The ELCAP Bronchiectasis Score provides a useful assessment of the progression of bronchiectasis. Reporting of bronchiectasis findings and continued assessment over the period of participation in the LDCT screening allows for documentation of change for future assessment of the benefit of early treatment.

T5A-SPCH-5 CT on Lung Cancer Screening is Useful for Adjuvant Comorbidity Diagnosis in Developing Countries

Participants
Bruno Hochhegger, PhD, Gainesville, FL (*Presenter*) Nothing to Disclose

PURPOSE

To analyze and quantify the prevalence of comorbidities derived from chest computed tomography (CT) of patients undergoing lung cancer screening in a developing country.

METHODS AND MATERIALS

For this retrospective study, low-dose CT scans (n=775) from patients undergoing LCS in a tertiary hospital between 2016 and 2020 were examined. A group of controls with similar age and gender but undergoing chest CT for other indications was also used for comparison (n=370). CT images were evaluated by experienced radiologists regarding coronary artery calcium (CAC) score, skeletal muscle area (SMA), interstitial lung abnormalities (ILA), presence of emphysema, osteoporosis, and hepatic steatosis using

a dedicated software. Prevalence of abnormalities and clinical characteristics of the groups were compared using t-test and chi-squared tests. Interclass correlation coefficient (ICCs) and kappa coefficients for interobserver agreement were also calculated. The level of significance was set at 0.05.

RESULTS

One or more comorbidities were identified on imaging in 86.6% of patients undergoing LCS and in 40% of the controls. The most prevalent comorbidity was osteoporosis, present in 44.2% of patients and 24.8% of controls. CAC was identified in 41.9% of cases (vs. 23.7% of controls), emphysema in 66.3% (vs. 8.9% of controls), and osteoporosis in 44.2% (vs. 24.8% of controls). Compared to information retrieved from the medical records, CAC, emphysema, and osteoporosis were newly diagnosed in 25%, 7%, and 46% of the LCS patients, respectively. Sarcopenia was identified on 9.9% of LCS patients (vs. 3.5% controls) and hepatic steatosis in 40.7% (vs. 15.9% of controls). The kappa coefficient for CAC was 0.906, while ICC for measurements in the liver, spleen, and bone density were 0.88, 0.93, and 0.96, respectively.

CONCLUSION

s Data derived from the CT of patients undergoing LCS may lead to the identification of potentially undiagnosed comorbidities in more than 80% of patients.

CLINICAL RELEVANCE/APPLICATION

Smoking-related comorbidities (CAC, emphysema, ILA, sarcopenia, osteoporosis, and hepatic steatosis) are highly prevalent in patients undergoing low-dose CT for LCS. Integrated assessment of the CT in LCS for features other than nodule screening may lead to the identification of these comorbidities early and increase the chances of a favorable outcome for patients.

T5A-SPCH-6 Is It Time to Replace Low-dose CT with Ultra-low-dose CT in Lung Cancer Screening?

Participants
Matheus Zanon, MD, MSc, Porto Alegre, Brazil (*Presenter*) Nothing to Disclose

PURPOSE

To assess the agreement between ultra-low-dose CT (ULDCT) and low-dose CT (LDCT) in the evaluation of pulmonary findings in smokers undergoing lung cancer screening (LCS).

METHODS AND MATERIALS

For one month, we prospectively included eligible patients for LCS that underwent both chest ULDCT and LDCT for one month. Eligibility for LCS followed the 2021 guidelines by the United States Preventive Services Task Force. Patients should be adults, aged 50 to 80 years, with a 20 pack-year smoking history, currently smoking or formers smokers that had quit within the past 15 years. Images were acquired in a 64-detector CT scanner as follows: LDCT: 100kVp/25mAs; ULDCT: 80kVp/15mAs. Two independent senior radiologists evaluated the presence of consolidation, ground-glass opacification (GGO), septal thickening, pulmonary nodule, bronchial wall thickening (BWT), pleural effusion, emphysema, bronchiectasis, and atelectasis.

RESULTS

From the 265 patients enrolled, 58 (21.9%) had abnormal CT scans. Mean effective radiation doses (ERD) for LDCT and ULDCT were 1.21±0.34 mSv and 0.39±0.15 mSv, respectively, representing a reduction in the mean ERD of 67.8%. Agreement was almost perfect for emphysema (?=0.92) and nodules (?=0.91). BWT, bronchiectasis, and atelectasis presented a strong agreement (?,0.80-0.90), and consolidation, septal thickening, and pleural effusion presented substantial agreement (?,0.60-0.80). Conversely, GGO presented a poor agreement (?=0.37).

CONCLUSION

s Although the mean ERD reduced dropped to almost a third from LDCT to ULDCT, inter-reader agreement was poor for significant findings, such as consolidation and GGO, that may represent other types of lung cancer (e.g., lepidic adenocarcinoma).

CLINICAL RELEVANCE/APPLICATION

Despite the exciting agreement for some pulmonary findings, these results question whether using an ULDCT protocol for LCS would be adequate, as many subsolid or GGO lesions could be missed. Also, despite the significant reduction in the RED, it is questionable whether there is a patient benefit from going to 1.2 to 0.39 mSv.

T5A-SPCH-7 Screening for the Screeners: Our Institutional Experience with Double Reading of CT Lung Cancer Screening

Participants
Padma Manapragada, MD, MBBS, Birmingham, AL (*Presenter*) Nothing to Disclose

PURPOSE

Our institution participated in the NLST and continued to offer screening. Post approval by the USPSTF and the CMS, patient volume and the number of readers increased. With faculty turnover, the participating readers also kept changing. This study evaluates if double reading would increase adherence to screening requirements, consistent Lung RADS interpretation and unify follow up recommendations.

METHODS AND MATERIALS

The local IRB approved this retrospective study and written informed consent was waived. All lung cancer screening [LCS] cases from 2015 to through 2021 [2347 cases] were evaluated. Patients met the 2015 CMS criteria for inclusion: age 55-77, 30 pack years, current smoker or less than 15 years since quitting. A separate LCS PACS reading list was established. In rotation two radiologists were assigned to read the list each day. The first reader dictated the templated report and placed it in draft status. The second reader reviewed the study and the draft report, made any changes needed, signed the report, recorded if there was a discrepancy and, if present, the type of discrepancy. An Excel sheet recorded patient screened, Lung-RADS score, yes/no discrepancy, and category of discrepancy. Retrospectively the discrepancies were graded as: Significant-1: Changed L-RADS status or coronary artery calcification [CAC] score, other cancers, or major vascular aneurysm. Equivocal-2: Additional nodules but no L-RADS score change, other lung disease . Incidental-3: Non-cancer potentially significant findings (cirrhosis, renal stones,

Pulmonary Artery HTN, AVM).

RESULTS

The majority of the 190 discrepancies were significant-109/190. Equivocal cases were 48/109 and incidental cases were 28/109. 5 cases were classified in more than one category. In eight cases the LR category changed from negative [1, 2] to positive [3.4]. The percentage of discrepancies initially increased as the number of cases increased, a new reader was added or new L-RADS introduced then decreased.

CONCLUSION

s Double reading improved consistency in evaluation of LCS CTs and the application of LungRADS. This provides more uniform patient care over time and when patient care is escalated to biopsy or treatment.

CLINICAL RELEVANCE/APPLICATION

Double reading in evaluation of LCS CTs provides consistent high quality reports and consistent application of LungRADS. This provides uniform high quality patient care over time and when patient care is escalated to biopsy or treatment.

T5A-SPCH-8 Risk of Exacerbations in Participants with Bronchiectasis in a Program of Low-dose CT Screening

Participants
Natthaya Triphuridet, MD, PhD, New York, NY (*Presenter*) Nothing to Disclose

PURPOSE

To predict future exacerbations during the two years following the initial LDCT in screening participants with bronchiectasis based on the LDCT findings including emphysema, and self-reported co-morbidities.

METHODS AND MATERIALS

Electronic medical record (EMR) review of prospectively enrolled participants who smoked in Early Lung and Cardiac Action Program, a LDCT screening program from 2010 to 2019. EMR were reviewed to identify participants with respiratory symptoms and exacerbations during two years before and two years after initial LDCT screening. Uni-and multivariable regression analysis were performed to identify predictors of future exacerbations using LDCT findings and self-reported co-morbidities at the time of screening.

RESULTS

Of 2191 participants, 504(23%) had bronchiectasis and EMR had available records on 300 (median age,69 years;154(51%) women). Emphysema was identified on LDCT in 152(51%). Exacerbations were identified during two years after LDCT screening in 84(28%) participants. Participants with emphysema, compared to those without emphysema, had significantly higher median ELCAP Bronchiectasis Score (13.0 vs. 11.5, p=.02), higher frequency of respiratory symptoms [97(64%) vs. 75(51%), p=.02] and exacerbations [49(32%) vs. 35(24%), p=.10]. Multivariable analyses showed that the ELCAP Bronchiectasis Score (OR=1.12,p<.001), self-reported COPD (OR=2.69,p<.001) and asthma (OR=2.47,p=.006) were independent predictors of exacerbations, but not emphysema. Considering ELCAP Bronchiectasis component scales instead of the total score, severity of bronchial dilatation (OR=1.30,p=.001) and bronchial wall thickening (OR=1.29,p=.004) were significant predictors. When including prior respiratory symptoms and exacerbations during two years prior to screening as predictors, ELCAP Bronchiectasis Score remained as an independent predictor of future exacerbations.

