold promise for discriminating PAH patients with different risk status.

CLINICAL RELEVANCE/APPLICATION

The combining model integrating native T1 times and CMR-based cardiac functional parameters may supplement the evaluation of the risk status in PAH patients.

Non-contrast-enhanced High-resolution REACT MR Angiography of The Great Vessels in Young Children with Complex Congenital Heart Disease

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - CA DPS

Participants
Alexander Isaak, MD, Bonn, Germany (*Presenter*) Nothing to Disclose

PURPOSE

High-resolution MR angiography (MRA) in small children with congenital heart disease (CHD) is challenging and generally requires contrast agent administration. This study aimed to evaluate the great vessels in young children with complex CHD using native 3D Relaxation-Enhanced Angiography without ContrasT (REACT) in comparison to high-resolution contrast-enhanced MRA.

METHODS AND MATERIALS

In this retrospective study from April to July 2021, respiratory- and electrocardiogram-gated REACT MRA was compared to contrast-enhanced single-phase MRA in young children with CHD (<10 years) that underwent cardiac MRI at 3T for pre- or postsurgical follow-up. Vascular assessment at predefined landmarks of the great vessels and proximal coronary arteries included (i) image quality (1=non-diagnostic, 5=excellent), (ii) vessel size, (iii) artifact burden, and (iv) diagnostic findings. For statistical analysis, paired t-test, Pearson correlation, Bland-Altman analysis, Wilcoxon test, and intraclass correlation coefficients (ICC) were applied.

RESULTS

36 children with complex CHD (median age, 4 years, interquartile range, 2-5; 20 males) who had undergone cardiac MRI under deep sedation were included. Native REACT MRA (mean scan time: 4:22±1:44min) demonstrated comparable overall image quality to contrast-enhanced MRA (3.9±1.0 vs 3.8±0.9, P=0.018). REACT MRA achieved better image quality at the ascending aorta (4.8±0.5 vs 4.3±0.8, P<0.001), proximal coronary arteries (e.g., left: 4.1±1.0 vs 3.3±1.1, P=0.001), and inferior vena cava (4.6±0.5 vs 3.2±0.8, P<0.001). Overall vessel diameters correlated strongly between both MRA methods (Pearson r=0.99; bias=0.04±0.61mm) with high interobserver reproducibility (ICCs: 0.99). Six new vascular findings were detected equally with native REACT MRA and the contrast-enhanced reference standard.

CONCLUSION

s In young children with complex CHD undergoing preoperative or postoperative follow-up, non-contrasted enhanced REACT MRA provides high image quality, accurate vascular measurements, and equivalent diagnostic quality of the great vessels and proximal coronary arteries compared to standard contrast-enhanced MRA.

CLINICAL RELEVANCE/APPLICATION

The use of REACT MRA can provide gadolinium-free vascular assessment in young children with CHD, eliminating potential risks of contrast-associated complications, reducing examination costs, and expediting clinical workflow.

Microvascular Dysfunction Predicts Outcomes in Hypertrophic Cardiomyopathy: Insights from the Intravoxel Incoherent Motion MRI

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - CA DPS

Participants
Xiaorui Xiang, MD, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

Although intravoxel incoherent motion (IVIM) magnetic resonance imaging (MRI) has emerged as an in vivo marker of microvascular dysfunction, its role in predicting outcomes of patients with hypertrophic cardiomyopathy (HCM) remains unclear. This study aimed to investigate the prognostic value of IVIM-MRI in patients with HCM.

METHODS AND MATERIALS

A total of 112 consecutive patients with HCM underwent cardiac MRI were enrolled in this study. The imaging protocol consisted of cine, IVIM, and late gadolinium enhancement (LGE). IVIM derived parameters (D, D* and f) were quantitively analyzed to assess microvascular dysfunction, and the relationship of IVIM derived parameters and LGE extent were analyzed based on 16 American Heart Association segments. All patients were followed up prospectively, the endpoint was set as major adverse cardiac events (MACEs) including cardiac death, aborted sudden death, heart transplantation, and unplanned rehospitalization for heart failure. The MACEs were examined with univariable and multivariable Cox proportional hazards models. Log-rank test and Kaplan-Meier survival analysis were performed to identify the association between variables and outcomes.