CONCLUSION

s High ELCAP Bronchiectasis Score, self-reported COPD and asthma are independent predictors of exacerbations. This type of information is needed to develop preventive management protocols.

CLINICAL RELEVANCE/APPLICATION

Among 300 participants with bronchiectasis and available electronic medical records, 84(28.0%) had exacerbations during two years following initial LDCT screening. Significant predictors of future exacerbations were: ELCAP Bronchiectasis Score [OR=1.12, p<.001], self-reported COPD [OR=2.69, p<.001] and asthma [OR=2.47, p=0.006].

T5A-SPCH-9 Computational Risk Stratification: A Deep Learning Approach to Predicting a Major Lung Biopsy Complication

Participants
Alexander Lindqwister, BS,MS, Lebanon, NH (*Presenter*) Nothing to Disclose

PURPOSE

CT-guided core needle biopsies (CT-CNB) are a major component of the diagnostic work-up of lung lesions. The most common associated risk is iatrogenic pneumothorax (PTX) which may require tube thoracostomy and subsequent hospitalization. The ability to predict PTX requiring tube thoracostomy in the pre-procedural setting would allow radiologists to make more individualized recommendations in patient management, improve the informed consent process, and augment care delivery through risk stratification.

METHODS AND MATERIALS

A retrospective study of 502 patients who underwent CT-CNB of the lung was performed. Procedural, patient demographic, and outcomes data were collected and descriptive statistics were performed to determine significant distinguishing features between patients who required chest tubes and those who did not. Six parameters (age, sex, emphysema, projected length of needle path, greatest dimension of lung lesion, lung lobe) encoded through 12 features were utilized by a deep neural network to create a predictive model. Exhaustive 5-fold cross validation in addition to an external dataset consisting of 449 patients was used to validate the model.

RESULTS

Deep learning models were highly successful in predicting PTX requiring tube thoracostomy, with a receiver operating characteristic

area under the curve (ROC-AUC) of 0.961 [+/- 0.033] averaged across 2,000 simulations. The model had consistent performance with the external dataset, achieving an ROC-AUC of 0.886 [+/- 0.059]. Testing metrics revealed a sensitivity of 0.879, specificity of 0.924, and a negative predictive value of 0.986 after adjusting for incidence of chest tube placement.

CONCLUSION

s The strong performance of deep learning models to predict chest tube placement demonstrates the possible clinical utility of machine learning in predicting post procedural complications in this setting. The model performed well on data collected from two different patient cohorts, which suggests generalizability and the potential for broad application.

CLINICAL RELEVANCE/APPLICATION

Neural networks and other data-driven approaches may be useful in predicting adverse post-procedural complications in the setting of lung CT-CNB.

Magnitude and Characteristics of Missed Lung Nodules during COVID-19 Pandemic

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - CH DPS

Participants
Arpit Kothari, Indore, India (*Presenter*) Research Consultant, Qure.ai;Research Consultant, Subtle Medical, Inc;Research Consultant, Lunit Inc;Research Consultant, FUJIFILM Holdings Corporation;Research Consultant, Level42AI;Director, Kothari Diagnostics Pvt Ltd;CEO, Kothari Diagnostics Pvt Ltd

PURPOSE

Lung cancer is the leading cause of cancer deaths. CT scans can identify cancer in early stages. During Coronavirus Pandemic, lot of CT scans were taken. It is possible that the already strained radiologists were only looking to either confirm or rule out COVID and missed nodules. The purpose of this study is to estimate the magnitude of such misses and the asses the role of a Deep Learning (DL) software in aiding the detection of nodules.

METHODS AND MATERIALS

2432 CT scans taken during the second and third wave of COVID from two radiology diagnosis chains were processed by qCT Lung-a DL software for nodules. The radiologist report of the scan which the DL flagged were reviewed for nodules. Cases for which nodules not mentioned were re-read by an independent radiologist with qCT assistance. This radiologist was asked to either confirm or refute the flagged abnormality as nodule. If a nodule is confirmed, the radiologist rated its malignancy potential in a 5-point positive directed Likert scale. The radiologist gave an alternative finding for false flag.

RESULTS

The DL system flagged 653 scans as having nodules. Of this 80 were identified in radiologist report. The remaining 573 scans were re-read, 111 (19.4%) were confirmed as having nodules. 44 of these scans had more than one nodule flagged. The median of the longest diameter was 14 mm (range: 6 to 48 mm) and 62.8% of them were solid nodules. The distribution of localization of the nodule was similar between upper and lower lobes. Common cause of false flags was ground-glass opacity with consolidation (94.8%) followed peripheral vessel (1.9%). 92 of the 111 scans were given a malignancy rating of 1 or 2 (non-malignant or probably non-malignant). 17 were given a rating of 3 (could be malignant or non-malignant) and 2 were rated as probably malignant. Spiculation was more likely in DLs output for those with higher rating..

CONCLUSION

s 111 scans with nodules were not reported. Looking at the independent radiologist malignancy rating, it is possible for some cases the initial radiologist did not report it due perceived risk. 19 of these cases would have been eligible for follow-up investigations. The presence of ground-glass opacity in COVID can explain some of the errors of this DL.

CLINICAL RELEVANCE/APPLICATION

Radiologist report only the findings which are relevant to the radiology request form and their perceived risk of incidental findings. A conservative approach would be to report all findings irrespective of the perceived risk so that the treating physician can take appropriate action.

Acceptability of NLST Image Data for Modern Quantitative Algorithm Development

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - CH DPS

Participants
Artit Jirapatnakul, PhD, New York, NY (*Presenter*) Nothing to Disclose

PURPOSE

To assess the applicability of CT images from the National Lung Screening Trial (NLST) to current lung cancer screening recommendations

METHODS AND MATERIALS

The NLST provides a public database of all CT images performed during the trial. With 73,118 studies and 203,099 image series, this is the largest publicly available database of chest CT images and is being used for the development and testing of quantitative algorithms, such as lung nodule measurement, detection, and diagnosis. However, the NLST screened participants between 2002 and 2006; these CT scans are now 15-20 years old. Minimum quality guidelines for scan acquisition and reconstruction have been developed by the Quantitative Imaging Biomarker Alliance (QIBA) of the Radiological Society of North America for tasks related to quantitative measurements in the context of LDCT. We downloaded all available NLST images from the Cancer Imaging Archive, excluding localizer or topogram images, or incomplete series. We analyzed DICOM header information of the remaining series to extract the scanner and protocol information. As a measure of modern quantitative image standards, we determined the proportion of scans meeting protocol recommendations of QIBA Small Nodule Committee.

RESULTS

70486 CT image series containing <20 images were excluded. Of the remaining 132613 CT series, 10321 (7.8%) were acquired with a slice thickness (ST) <= 1.25 mm, the current QIBA Small Lung Nodule recommendation. Of this group, the 10 most frequent combinations account for 97.8% (10098/10321) of the CT series. After eliminating scans with edge-enhancing kernels (4185) and from scanners in which spatial warping has been identified (4649), only 1487 meet QIBA eligibility criteria. There were 4447 CT images series for NLST participants with lung cancer, of which only 399 CT image series in 139 participants were acquired with a slice thickness <= 1.25 mm.

CONCLUSION

s With advances in image processing, quantitation, and artificial intelligence, there is a need for high quality image databases for software development for automation and standardization of screening CT image analysis. The NLST CT images have been made openly available for this purpose, but over 95% of the images do not meet the image acquisition and reconstruction quality standards required for optimizing algorithm performance. New databases and distribution approaches are necessary for progression of software development; various organizations are now in the process of developing newer databases that will be made available.

CLINICAL RELEVANCE/APPLICATION

Databases of modern, clinically relevant images are critical for continued development of AI algorithms; care must be taken in the interpretation of results of studies using outdated CT scans.

T5A-SPCH-2

Transfer-learning deep radiomics and binary dilation for predicting PET-positive thoracic lymph nodes from contrast enhanced computed tomography in lung cancer.

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - CH DPS

Participants
Fabian Laqua, (*Presenter*) Research Grant, Koninklijke Philips NV

PURPOSE

Positron emission tomography (PET) is currently the non-invasive reference standard for staging of lymph nodes in lung cancer. However, due to high costs, limited availability, and additional radiation exposure, not all patients can undergo this diagnostic procedure. Purpose of this study was to build a classification model, that predicts the PET result from traditional contrast-enhanced computed tomography (CT) and to test different feature extraction strategies.

METHODS AND MATERIALS

All thoracic lymph nodes of consecutive lung cancer patients in a single center, that underwent routine contrast-enhanced thoracic CT and subsequent PET for staging between 2014 and 2019, were segmented. Penalized ('elastic') logistic regression models were trained to predict whether a lymph node shows 18-fluorodeoxyglucose uptake in the subsequent PET-scan. Radiomics features were extracted i) as traditional hand-crafted radiomics features from the segmented lymph nodes, ii) from segmentations dilated by varying radiuses around the original segmentation, iii) by applying the first k layers of a EfficientNet-CNN pretrained on ImageNet database on the segmented lymph nodes and iv) a hybrid approach that combines the features of iii) with traditional shape and first-order features.

RESULTS

In total, 2734 lymph nodes [555 (20.3 %) PET-positive] from 100 patients [49% female, median age 67 (IQR: 60-71)] with lung cancer (60% adeno carcinoma, 21% plate epithelial carcinoma, 8% small cell lung cancer) were included in this study. The Area-under-the-receiver-operating-characteristics (AUC) was slightly but significantly [$z=4.2$, $p<0.001$; 0.881 (95% CI 0.873-0.889) vs. 0.873 (0.865-0.882)] netter for the features extracted from segmentations dilated by 1 pixel compared to the original segmentation. The combination of the features of iii) and shape and first-order features yielded best results [AUC 0.890 (0.881 - 0.902)], that were significantly better than i) traditional ($z=3.8$, $p=0.02$) and iii) transfer-learning CNN features ($z=10.4$, $p<0.001$).

CONCLUSION

s Minor binary dilatation of lymph node segmentation improves machine learning classification of lymph nodes. Both, traditional radiomics features and transfer-learning deep radiomics features provide relevant and complimentary information for classification of lymph nodes in lung cancer staging.

CLINICAL RELEVANCE/APPLICATION

Prediction of thoracic nodal status using radiomics and machine learning techniques on standard contrast-enhanced CT provides very good classification performance compared to PET. Even in absence of available PET, exploitation of the available information by the approach presented in this study may be a good alternative for non-invasive nodal staging in lung cancer.

T5A-SPCH-3

Clinicopathological and CT Features of Tumor Spread Through Air Space in Invasive Lung Adenocarcinoma

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - CH DPS

Participants
Lili Qin, (*Presenter*) Nothing to Disclose

PURPOSE

Tumor spread through air spaces (STAS) has recently been reported as a novel invasive pattern in lung adenocarcinoma, the aim of this study was to investigate the clinialpathological and radiological features in invasive lung adenocarcinoma with tumor spread through air space(STAS).

METHODS AND MATERIALS

Data of 503 invasive lung adenocarcinoma who underwent operation between January1,2015 and December 31,2021 were collected. The correlations of STAS presence and clinicopathological and radiological characteristics were analyzed. Statistical analysis was performed using SPSS 22.0.

RESULTS

Among the 503 patients with invasive adenocarcinoma, 247(47.9%) were positive for STAS and 262(52.1%) were negative for STAS. STAS were more common in papillary,micropapillary and solid tumors(P<0.01).STAS was associated with advanced pN(P<0.001) and pTNM (P<0.001)stage,more lymph node metastases(P<0.01),more pleural invasion(P<0.01),more neurovascular invasion(P=0.025). The maximum diameter(P<0.01),the maximum diameters of the solid component(P<0.01),the consolidation/tumor ratio(CTR,P<0.01) was significantly larger in STAS-positive than in STAS-negative adenocarcinoma.Other common CT features of adenocarcinomas,ie, lobulation(P<0.01),spiculation(P<0.01), vacuole(P<0.01),air bronchogram(P=0.020),vascular convergence(P<0.01), pleural indentation(P<0.01) were shown to be significantly associated with STAS. In a multivariable analysis, maximum diameter of solid component was an independent predictor of STAS (odds ratio, 2.505; 95% confidence interval: 1.886, 3.329) and a cut-off value of 1.18cm showed a discriminatory power with a sensitivity of 73.9% and a specificity of 69.1%.

CONCLUSION

s STAS was significantly correlated with several invasive clinicopathological and radiological characteristics,the maximum diameter was an independent predictor of STAS.These results will prove helpful in identifying STAS-positive adenocarcinoma by CT before surgical resection.

CLINICAL RELEVANCE/APPLICATION

As a newly named and pathologically diagnosed tumour invasion pattern in lung adenocarcinoma, STAS not only has an impact on the determination of the degree of invasion on its pathological tissues, but also has a significant impact on the selection and assessment of surgical treatment modalities for lung adenocarcinoma patients and the intervention of patient prognosis. The results of this study show that the largest diameter of solid component in lung adenocarcinoma lesions on CT and CRT are important signs for predicting STAS, and other common signs of malignancies also have some predictive value.

T5A-SPCH-4

Progression of Bronchiectasis during Five or More years Follow-up in Low-Dose CT Screening for Lung Cancer

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - CH DPS

Participants
Qiang Cai, PhD, MD, New York, NY (*Presenter*) Nothing to Disclose

PURPOSE

To assess the frequency of development of bronchiectasis among participants without previous bronchiectasis as well as the progression of bronchiectasis in participants with bronchiectasis on the baseline LDCT for five or more years after enrollment in a screening program.

METHODS AND MATERIALS

Changes in the ELCAP Bronchiectasis Score between baseline and the last LDCT were reviewed for smokers aged 40-90 years who had five or more years of follow-up screening after the baseline LDCT in the Mount Sinai ELCAP screening study between 2010 and 2019. MANOVA was used to assess the change in the four ELCAP Bronchiectasis component scores (severity and extent of bronchial dilatation, bronchial wall thickening (BWT), and mucoid impaction (MI)) as well as the total score.

RESULTS

Of the 2191 participants at baseline, 534 participants had five or more years of follow-up LDCTs. Among the 534 participants, baseline LDCT showed 408 (76.4%) without bronchiectasis while it was present in 126 (23.6%). Development of bronchiectasis was found in 9 (2.2%) of the 408 participants without bronchiectasis on baseline LDCT, with subsequent ELCAP Bronchiectasis Scores ranging from 2 to 20. Progression was present in 25 (19.8%) of the 126 with bronchiectasis on baseline LDCT and the increase in the ELCAP Bronchiectasis Scores ranged from 1 to 8. Progression of severity in bronchial dilatation was associated with increasing age (p=0.006) and self-reported stroke (p=0.01) at baseline enrollment, as well as progression in the extent of bronchial dilatation (p=0.01), BWT (p=0.04) and MI (p<.0001). Progression of extent was associated with increasing age (p=0.03) and higher MI score (p=.0001) on baseline CT. Progression of BWT was associated with increasing pack-years of smoking (p=0.0007), self-reported COPD (p=0.047), and lower BWT (p=0.03) on baseline LDCT. An increase in MI was a significant predictor of increasing age, increase in severity and extent of bronchial dilatation (p=.001).

CONCLUSION

s Awareness of bronchiectasis in LDCT screening for lung cancer is necessary as one-fifth of participants during long-term follow-up had progression compared to those without bronchiectasis on initial LDCT screening.

CLINICAL RELEVANCE/APPLICATION

The ELCAP Bronchiectasis Score provides a useful assessment of the progression of bronchiectasis. Reporting of bronchiectasis findings and continued assessment over the period of participation in the LDCT screening allows for documentation of change for future assessment of the benefit of early treatment.

T5A-SPCH-5

CT on Lung Cancer Screening is Useful for Adjuvant Comorbidity Diagnosis in Developing Countries

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - CH DPS

Participants
Bruno Hochhegger, PhD, Gainesville, FL (*Presenter*) Nothing to Disclose

PURPOSE

To analyze and quantify the prevalence of comorbidities derived from chest computed tomography (CT) of patients undergoing lung cancer screening in a developing country.

METHODS AND MATERIALS

For this retrospective study, low-dose CT scans (n=775) from patients undergoing LCS in a tertiary hospital between 2016 and 2020 were examined. A group of controls with similar age and gender but undergoing chest CT for other indications was also used for comparison (n=370). CT images were evaluated by experienced radiologists regarding coronary artery calcium (CAC) score, skeletal muscle area (SMA), interstitial lung abnormalities (ILA), presence of emphysema, osteoporosis, and hepatic steatosis using a dedicated software. Prevalence of abnormalities and clinical characteristics of the groups were compared using t-test and chi-squared tests. Interclass correlation coefficient (ICCs) and kappa coefficients for interobserver agreement were also calculated. The level of significance was set at 0.05.

RESULTS

One or more comorbidities were identified on imaging in 86.6% of patients undergoing LCS and in 40% of the controls. The most prevalent comorbidity was osteoporosis, present in 44.2% of patients and 24.8% of controls. CAC was identified in 41.9% of cases (vs. 23.7% of controls), emphysema in 66.3% (vs. 8.9% of controls), and osteoporosis in 44.2% (vs. 24.8% of controls). Compared to information retrieved from the medical records, CAC, emphysema, and osteoporosis were newly diagnosed in 25%, 7%, and 46% of the LCS patients, respectively. Sarcopenia was identified on 9.9% of LCS patients (vs. 3.5% controls) and hepatic steatosis in 40.7% (vs. 15.9% of controls). The kappa coefficient for CAC was 0.906, while ICC for measurements in the liver, spleen, and bone density were 0.88, 0.93, and 0.96, respectively.

CONCLUSION

s Data derived from the CT of patients undergoing LCS may lead to the identification of potentially undiagnosed comorbidities in more than 80% of patients.

CLINICAL RELEVANCE/APPLICATION

Smoking-related comorbidities (CAC, emphysema, ILA, sarcopenia, osteoporosis, and hepatic steatosis) are highly prevalent in patients undergoing low-dose CT for LCS. Integrated assessment of the CT in LCS for features other than nodule screening may lead to the identification of these comorbidities early and increase the chances of a favorable outcome for patients.

T5A-SPCH-6

Is It Time to Replace Low-dose CT with Ultra-low-dose CT in Lung Cancer Screening?

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - CH DPS

Participants
Matheus Zanon, MD, MSc, Porto Alegre, Brazil (*Presenter*) Nothing to Disclose

PURPOSE

To assess the agreement between ultra-low-dose CT (ULDCT) and low-dose CT (LDCT) in the evaluation of pulmonary findings in smokers undergoing lung cancer screening (LCS).