RESULTS

During an average follow-up of 40.84±10.47 months, 19 patients (16.9%) reached endpoints. Patients with MACEs showed a trend towards impaired D* value (43.02 ± 14.24μm2/ms, p = 0.01), lower f value (10.57 ± 1.72%, p=0.02), and more extensive LGE (19.95 ± 8.99%, p <0.001) than those without events, while D value (4.75 ± 1.63μm2/ms, p = 0.285) was preserved. Significant correlations were demonstrated between D* value, f value and LGE extent. In the stepwise multivariate Cox regression analysis, D* value (HR 0.93, 95% CI 0.88-0.98, p = 0.001) and f value (HR 0.65, 95% CI 0.45-0.92, p = 0.002) emerged as independent predictors of MACEs, even after adjustment for other relevant disease variables. In the Kaplan-Meier survival analysis, the incidence of MACEs was significantly higher in patients with decreased D* value and f value (all, p < 0.001).

CONCLUSION

s Microvascular dysfunction accessed by IVIM is associated with adverse clinical outcomes in patients with HCM, D* value and f value are independent predictors in addition to LGE.

CLINICAL RELEVANCE/APPLICATION

This is the &7;rst study to apply IVIM-MRI to predict clinical outcomes in HCM patients, providing real world evidence for the use of non-contrast IVIM-MRI to aid in assessing microvascular dysfunction in routine practice.

T5A-SPCA-4

Cardiac Magnetic Resonance Native T1 mapping for Risk Stratification in Pulmonary Arterial Hypertension

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - CA DPS

Participants
Yue Wang, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the value of cardiac magnetic resonance (CMR) native T1 mapping for risk stratification in patients with pulmonary arterial hypertension (PAH)

METHODS AND MATERIALS

A total of 59 patients with diagnosed PAH who received CMR examination at our institution was retrospectively included. Patients were subdivided into two groups based on the clinically-assessed risk status: low-risk group and intermediate- or high-risk group. Thirty healthy individuals were included as normal controls. Anterior right ventricular insertion point (ARVIP), interventricular septum (IVS) and inferior right ventricular insertion point (IRVIP) native T1 times were evaluated manually. CMR-based cardiac functional parameters such as ejection fraction (EF), end diastolic ventricular volume index (EDV-index) and end systolic ventricular volume index (ESV index) of left ventricular (LV) and right ventricular (RF) were also measured and recorded. Native T1 times at ARVIP, IVS and IRVIP as well as CMR-based functional parameters were compared between groups. Receiver operating characteristics (ROC) curves and area under the curves (AUC) were calculated.

RESULTS

ARVIP, IVS and IRVIP native T1 times were significantly higher in PAH patients as compared with normal controls. Patients in intermediate- or high-risk status showed higher native T1 times in ARVIP and IRVIP. The AUC for ARVIP and IRVIP native T1 times for discriminating patients with different risk status were 0.741 and 0.702, respectively. LV EDV index, LV ESV index, RVEF, RV EDV index, RV ESV index were also obviously differed between patients with different risk status,with AUC ranged between 0.701 to 0.801. The combining model which integrated ARVIP and IRVIP native T1 times as well as CMR-based cardiac functional parameters showed an AUC of 0.846 for discriminating patients with intermediate- or high-risk status.

CONCLUSION

s ARVIP, and IRVIP native T1 times hold promise for discriminating PAH patients with different risk status.

CLINICAL RELEVANCE/APPLICATION

The combining model integrating native T1 times and CMR-based cardiac functional parameters may supplement the evaluation of the risk status in PAH patients.

T5A-SPCH-1 Magnitude and Characteristics of Missed Lung Nodules during COVID-19 Pandemic

Participants
Arpit Kothari, Indore, India (*Presenter*) Research Consultant, Qure.ai;Research Consultant, Subtle Medical, Inc;Research Consultant, Lunit Inc;Research Consultant, FUJIFILM Holdings Corporation;Research Consultant, Level42AI;Director, Kothari Diagnostics Pvt Ltd;CEO, Kothari Diagnostics Pvt Ltd

PURPOSE

Lung cancer is the leading cause of cancer deaths. CT scans can identify cancer in early stages. During Coronavirus Pandemic, lot of CT scans were taken. It is possible that the already strained radiologists were only looking to either confirm or rule out COVID and missed nodules. The purpose of this study is to estimate the magnitude of such misses and the asses the role of a Deep Learning (DL) software in aiding the detection of nodules.