METHODS AND MATERIALS

For one month, we prospectively included eligible patients for LCS that underwent both chest ULDCT and LDCT for one month. Eligibility for LCS followed the 2021 guidelines by the United States Preventive Services Task Force. Patients should be adults, aged 50 to 80 years, with a 20 pack-year smoking history, currently smoking or formers smokers that had quit within the past 15 years. Images were acquired in a 64-detector CT scanner as follows: LDCT: 100kVp/25mAs; ULDCT: 80kVp/15mAs. Two independent senior radiologists evaluated the presence of consolidation, ground-glass opacification (GGO), septal thickening, pulmonary nodule, bronchial wall thickening (BWT), pleural effusion, emphysema, bronchiectasis, and atelectasis.

RESULTS

From the 265 patients enrolled, 58 (21.9%) had abnormal CT scans. Mean effective radiation doses (ERD) for LDCT and ULDCT were 1.21±0.34 mSv and 0.39±0.15 mSv, respectively, representing a reduction in the mean ERD of 67.8%. Agreement was almost perfect for emphysema (?=0.92) and nodules (?=0.91). BWT, bronchiectasis, and atelectasis presented a strong agreement (?,0.80-0.90), and consolidation, septal thickening, and pleural effusion presented substantial agreement (?,0.60-0.80). Conversely, GGO presented a poor agreement (?=0.37).

CONCLUSION

s Although the mean ERD reduced dropped to almost a third from LDCT to ULDCT, inter-reader agreement was poor for significant findings, such as consolidation and GGO, that may represent other types of lung cancer (e.g., lepidic adenocarcinoma).

CLINICAL RELEVANCE/APPLICATION

Despite the exciting agreement for some pulmonary findings, these results question whether using an ULDCT protocol for LCS would be adequate, as many subsolid or GGO lesions could be missed. Also, despite the significant reduction in the RED, it is questionable whether there is a patient benefit from going to 1.2 to 0.39 mSv.

Screening for the Screeners: Our Institutional Experience with Double Reading of CT Lung Cancer Screening

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - CH DPS

Participants
Padma Manapragada, MD, MBBS, Birmingham, AL (*Presenter*) Nothing to Disclose

PURPOSE

Our institution participated in the NLST and continued to offer screening. Post approval by the USPSTF and the CMS, patient volume and the number of readers increased. With faculty turnover, the participating readers also kept changing. This study evaluates if double reading would increase adherence to screening requirements, consistent Lung RADS interpretation and unify follow up recommendations.

METHODS AND MATERIALS

The local IRB approved this retrospective study and written informed consent was waived. All lung cancer screening [LCS] cases from 2015 to through 2021 [2347 cases] were evaluated. Patients met the 2015 CMS criteria for inclusion: age 55-77, 30 pack years, current smoker or less than 15 years since quitting. A separate LCS PACS reading list was established. In rotation two radiologists were assigned to read the list each day. The first reader dictated the templated report and placed it in draft status. The second reader reviewed the study and the draft report, made any changes needed, signed the report, recorded if there was a discrepancy and, if present, the type of discrepancy. An Excel sheet recorded patient screened, Lung-RADS score, yes/no discrepancy, and category of discrepancy. Retrospectively the discrepancies were graded as: Significant-1: Changed L-RADS status or coronary artery calcification [CAC] score, other cancers, or major vascular aneurysm. Equivocal-2: Additional nodules but no L-RADS score change, other lung disease . Incidental-3: Non-cancer potentially significant findings (cirrhosis, renal stones, Pulmonary Artery HTN, AVM).

RESULTS

The majority of the 190 discrepancies were significant-109/190. Equivocal cases were 48/109 and incidental cases were 28/109. 5 cases were classified in more than one category. In eight cases the LR category changed from negative [1, 2] to positive [3.4]. The percentage of discrepancies initially increased as the number of cases increased, a new reader was added or new L-RADS introduced then decreased.

CONCLUSION

s Double reading improved consistency in evaluation of LCS CTs and the application of LungRADS. This provides more uniform patient care over time and when patient care is escalated to biopsy or treatment.

CLINICAL RELEVANCE/APPLICATION

Double reading in evaluation of LCS CTs provides consistent high quality reports and consistent application of LungRADS. This provides uniform high quality patient care over time and when patient care is escalated to biopsy or treatment.

T5A-SPCH-8

Risk of Exacerbations in Participants with Bronchiectasis in a Program of Low-dose CT Screening

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - CH DPS

Participants
Natthaya Triphuridet, MD, PhD, New York, NY (*Presenter*) Nothing to Disclose

PURPOSE

To predict future exacerbations during the two years following the initial LDCT in screening participants with bronchiectasis based on the LDCT findings including emphysema, and self-reported co-morbidities.

METHODS AND MATERIALS

Electronic medical record (EMR) review of prospectively enrolled participants who smoked in Early Lung and Cardiac Action Program, a LDCT screening program from 2010 to 2019. EMR were reviewed to identify participants with respiratory symptoms and exacerbations during two years before and two years after initial LDCT screening. Uni-and multivariable regression analysis were performed to identify predictors of future exacerbations using LDCT findings and self-reported co-morbidities at the time of screening.

RESULTS

Of 2191 participants, 504(23%) had bronchiectasis and EMR had available records on 300 (median age,69 years;154(51%) women). Emphysema was identified on LDCT in 152(51%). Exacerbations were identified during two years after LDCT screening in 84(28%) participants. Participants with emphysema, compared to those without emphysema, had significantly higher median ELCAP Bronchiectasis Score (13.0 vs. 11.5, p=.02), higher frequency of respiratory symptoms [97(64%) vs. 75(51%), p=.02] and exacerbations [49(32%) vs. 35(24%), p=.10]. Multivariable analyses showed that the ELCAP Bronchiectasis Score (OR=1.12,p<.001), self-reported COPD (OR=2.69,p<.001) and asthma (OR=2.47,p=.006) were independent predictors of exacerbations, but not emphysema. Considering ELCAP Bronchiectasis component scales instead of the total score, severity of bronchial dilatation (OR=1.30,p=.001) and bronchial wall thickening (OR=1.29,p=.004) were significant predictors. When including prior respiratory symptoms and exacerbations during two years prior to screening as predictors, ELCAP Bronchiectasis Score remained as an independent predictor of future exacerbations.

CONCLUSION

s High ELCAP Bronchiectasis Score, self-reported COPD and asthma are independent predictors of exacerbations. This type of information is needed to develop preventive management protocols.

CLINICAL RELEVANCE/APPLICATION

Among 300 participants with bronchiectasis and available electronic medical records, 84(28.0%) had exacerbations during two years following initial LDCT screening. Significant predictors of future exacerbations were: ELCAP Bronchiectasis Score [OR=1.12, p<.001], self-reported COPD [OR=2.69, p<.001] and asthma [OR=2.47, p=0.006].

Computational Risk Stratification: A Deep Learning Approach to Predicting a Major Lung Biopsy Complication

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - CH DPS

Participants
Alexander Lindqwister, BS,MS, Lebanon, NH (*Presenter*) Nothing to Disclose

PURPOSE

CT-guided core needle biopsies (CT-CNB) are a major component of the diagnostic work-up of lung lesions. The most common associated risk is iatrogenic pneumothorax (PTX) which may require tube thoracostomy and subsequent hospitalization. The ability to predict PTX requiring tube thoracostomy in the pre-procedural setting would allow radiologists to make more individualized recommendations in patient management, improve the informed consent process, and augment care delivery through risk stratification.

METHODS AND MATERIALS

A retrospective study of 502 patients who underwent CT-CNB of the lung was performed. Procedural, patient demographic, and outcomes data were collected and descriptive statistics were performed to determine significant distinguishing features between patients who required chest tubes and those who did not. Six parameters (age, sex, emphysema, projected length of needle path, greatest dimension of lung lesion, lung lobe) encoded through 12 features were utilized by a deep neural network to create a predictive model. Exhaustive 5-fold cross validation in addition to an external dataset consisting of 449 patients was used to validate the model.

RESULTS

Deep learning models were highly successful in predicting PTX requiring tube thoracostomy, with a receiver operating characteristic area under the curve (ROC-AUC) of 0.961 [+/- 0.033] averaged across 2,000 simulations. The model had consistent performance with the external dataset, achieving an ROC-AUC of 0.886 [+/- 0.059]. Testing metrics revealed a sensitivity of 0.879, specificity of 0.924, and a negative predictive value of 0.986 after adjusting for incidence of chest tube placement.

CONCLUSION

s The strong performance of deep learning models to predict chest tube placement demonstrates the possible clinical utility of machine learning in predicting post procedural complications in this setting. The model performed well on data collected from two different patient cohorts, which suggests generalizability and the potential for broad application.

CLINICAL RELEVANCE/APPLICATION

Neural networks and other data-driven approaches may be useful in predicting adverse post-procedural complications in the setting of lung CT-CNB.

T5A-SPER-1 Spot and Leakage Signs: Predicting Intracerebral Hemorrhage Expansion

Participants
Maria del Carmen Gonzalez Dominguez, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To describe the acquisition protocol, the diagnostic criteria, and the utility of "spot sign" and "leakage sign" as predicting factors for intracerebral hemorrhage expansion. To assess the consequences and the impact on clinical factors such as neurologic impairment and in-hospital mortality.

METHODS AND MATERIALS

A prospective study was performed on 117 patients with spontaneous intracerebral hemorrhagic (ICH) stroke. These patients underwent non-enhanced computed tomography (NECT) and computed tomography angiogram (CTA), which were acquired in both arterial (35 seconds) and delayed (300 seconds) phases. The initial study obtained the hematoma volume, location (lobar or in basal ganglia), and attenuation values. We consider active bleeding the presence of a "spot sign" and/or "leakage sign". Spot sign was defined as a focal accumulation of contrast within the hematoma in the arterial phase). Leakage sign was established as increased contrast extravasation from the early phase or its onset in the delayed phase. Later, hematoma volume was recalculated in follow-up NECT. We defined hematoma expansion as a >15% increase in hematoma size. Other variables were also evaluated, particularly neurological deterioration (increase in National Institute of Health (NIH) stroke score) and in-hospital mortality.

RESULTS

Spot sign [OR: 4,27 (1,55-11,75)] and Leakage sign [OR: 4,80 (1,82-12,68)] were independently associated with hematoma volume expansion. In the neurologic impairment course group, a positive spot sign was present in 68,75 % of patients, and a positive leakage sign was present in 75% of patients with a independently statistically significant association [OR: 2,95 (1,28-6,77)] and [OR: 3,26 (1.42-7,51)], respectively.The presentation of active bleeding signs was also independently associated with a significant increase in-hospital deaths, for Leakage sign [OR: 6,86 (2.73-17,25)] and Spot sign [OR: 9,31 (3,50-24,80)].

CONCLUSION

s Determining active bleeding signs in two phases improves the prediction of intraparenchymal hematoma volume expansion, neurologic impairment, and hospital deaths.

CLINICAL RELEVANCE/APPLICATION

Patients with positive leakage signs were associated with worse clinical prognoses and increased probability of in-hospital mortality. The possibility of surgical evacuation or strict control of blood pressure of intraparenchymal hematomas with positive leakage signs was proposed in our hospital, and they are currently being carried out in selected patients. So, in our study, imaging tools play a key role in the diagnosis and prognosis of ICH stroke patients and provide therapeutic decision support.

Sub-Events

T5A-SPGI-1 Laparoscopic Cholecystectomy and Percutaneous Cholecystostomy: An Analysis of Trends in Procedure Volume Among Medicare Patients from 2010-2018.

Participants
Abdullah Khan, MD, Sacramento, CA (*Presenter*) Nothing to Disclose

PURPOSE

Cholecystectomies represent the most common procedure performed by general surgeons, with hundreds of thousands being performed annually. Percutaneous image-guided cholecystostomy is an alternative option for acute cholecystitis, particularly in patients that are high risk surgical candidates. Currently, minimal data exists on national trends in the utilization of these techniques including procedure volume, inpatient status, and procedural costs.

METHODS AND MATERIALS

This study utilized data derived from publicly available databases provided by the Center for Medicare and Medicaid Services (CMS). Billing data from the CMS Physicians/Supplier Procedure Summary (PSPS) Master Files from 2010 to 2018 were obtained. Billing codes 47562, 47563, 47564 were combined to designate laparoscopic cholecystectomy. Code 47490 was used to capture data for percutaneous cholecystostomy tube placement. The Mann-Kendall test was used to analyze for statistically significant trends in procedure volume and cost.

RESULTS

The volume of annual laparoscopic cholecystectomy surgeries decreased significantly over the study period, from 218637 performed in 2010 to 173845 performed in 2018 (-20.0%, $p<0.001$). Conversely, the volume of annual percutaneous cholecystostomy tube placements increased significantly, rising from 7225 in 2010 to 12135 in 2018 (+68.0%, $p<0.001$). Mean submitted charge increased from 2240 to 2620 for cholecystectomy (17%, $p<0.001$) and from 1490 to 1560 for cholecystostomy (4.7%, $p=0.11$). 91.5% of cholecystostomy tube placements and 41.3% of cholecystectomies were completed in an inpatient setting, which remained stable over the study period.

CONCLUSION

s Medicare data demonstrates an increasing trend in percutaneous cholecystostomy tube placement between 2010 and 2018, and a decreasing trend in the number of charges for laparoscopic cholecystectomy. Increasing cholecystostomy procedures may reflect trends in the aging patient population as well as increased provider familiarity with the procedure. Concurrently, the decreasing numbers of laparoscopic cholecystectomy performed may represent increasingly cautious surgical risk stratification and associated changes in the treatment algorithms for acute cholecystitis.

CLINICAL RELEVANCE/APPLICATION

Data from Medicare demonstrates an increasing number of percutaneous cholecystostomy tube placements with a concurrent decrease in laparoscopic cholecystectomies, which may reflect trends associated with an aging patient population and changing treatment algorithms.

T5A-SPGI-10 Radiomic Features of Hepatocellular Carcinoma at Ultra-High-Resolution CT with a 1024 Matrix: Dependencies on Matrix Size and Reconstruction Algorithm

Participants
Masatoshi Hori, MD, Kobe, Japan (*Presenter*) Research Grant, Canon Medical Systems Corporation

PURPOSE

Ultra-high-resolution (UHR) CT yields 1024-matrix CT images of higher spatial resolution compared to conventional 512-matrix images. However, the role of UHR CT in radiomics is not well understood. Thus, the aim was to determine the effects of CT matrix size and reconstruction algorithm on the quantification of UHR CT radiomic features to characterize hepatocellular carcinoma.

METHODS AND MATERIALS

This retrospective study included 27 patients (14 men and 13 women; median age, 71 years) with hepatocellular carcinoma who underwent contrast-enhanced multi-phasic CT during the late arterial and the portal venous phase (LAP and PVP) in super-high-resolution mode using a UHR CT scanner (Aquilion Precision; Canon). The mean size of lesions was 48.3 ± 37.0 mm (range, 11?129 mm). UHR CT images with a 1024- and 512-matrix were reconstructed using filtered back projection (FBP) and hybrid iterative

reconstruction (hybrid IR). The slice thickness was 1 mm. A representative tumor was three-dimensionally segmented in each patient. Then, 120 radiomic features were calculated for each image set. Features were categorized as first order (n=19), shape (26), and texture features (75). A linear mixed-effects model was used to assess the effect of matrix size and reconstruction algorithm on features. A P value less than 0.05 divided by 120 was considered significant (approximately 0.00041; Bonferroni correction for the 120 responses).

RESULTS

The matrix size had a significant effect on 94 features (78.3 %) in LAP and 90 features (75.0 %) in PVP out of 120 features ($P < 0.00041$ for all). It showed significant effects on 17 first-order features (89.5 %) for LAP and 17 features (89.5 %) for PVP, 12 shape features (46.2 %) for LAP and 10 features (38.5 %) for PVP, and 65 texture features (86.7 %) for LAP and 63 features (84.0 %) for PVP ($P < 0.00041$ for all). Reconstruction algorithm had a significant effect on 44 (36.7 %) in LAP and 43 (35.8 %) in PVP out of 120 features ($P < 0.00041$ for all). No significant effect of the reconstruction algorithm was observed for 26 shape features and 5 neighboring gray-tone difference matrix (NGTDM) texture features for both LAP and PVP.

CONCLUSION

s Both matrix size and reconstruction algorithm affect the radiomic features in hepatocellular carcinoma at UHR CT. Above all, 1024-matrix size had a significant effect on approximately 90 % of the first-order features and texture features.

CLINICAL RELEVANCE/APPLICATION

It should be noted that radiomics from UHR CT with a 1024 matrix have different properties than those from conventional CT with a 512 matrix.

T5A-SPGI-2 MR Guided Liver Biopsies - Depiction Of The Biopsy Site On Immediate Postintervenional Contrast Enhanced MRI

Participants
Guenther K. Schneider, MD, PhD, Homburg, Germany (*Presenter*) Research Grant, Siemens AG;Speakers Bureau, Siemens AG;Speakers Bureau, Bracco Group;Research Grant, Bracco Group

PURPOSE

Sampling errors in image guided biopsies of primary, hypervascular focal liver lesions are a common problem in clinical routine, resulting in unnecessary delay or even inadequate treatment of patients. The purpose of our study was to evaluate as if immediate post biopsy MRI may detect the exact location where a liver biopsy was taken and confirm or exclude sampling of representative tissue.

METHODS AND MATERIALS

MRI guided liver biopsy was performed in 68 patients with primary liver tumors (HCC, FNH, Adenoma, NRH) using a 18G core biopsy device. Lesion size ranged from 7 mm to 2.7 cm. Following tissue sampling the biopsy tract was closed with gelatin foam pledgets. Immediately post biopsy a diagnostic MRI was performed in order to detect possible complications and to depict the exact area, where the biopsy was sampled. Imaging included T1-/T2-weighted unenhanced sequences (T2 TSE, HASTE, T1w flash 2D and 3D VIBE-DIXON Sequences) as well as dynamic 3D VIBE-DIXON imaging post bolus CM injection (0.05 mmol/kg MultiHance) in the arterial and portalvenous phase. Furthermore T1w images with and without fat suppression in the equilibrium and hepatobiliary phase (hb-phase) were acquired.

RESULTS

In all patients the biopsy tract could be depicted at least in one sequence. On unenhanced images the biopsy tract was best detected on T1w flash-2D sequences (57/68) followed by the 3D VIBE-DIXON sequence (51/68). T2w (12/68) and HASTE images (28/68) could not delineate the biopsy tract sufficiently. On CE images the biopsy tract together with the lesion was depicted best in the arterial phase both on the T1w flash 2D and 3D VIBE DIXON sequence (61/68). In the biliary phase depiction of the sampling area together with the lesion was possible in 59 of 41 patients. In 63 of 68 patients MRI confirmed that tissue was taken from the lesions and facilitated histologic diagnosis. In 5 cases lesions were missed, both based on findings in MRI and histology and biopsy was repeated.