METHODS AND MATERIALS

2432 CT scans taken during the second and third wave of COVID from two radiology diagnosis chains were processed by qCT Lung-a DL software for nodules. The radiologist report of the scan which the DL flagged were reviewed for nodules. Cases for which nodules not mentioned were re-read by an independent radiologist with qCT assistance. This radiologist was asked to either confirm or refute the flagged abnormality as nodule. If a nodule is confirmed, the radiologist rated its malignancy potential in a 5-point positive directed Likert scale. The radiologist gave an alternative finding for false flag.

RESULTS

The DL system flagged 653 scans as having nodules. Of this 80 were identified in radiologist report. The remaining 573 scans were re-read, 111 (19.4%) were confirmed as having nodules. 44 of these scans had more than one nodule flagged. The median of the longest diameter was 14 mm (range: 6 to 48 mm) and 62.8% of them were solid nodules. The distribution of localization of the nodule was similar between upper and lower lobes. Common cause of false flags was ground-glass opacity with consolidation (94.8%) followed peripheral vessel (1.9%). 92 of the 111 scans were given a malignancy rating of 1 or 2 (non-malignant or probably non-malignant). 17 were given a rating of 3 (could be malignant or non-malignant) and 2 were rated as probably malignant. Spiculation was more likely in DLs output for those with higher rating..

CONCLUSION

s 111 scans with nodules were not reported. Looking at the independent radiologist malignancy rating, it is possible for some cases the initial radiologist did not report it due perceived risk. 19 of these cases would have been eligible for follow-up investigations. The presence of ground-glass opacity in COVID can explain some of the errors of this DL.

CLINICAL RELEVANCE/APPLICATION

Radiologist report only the findings which are relevant to the radiology request form and their perceived risk of incidental findings. A conservative approach would be to report all findings irrespective of the perceived risk so that the treating physician can take appropriate action.

T5A-SPCH-10 Acceptability of NLST Image Data for Modern Quantitative Algorithm Development

Participants
Artit Jirapatnakul, PhD, New York, NY (*Presenter*) Nothing to Disclose

PURPOSE

To assess the applicability of CT images from the National Lung Screening Trial (NLST) to current lung cancer screening recommendations

METHODS AND MATERIALS

The NLST provides a public database of all CT images performed during the trial. With 73,118 studies and 203,099 image series, this is the largest publicly available database of chest CT images and is being used for the development and testing of quantitative algorithms, such as lung nodule measurement, detection, and diagnosis. However, the NLST screened participants between 2002 and 2006; these CT scans are now 15-20 years old. Minimum quality guidelines for scan acquisition and reconstruction have been developed by the Quantitative Imaging Biomarker Alliance (QIBA) of the Radiological Society of North America for tasks related to

quantitative measurements in the context of LDCT. We downloaded all available NLST images from the Cancer Imaging Archive, excluding localizer or topogram images, or incomplete series. We analyzed DICOM header information of the remaining series to extract the scanner and protocol information. As a measure of modern quantitative image standards, we determined the proportion of scans meeting protocol recommendations of QIBA Small Nodule Committee.

RESULTS

70486 CT image series containing <20 images were excluded. Of the remaining 132613 CT series, 10321 (7.8%) were acquired with a slice thickness (ST) <= 1.25 mm, the current QIBA Small Lung Nodule recommendation. Of this group, the 10 most frequent combinations account for 97.8% (10098/10321) of the CT series. After eliminating scans with edge-enhancing kernels (4185) and from scanners in which spatial warping has been identified (4649), only 1487 meet QIBA eligibility criteria. There were 4447 CT images series for NLST participants with lung cancer, of which only 399 CT image series in 139 participants were acquired with a slice thickness <= 1.25 mm.