CONCLUSION

s Immediate post liver biopsy MRI allows for depiction of the biopsy tract both on unenhanced and CE MRI with advantages seen for CE images. T2w imaging did not reliably depict the biopsy tract. By identifying the biopsy area, sampling errors can be detected post biopsy what is of special importance in small lesions, lesions which are similar to normal liver tissue on histology like FNH or regenerative nodules and in lesions in a cirrhotic liver, where findings of regenerating tissue might imply correct tissue sampling in cases in which an HCC was missed.

CLINICAL RELEVANCE/APPLICATION

MRI immediately post liver biopsy reliably depicts biopsy tracts and thus can confirm or exclude sampling of representative tissue and avoid unnecessary delay in diagnosis.

T5A-SPGI-3 Automated AI-Based Splenic Segmentation for Predicting Survival and Estimating the Risk of Hepatic Decompensation in TACE Patients With HCC

Participants
Lukas Mueller, MD, Mainz, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Splenic volume was proposed as a relevant prognostic factor for patients with hepatocellular carcinoma (HCC). We trained a deep-learning algorithm to fully-automatically assess splenic volume based on computed tomography (CT) scans. Then, we investigated splenic volume as a prognostic factor for patients with HCC undergoing transarterial chemoembolization (TACE).

METHODS AND MATERIALS

This retrospective study included 327 treatment-naïve patients with HCC undergoing initial TACE at our tertiary care center

between 2010 and 2020. A convolutional neural network was trained and validated on the first 100 consecutive cases for spleen segmentation. Then, we used the algorithm to evaluate splenic volume in all 327 patients. Subsequently, we evaluated correlations between splenic volume and survival as well as the risk of hepatic decompensation during TACE.

RESULTS

The algorithm showed Sørensen Dice Scores of 0.96 during both training and validation. In the remaining 227 patients assessed with the algorithm, spleen segmentation was visually approved in 223 patients (98.2%) and failed in four patients (1.8%), which required manual re-assessments. Mean splenic volume was 551ml. Median survival was significantly lower in patients with high splenic volume (10.9 months), compared to low splenic volume (22.0 months, p=0.001). In contrast, overall survival was not significantly predicted by axial and craniocaudal spleen diameter. Furthermore, patients with a hepatic decompensation after TACE had significantly higher splenic volumes (p<0.001).

CONCLUSION

s Automated splenic volume assessments showed superior survival predictions in patients with HCC undergoing TACE compared to two-dimensional spleen size estimates and identified patients at risk of hepatic decompensation.

CLINICAL RELEVANCE/APPLICATION

Thus, splenic volume could serve as an automatically available, currently underappreciated imaging biomarker.

T5A-SPGI-4 Performance of LI-RADS Major Feature Combinations within the CT/MRI Diagnostic Algorithm: Individual Patient Data Meta-analysis

Participants
Jean-Paul Salameh, MSc, (*Presenter*) Nothing to Disclose

PURPOSE

The Liver Imaging Reporting and Data System (LI-RADS) assigns a risk for hepatocellular carcinoma (HCC) to imaging observations. The purpose of this study is to perform an individual-patient data (IPD) meta-analysis to establish the percentage of HCC for combinations of LI-RADS major features using the CT/MRI LI-RADS diagnostic algorithm in high-risk patients

METHODS AND MATERIALS

Multiple databases (MEDLINE, Embase, Cochrane Central Register of Controlled Trials, and Scopus) were searched for studies from January 2014 to September 2019 that evaluated the accuracy of CT/MRI using LI-RADS (v2014/17/18). IPD were pooled to compute the percentage of HCC for each major feature combination using a random-effects model. Percentage of HCC with 95% confidence intervals (95%CI) are presented. Heterogeneity was quantified using the I-squared statistic. Risk of bias was assessed using Quality Assessment of Diagnostic Accuracy Studies 2

RESULTS

Thirty-one studies (2602 patients; 3350 observations) were included. Pooled percentage of HCC for combinations of LI-RADS major features ranged between 15.5% (95%CI 6.0%-34.5%) and 50.7% (95%CI 27.5%-73.6%) for LR3 combinations, 56.7% (95%CI 34.2%-76.8%) and 100% (95%CI 20.3%-100%) for LR4 combinations, and 81.8% (95%CI 61.7%-92.6%) and 96.1% (95%CI 83.4%-99.2%) for LR5 combinations (Figure 1). Twenty-five studies (78%) had high risk of bias due to reporting ambiguity or study design flaws

CONCLUSION

s Our findings document increasing percentage of HCC with each LI-RADS category; however, substantial variability exists within each category depending on feature combination. This data will inform updates of the LI-RADS diagnostic algorithms to better align feature combinations with intended percentage of HCC in each LI-RADS category

CLINICAL RELEVANCE/APPLICATION

Our findings will help determine which observations are definite HCC based on feature combinations. This will impact patient care by providing timely access to treatment and avoiding unnecessary biopsy

T5A-SPGI-5 Extracellular Volume Fraction Using Contrast Enhanced CT Is Useful In Differentiating Intrahepatic Cholangiocellular Carcinoma From Hepatocellular Carcinoma

Participants
Takashi Ota, MD,PhD, Suita, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate whether extracellular volume fraction (fECV) of the tumors using contrast-enhanced computed tomography (CT) aids in the differentiation of hepatocellular carcinoma (HCC) and intrahepatic cholangiocellular carcinoma (ICC).

METHODS AND MATERIALS

In this retrospective study, 113 patients with pathologically confirmed HCC (n = 74) or ICC (n = 39) who had undergone preoperative contrast-enhanced CT examinations were enrolled. Enhancement values of the tumor (Etumor) and aorta (Eaorta) were obtained based on the precontrast and equilibrium phase CT images. The fECV was calculated using the following equation: fECV [%] = Etumor/Eaorta × (100 - Hematocrit [%]). The fECVs were compared between HCC and ICC groups using Welch's t-test. The diagnostic performance of fECV in the differentiation of HCC and ICC was assessed using receiver operating characteristic (ROC) analysis. The imaging features including tumor demarcation, shape, arterial enhancement pattern, washout pattern, bile duct dilatation, and tortuous tumoral vessels were evaluated by two radiologists and were examined by the ?2 test or Fisher’s exact test (when n<5). A multivariate logistic regression analysis was also performed to identify factors predicting a diagnosis of ICC; variables with a P-value of <0.1 were entered into the final model.

RESULTS

The mean fECV of ICCs (43.8±13.2%) was significantly higher than that of HCCs (31.6±9.0%, P < .001). The area under the curve

was 0.763. Lobulated and irregular shape, indistinct margin, peripheral rim enhancement in the arterial phase, and the presence of bile duct dilatation were CT features favoring ICC, whereas a round shape, distinct margin, non-rim enhancement in the arterial phase, and washout pattern were CT features favoring HCC in the univariate analysis (P < .001). In the multivariate analysis, fECV and a washout pattern were independent CT features for distinguishing between the two types. (P = 0.03, P < .001, respectively).

CONCLUSION

s A higher value of fECV and a washout pattern were respectively independent factors of multivariate analysis in distinguishing between ICC and HCC and more indicative of ICC than HCC on contrast-enhanced CT.

CLINICAL RELEVANCE/APPLICATION

The addition of extracellular volume fraction analysis to the imaging features evaluation on contrast-enhanced CT may allow more accurately differentiating ICC from HCC.

T5A-SPGI-7 Tomoelastography-based Viscoelastic Signatures for Prediction of Proliferative Phenotype in Hepatocellular Carcinoma

Participants
Gui Liu, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the biomechanical signatures of proliferative hepatocellular carcinoma (HCC) and the value of tomoelastography in characterizing the proliferative HCC phenotype.

METHODS AND MATERIALS

A total of 121 patients with 124 pathologically confirmed HCC lesions (63 proliferative and 61 non-proliferative HCC) were included in this prospective study. All participants underwent preoperative MRI and tomoelastography. Rim arterial phase hyperenhancement [APHE], nonperipheral washout, enhancing capsule and LI-RADS categorization were evaluated. Tumor and liver viscoelasticity were quantified as shear wave speed (c, m/s), representing tissue stiffness, and loss angle (f, rad), indicating fluidity. Univariate and multivariate logistic regression analyses were used to determine predictors of proliferative HCC. A prediction nomogram of proliferative HCC was constructed.

RESULTS

Multivariate logistic regression analysis results showed that tumor c (OR: 0.24, 95%CI: 0.089-0.63; P = 0.0037), tumor f (OR: 39.12, 95%CI: 2.72-561.94; P=0.007), liver c (OR: 0.12, 95%CI: 0.027- 0.54; P = 0.0056), liver f (OR: 540.64, 95%CI:6.72 - 43521.86; P = 0.0049) and rim APHE (OR: 15.32, 95%CI: 2.87- 81.87; P=0.0014) were independent predictors of proliferative HCC. Combining these variables yielded an AUC of 0.77 (95%CI: 0.69-0.84), sensitivity of 73.02% (95%CI: 0.64-0.86), specificity of 68.85% (95%CI: 0.54-0.79), and accuracy of 70.97% (95%CI: 0.62-0.79), respectively, for predicting proliferative HCC. The C-index of the corresponding nomogram was 0.77 (95%CI: 0.69-0.84).

CONCLUSION

s Proliferative HCC reveals decreased stiffness and increased fluidity for both tumor and liver. Combining biomechanical signature and viscoelasticity could predicate proliferative HCC.

CLINICAL RELEVANCE/APPLICATION

The proliferation class accounts for about 50% of HCCs,which has strong invasiveness and poor prognosis. Therefore, predicting proliferative HCC was urgent and importantto characterize morpho-molecular subtypes for the prediction of prognosis and therapeutic response in clinical practice. We investigated the diagnostic ability of the biomechanical parameters quantified by in vivo tomoelastography for predicting proliferative HCC subtypes. To our knowledge, this is the first study to connect biomechanical properties with the proliferative nature of HCCs. Based on our data, Proliferative HCC may be softer, more liquid like and more bioinvasive than non-proliferative HCC. Additionally, proliferative HCC could be predicted with good accuracy by combing stiffness and fluidity of both the tumor and the liver.

T5A-SPGI-9 Preliminary Radiogenomic Study of Hepatitis B-related Hepatocellular Carcinoma: Associations between MR Features and Mutations

Participants
Ruofan Sheng, MD, Shanghai, China (*Presenter*) Nothing to Disclose

PURPOSE

Hepatocellular carcinoma (HCC) is the most common primary liver cancer, and radiogenomics plays an important role in providing accurate imaging substitutes which are associated with genetic expression. This study aimed to investigate associations between MR features and the high-frequency mutations of hepatitis B virus (HBV) related hepatocellular carcinoma (HCC).

METHODS AND MATERIALS

This retrospective study included 58 HCC patients who underwent abdominal contrast-enhanced MRI prior to surgical resection and genome sequencing. MR imaging features and mutation information were evaluated. Associations between MR features and the high-frequency mutations as well as tumor mutation burden (TMB) level were tested by using Pearson's chi-squared test or Fisher exact test.

RESULTS

The top 5 most frequently mutated genes of HCC were TP53 (53.45%), TAF1(24.14%), PDE4DIP (22.41%), ABCA13 (18.97%), LRP1B (17.24%). Mutations of TP53 were associated with the presence of tumor necrosis (P=0.035). Mutations of ABCA13 were associated with the presence of mosaic architecture (P=0.025) and necrosis (P=0.010). Mutations of LRP1B were associated with the presence of mosaic architecture (P=0.015). MR features were not correlated to the TMB level (P=0.945 to P>0.99).

CONCLUSION

s This preliminary radiogenomic analysis revealed associations between MR features and the high-frequency mutations in HBV

s This preliminary radiogenomic analysis revealed associations between MR features and the high-frequency mutations in HBV-related HCC.

CLINICAL RELEVANCE/APPLICATION

This preliminary radiogenomics analysis showed associations between MR features and the high-frequency mutations in HBV-related HCCs, which demonstrated potential clinical value of imaging traits as surrogate markers of molecular portraits in HCC.

Laparoscopic Cholecystectomy and Percutaneous Cholecystostomy: An Analysis of Trends in Procedure Volume Among Medicare Patients from 2010-2018.

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - GI DPS

Participants
Abdullah Khan, MD, Sacramento, CA (*Presenter*) Nothing to Disclose

PURPOSE

Cholecystectomies represent the most common procedure performed by general surgeons, with hundreds of thousands being performed annually. Percutaneous image-guided cholecystostomy is an alternative option for acute cholecystitis, particularly in patients that are high risk surgical candidates. Currently, minimal data exists on national trends in the utilization of these techniques including procedure volume, inpatient status, and procedural costs.

METHODS AND MATERIALS

This study utilized data derived from publicly available databases provided by the Center for Medicare and Medicaid Services (CMS). Billing data from the CMS Physicians/Supplier Procedure Summary (PSPS) Master Files from 2010 to 2018 were obtained. Billing codes 47562, 47563, 47564 were combined to designate laparoscopic cholecystectomy. Code 47490 was used to capture data for percutaneous cholecystostomy tube placement. The Mann-Kendall test was used to analyze for statistically significant trends in procedure volume and cost.

RESULTS

The volume of annual laparoscopic cholecystectomy surgeries decreased significantly over the study period, from 218637 performed in 2010 to 173845 performed in 2018 (-20.0%, $p<0.001$). Conversely, the volume of annual percutaneous cholecystostomy tube placements increased significantly, rising from 7225 in 2010 to 12135 in 2018 (+68.0%, $p<0.001$). Mean submitted charge increased from 2240 to 2620 for cholecystectomy (17%, $p<0.001$) and from 1490 to 1560 for cholecystostomy (4.7%, $p=0.11$). 91.5% of cholecystostomy tube placements and 41.3% of cholecystectomies were completed in an inpatient setting, which remained stable over the study period.

CONCLUSION

s Medicare data demonstrates an increasing trend in percutaneous cholecystostomy tube placement between 2010 and 2018, and a decreasing trend in the number of charges for laparoscopic cholecystectomy. Increasing cholecystostomy procedures may reflect trends in the aging patient population as well as increased provider familiarity with the procedure. Concurrently, the decreasing numbers of laparoscopic cholecystectomy performed may represent increasingly cautious surgical risk stratification and associated changes in the treatment algorithms for acute cholecystitis.

CLINICAL RELEVANCE/APPLICATION

Data from Medicare demonstrates an increasing number of percutaneous cholecystostomy tube placements with a concurrent decrease in laparoscopic cholecystectomies, which may reflect trends associated with an aging patient population and changing treatment algorithms.

Radiomic Features of Hepatocellular Carcinoma at Ultra-High-Resolution CT with a 1024 Matrix: Dependencies on Matrix Size and Reconstruction Algorithm

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - GI DPS

Participants
Masatoshi Hori, MD, Kobe, Japan (*Presenter*) Research Grant, Canon Medical Systems Corporation

PURPOSE

Ultra-high-resolution (UHR) CT yields 1024-matrix CT images of higher spatial resolution compared to conventional 512-matrix images. However, the role of UHR CT in radiomics is not well understood. Thus, the aim was to determine the effects of CT matrix size and reconstruction algorithm on the quantification of UHR CT radiomic features to characterize hepatocellular carcinoma.

METHODS AND MATERIALS

This retrospective study included 27 patients (14 men and 13 women; median age, 71 years) with hepatocellular carcinoma who underwent contrast-enhanced multi-phasic CT during the late arterial and the portal venous phase (LAP and PVP) in super-high-resolution mode using a UHR CT scanner (Aquilion Precision; Canon). The mean size of lesions was 48.3 ± 37.0 mm (range, 11?129 mm). UHR CT images with a 1024- and 512-matrix were reconstructed using filtered back projection (FBP) and hybrid iterative reconstruction (hybrid IR). The slice thickness was 1 mm. A representative tumor was three-dimensionally segmented in each patient. Then, 120 radiomic features were calculated for each image set. Features were categorized as first order (n=19), shape (26), and texture features (75). A linear mixed-effects model was used to assess the effect of matrix size and reconstruction algorithm on features. A P value less than 0.05 divided by 120 was considered significant (approximately 0.00041; Bonferroni correction for the 120 responses).

RESULTS

The matrix size had a significant effect on 94 features (78.3 %) in LAP and 90 features (75.0 %) in PVP out of 120 features ($P < 0.00041$ for all). It showed significant effects on 17 first-order features (89.5 %) for LAP and 17 features (89.5 %) for PVP, 12 shape features (46.2 %) for LAP and 10 features (38.5 %) for PVP, and 65 texture features (86.7 %) for LAP and 63 features (84.0 %) for PVP ($P < 0.00041$ for all). Reconstruction algorithm had a significant effect on 44 (36.7 %) in LAP and 43 (35.8 %) in PVP out of 120 features ($P < 0.00041$ for all). No significant effect of the reconstruction algorithm was observed for 26 shape features and 5 neighboring gray-tone difference matrix (NGTDM) texture features for both LAP and PVP.

CONCLUSION

s Both matrix size and reconstruction algorithm affect the radiomic features in hepatocellular carcinoma at UHR CT. Above all, 1024-matrix size had a significant effect on approximately 90 % of the first-order features and texture features.

CLINICAL RELEVANCE/APPLICATION

It should be noted that radiomics from UHR CT with a 1024 matrix have different properties than those from conventional CT with a 512 matrix.

MR Guided Liver Biopsies - Depiction Of The Biopsy Site On Immediate Postintervenional Contrast Enhanced MRI

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - GI DPS

Participants
Guenther K. Schneider, MD, PhD, Homburg, Germany (*Presenter*) Research Grant, Siemens AG;Speakers Bureau, Siemens AG;Speakers Bureau, Bracco Group;Research Grant, Bracco Group

PURPOSE

Sampling errors in image guided biopsies of primary, hypervascular focal liver lesions are a common problem in clinical routine, resulting in unnecessary delay or even inadequate treatment of patients. The purpose of our study was to evaluate as if immediate post biopsy MRI may detect the exact location where a liver biopsy was taken and confirm or exclude sampling of representative tissue.

METHODS AND MATERIALS

MRI guided liver biopsy was performed in 68 patients with primary liver tumors (HCC, FNH, Adenoma, NRH) using a 18G core biopsy device. Lesion size ranged from 7 mm to 2.7 cm. Following tissue sampling the biopsy tract was closed with gelatin foam pledgets. Immediately post biopsy a diagnostic MRI was performed in order to detect possible complications and to depict the exact area, where the biopsy was sampled. Imaging included T1-/T2-weighted unenhanced sequences (T2 TSE, HASTE, T1w flash 2D and 3D VIBE-DIXON Sequences) as well as dynamic 3D VIBE-DIXON imaging post bolus CM injection (0.05 mmol/kg MultiHance) in the arterial and portalvenous phase. Furthermore T1w images with and without fat suppression in the equilibrium and hepatobiliary phase (hb-phase) were acquired.