CONCLUSION

s With advances in image processing, quantitation, and artificial intelligence, there is a need for high quality image databases for software development for automation and standardization of screening CT image analysis. The NLST CT images have been made openly available for this purpose, but over 95% of the images do not meet the image acquisition and reconstruction quality standards required for optimizing algorithm performance. New databases and distribution approaches are necessary for progression of software development; various organizations are now in the process of developing newer databases that will be made available.

CLINICAL RELEVANCE/APPLICATION

Databases of modern, clinically relevant images are critical for continued development of AI algorithms; care must be taken in the interpretation of results of studies using outdated CT scans.

T5A-SPCH-2 Transfer-learning deep radiomics and binary dilation for predicting PET-positive thoracic lymph nodes from contrast enhanced computed tomography in lung cancer.

Participants
Fabian Laqua, (*Presenter*) Research Grant, Koninklijke Philips NV

PURPOSE

Positron emission tomography (PET) is currently the non-invasive reference standard for staging of lymph nodes in lung cancer. However, due to high costs, limited availability, and additional radiation exposure, not all patients can undergo this diagnostic procedure. Purpose of this study was to build a classification model, that predicts the PET result from traditional contrast-enhanced computed tomography (CT) and to test different feature extraction strategies.

METHODS AND MATERIALS

All thoracic lymph nodes of consecutive lung cancer patients in a single center, that underwent routine contrast-enhanced thoracic CT and subsequent PET for staging between 2014 and 2019, were segmented. Penalized ('elastic') logistic regression models were trained to predict whether a lymph node shows 18-fluorodeoxyglucose uptake in the subsequent PET-scan. Radiomics features were extracted i) as traditional hand-crafted radiomics features from the segmented lymph nodes, ii) from segmentations dilated by varying radiuses around the original segmentation, iii) by applying the first k layers of a EfficientNet-CNN pretrained on ImageNet database on the segmented lymph nodes and iv) a hybrid approach that combines the features of iii) with traditional shape and first-order features.

RESULTS

In total, 2734 lymph nodes [555 (20.3 %) PET-positive] from 100 patients [49% female, median age 67 (IQR: 60-71)] with lung cancer (60% adeno carcinoma, 21% plate epithelial carcinoma, 8% small cell lung cancer) were included in this study. The Area-under-the-receiver-operating-characteristics (AUC) was slightly but significantly [z=4.2, p<0.001; 0.881 (95% CI 0.873-0.889) vs. 0.873 (0.865-0.882)] netter for the features extracted from segmentations dilated by 1 pixel compared to the original segmentation. The combination of the features of iii) and shape and first-order features yielded best results [AUC 0.890 (0.881 - 0.902)], that were significantly better than i) traditional (z=3.8, p=0.02) and iii) transfer-learning CNN features (z=10.4, p<0.001).

CONCLUSION

s Minor binary dilatation of lymph node segmentation improves machine learning classification of lymph nodes. Both, traditional radiomics features and transfer-learning deep radiomics features provide relevant and complimentary information for classification of lymph nodes in lung cancer staging.

CLINICAL RELEVANCE/APPLICATION

Prediction of thoracic nodal status using radiomics and machine learning techniques on standard contrast-enhanced CT provides very good classification performance compared to PET. Even in absence of available PET, exploitation of the available information by the approach presented in this study may be a good alternative for non-invasive nodal staging in lung cancer.

T5A-SPCH-3 Clinicopathological and CT Features of Tumor Spread Through Air Space in Invasive Lung Adenocarcinoma

Participants
Lili Qin, (*Presenter*) Nothing to Disclose

PURPOSE

Tumor spread through air spaces (STAS) has recently been reported as a novel invasive pattern in lung adenocarcinoma, the aim of this study was to investigate the clinialpathological and radiological features in invasive lung adenocarcinoma with tumor spread through air space(STAS).

METHODS AND MATERIALS

Data of 503 invasive lung adenocarcinoma who underwent operation between January1,2015 and December 31,2021 were collected. The correlations of STAS presence and clinicopathological and radiological characteristics were analyzed. Statistical

analysis was performed using SPSS 22.0.

RESULTS

Among the 503 patients with invasive adenocarcinoma, 247(47.9%) were positive for STAS and 262(52.1%) were negative for STAS. STAS were more common in papillary,micropapillary and solid tumors(P<0.01).STAS was associated with advanced pN(P<0.001) and pTNM (P<0.001)stage,more lymph node metastases(P<0.01),more pleural invasion(P<0.01),more neurovascular invasion(P=0.025). The maximum diameter(P<0.01),the maximum diameters of the solid component(P<0.01),the consolidation/tumor ratio(CTR,P<0.01) was significantly larger in STAS-positive than in STAS-negative adenocarcinoma.Other common CT features of adenocarcinomas,ie, lobulation(P<0.01),spiculation(P<0.01), vacuole(P<0.01),air bronchogram(P=0.020),vascular convergence(P<0.01), pleural indentation(P<0.01) were shown to be significantly associated with STAS. In a multivariable analysis, maximum diameter of solid component was an independent predictor of STAS (odds ratio, 2.505; 95% confidence interval: 1.886, 3.329) and a cut-off value of 1.18cm showed a discriminatory power with a sensitivity of 73.9% and a specificity of 69.1%.

CONCLUSION

s STAS was significantly correlated with several invasive clinicopathological and radiological characteristics,the maximum diameter was an independent predictor of STAS.These results will prove helpful in identifying STAS-positive adenocarcinoma by CT before surgical resection.

CLINICAL RELEVANCE/APPLICATION

As a newly named and pathologically diagnosed tumour invasion pattern in lung adenocarcinoma, STAS not only has an impact on the determination of the degree of invasion on its pathological tissues, but also has a significant impact on the selection and assessment of surgical treatment modalities for lung adenocarcinoma patients and the intervention of patient prognosis. The results of this study show that the largest diameter of solid component in lung adenocarcinoma lesions on CT and CRT are important signs for predicting STAS, and other common signs of malignancies also have some predictive value.

T5A-SPCH-4 Progression of Bronchiectasis during Five or More years Follow-up in Low-Dose CT Screening for Lung Cancer

Participants
Qiang Cai, PhD, MD, New York, NY (*Presenter*) Nothing to Disclose

PURPOSE

To assess the frequency of development of bronchiectasis among participants without previous bronchiectasis as well as the progression of bronchiectasis in participants with bronchiectasis on the baseline LDCT for five or more years after enrollment in a screening program.

METHODS AND MATERIALS

Changes in the ELCAP Bronchiectasis Score between baseline and the last LDCT were reviewed for smokers aged 40-90 years who had five or more years of follow-up screening after the baseline LDCT in the Mount Sinai ELCAP screening study between 2010 and 2019. MANOVA was used to assess the change in the four ELCAP Bronchiectasis component scores (severity and extent of bronchial dilatation, bronchial wall thickening (BWT), and mucoid impaction (MI)) as well as the total score.

RESULTS

Of the 2191 participants at baseline, 534 participants had five or more years of follow-up LDCTs. Among the 534 participants, baseline LDCT showed 408 (76.4%) without bronchiectasis while it was present in 126 (23.6%). Development of bronchiectasis was found in 9 (2.2%) of the 408 participants without bronchiectasis on baseline LDCT, with subsequent ELCAP Bronchiectasis Scores ranging from 2 to 20. Progression was present in 25 (19.8%) of the 126 with bronchiectasis on baseline LDCT and the increase in the ELCAP Bronchiectasis Scores ranged from 1 to 8. Progression of severity in bronchial dilatation was associated with increasing age (p=0.006) and self-reported stroke (p=0.01) at baseline enrollment, as well as progression in the extent of bronchial dilatation (p=0.01), BWT (p=0.04) and MI (p<.0001). Progression of extent was associated with increasing age (p=0.03) and higher MI score (p=.0001) on baseline CT. Progression of BWT was associated with increasing pack-years of smoking (p=0.0007), self-reported COPD (p=0.047), and lower BWT (p=0.03) on baseline LDCT. An increase in MI was a significant predictor of increasing age, increase in severity and extent of bronchial dilatation (p=.001).

CONCLUSION

s Awareness of bronchiectasis in LDCT screening for lung cancer is necessary as one-fifth of participants during long-term follow-up had progression compared to those without bronchiectasis on initial LDCT screening.

CLINICAL RELEVANCE/APPLICATION