RESULTS

In all patients the biopsy tract could be depicted at least in one sequence. On unenhanced images the biopsy tract was best detected on T1w flash-2D sequences (57/68) followed by the 3D VIBE-DIXON sequence (51/68). T2w (12/68) and HASTE images (28/68) could not delineate the biopsy tract sufficiently. On CE images the biopsy tract together with the lesion was depicted best in the arterial phase both on the T1w flash 2D and 3D VIBE DIXON sequence (61/68). In the biliary phase depiction of the sampling area together with the lesion was possible in 59 of 41 patients. In 63 of 68 patients MRI confirmed that tissue was taken from the lesions and facilitated histologic diagnosis. In 5 cases lesions were missed, both based on findings in MRI and histology and biopsy was repeated.

CONCLUSION

s Immediate post liver biopsy MRI allows for depiction of the biopsy tract both on unenhanced and CE MRI with advantages seen for CE images. T2w imaging did not reliably depict the biopsy tract. By identifying the biopsy area, sampling errors can be detected post biopsy what is of special importance in small lesions, lesions which are similar to normal liver tissue on histology like FNH or regenerative nodules and in lesions in a cirrhotic liver, where findings of regenerating tissue might imply correct tissue sampling in cases in which an HCC was missed.

CLINICAL RELEVANCE/APPLICATION

MRI immediately post liver biopsy reliably depicts biopsy tracts and thus can confirm or exclude sampling of representative tissue and avoid unnecessary delay in diagnosis.

T5A-SPGI-3

Automated AI-Based Splenic Segmentation for Predicting Survival and Estimating the Risk of Hepatic Decompensation in TACE Patients With HCC

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - GI DPS

Participants
Lukas Mueller, MD, Mainz, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Splenic volume was proposed as a relevant prognostic factor for patients with hepatocellular carcinoma (HCC). We trained a deep-learning algorithm to fully-automatically assess splenic volume based on computed tomography (CT) scans. Then, we investigated splenic volume as a prognostic factor for patients with HCC undergoing transarterial chemoembolization (TACE).

METHODS AND MATERIALS

This retrospective study included 327 treatment-naïve patients with HCC undergoing initial TACE at our tertiary care center between 2010 and 2020. A convolutional neural network was trained and validated on the first 100 consecutive cases for spleen segmentation. Then, we used the algorithm to evaluate splenic volume in all 327 patients. Subsequently, we evaluated correlations between splenic volume and survival as well as the risk of hepatic decompensation during TACE.

RESULTS

The algorithm showed Sørensen Dice Scores of 0.96 during both training and validation. In the remaining 227 patients assessed with the algorithm, spleen segmentation was visually approved in 223 patients (98.2%) and failed in four patients (1.8%), which required manual re-assessments. Mean splenic volume was 551ml. Median survival was significantly lower in patients with high splenic volume (10.9 months), compared to low splenic volume (22.0 months, p=0.001). In contrast, overall survival was not significantly predicted by axial and craniocaudal spleen diameter. Furthermore, patients with a hepatic decompensation after TACE had significantly higher splenic volumes (p<0.001).

CONCLUSION

s Automated splenic volume assessments showed superior survival predictions in patients with HCC undergoing TACE compared to two-dimensional spleen size estimates and identified patients at risk of hepatic decompensation.

CLINICAL RELEVANCE/APPLICATION

Thus, splenic volume could serve as an automatically available, currently underappreciated imaging biomarker.

T5A-SPGI-4

Performance of LI-RADS Major Feature Combinations within the CT/MRI Diagnostic Algorithm: Individual Patient Data Meta-analysis

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - GI DPS

Participants
Jean-Paul Salameh, MSc, (*Presenter*) Nothing to Disclose

PURPOSE

The Liver Imaging Reporting and Data System (LI-RADS) assigns a risk for hepatocellular carcinoma (HCC) to imaging observations. The purpose of this study is to perform an individual-patient data (IPD) meta-analysis to establish the percentage of HCC for combinations of LI-RADS major features using the CT/MRI LI-RADS diagnostic algorithm in high-risk patients

METHODS AND MATERIALS

Multiple databases (MEDLINE, Embase, Cochrane Central Register of Controlled Trials, and Scopus) were searched for studies from January 2014 to September 2019 that evaluated the accuracy of CT/MRI using LI-RADS (v2014/17/18). IPD were pooled to compute the percentage of HCC for each major feature combination using a random-effects model. Percentage of HCC with 95% confidence intervals (95%CI) are presented. Heterogeneity was quantified using the I-squared statistic. Risk of bias was assessed using Quality Assessment of Diagnostic Accuracy Studies 2

RESULTS

Thirty-one studies (2602 patients; 3350 observations) were included. Pooled percentage of HCC for combinations of LI-RADS major features ranged between 15.5% (95%CI 6.0%-34.5%) and 50.7% (95%CI 27.5%-73.6%) for LR3 combinations, 56.7% (95%CI 34.2%-76.8%) and 100% (95%CI 20.3%-100%) for LR4 combinations, and 81.8% (95%CI 61.7%-92.6%) and 96.1% (95%CI 83.4%-99.2%) for LR5 combinations (Figure 1). Twenty-five studies (78%) had high risk of bias due to reporting ambiguity or study design flaws

CONCLUSION

s Our findings document increasing percentage of HCC with each LI-RADS category; however, substantial variability exists within each category depending on feature combination. This data will inform updates of the LI-RADS diagnostic algorithms to better align feature combinations with intended percentage of HCC in each LI-RADS category

CLINICAL RELEVANCE/APPLICATION

Our findings will help determine which observations are definite HCC based on feature combinations. This will impact patient care by providing timely access to treatment and avoiding unnecessary biopsy

Extracellular Volume Fraction Using Contrast Enhanced CT Is Useful In Differentiating Intrahepatic Cholangiocellular Carcinoma From Hepatocellular Carcinoma

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - GI DPS

Participants
Takashi Ota, MD,PhD, Suita, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate whether extracellular volume fraction (fECV) of the tumors using contrast-enhanced computed tomography (CT) aids in the differentiation of hepatocellular carcinoma (HCC) and intrahepatic cholangiocellular carcinoma (ICC).

METHODS AND MATERIALS

In this retrospective study, 113 patients with pathologically confirmed HCC (n = 74) or ICC (n = 39) who had undergone preoperative contrast-enhanced CT examinations were enrolled. Enhancement values of the tumor (Etumor) and aorta (Eaorta) were obtained based on the precontrast and equilibrium phase CT images. The fECV was calculated using the following equation: fECV [%] = Etumor/Eaorta × (100 - Hematocrit [%]). The fECVs were compared between HCC and ICC groups using Welch's t-test. The diagnostic performance of fECV in the differentiation of HCC and ICC was assessed using receiver operating characteristic (ROC) analysis. The imaging features including tumor demarcation, shape, arterial enhancement pattern, washout pattern, bile duct dilatation, and tortuous tumoral vessels were evaluated by two radiologists and were examined by the ?2 test or Fisher's exact test (when n<5). A multivariate logistic regression analysis was also performed to identify factors predicting a diagnosis of ICC; variables with a P-value of <0.1 were entered into the final model.

RESULTS

The mean fECV of ICCs (43.8±13.2%) was significantly higher than that of HCCs (31.6±9.0%, P < .001). The area under the curve was 0.763. Lobulated and irregular shape, indistinct margin, peripheral rim enhancement in the arterial phase, and the presence of bile duct dilatation were CT features favoring ICC, whereas a round shape, distinct margin, non-rim enhancement in the arterial phase, and washout pattern were CT features favoring HCC in the univariate analysis (P < .001). In the multivariate analysis, fECV and a washout pattern were independent CT features for distinguishing between the two types. (P = 0.03, P < .001, respectively).

CONCLUSION

s A higher value of fECV and a washout pattern were respectively independent factors of multivariate analysis in distinguishing between ICC and HCC and more indicative of ICC than HCC on contrast-enhanced CT.

CLINICAL RELEVANCE/APPLICATION

The addition of extracellular volume fraction analysis to the imaging features evaluation on contrast-enhanced CT may allow more accurately differentiating ICC from HCC.

Tomoelastography-based Viscoelastic Signatures for Prediction of Proliferative Phenotype in Hepatocellular Carcinoma

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - GI DPS

Participants
Gui Liu, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the biomechanical signatures of proliferative hepatocellular carcinoma (HCC) and the value of tomoelastography in characterizing the proliferative HCC phenotype.

METHODS AND MATERIALS

A total of 121 patients with 124 pathologically confirmed HCC lesions (63 proliferative and 61 non-proliferative HCC) were included in this prospective study. All participants underwent preoperative MRI and tomoelastography. Rim arterial phase hyperenhancement [APHE], nonperipheral washout, enhancing capsule and LI-RADS categorization were evaluated. Tumor and liver viscoelasticity were quantified as shear wave speed (c, m/s), representing tissue stiffness, and loss angle (f, rad), indicating fluidity. Univariate and multivariate logistic regression analyses were used to determine predictors of proliferative HCC. A prediction nomogram of proliferative HCC was constructed.

RESULTS

Multivariate logistic regression analysis results showed that tumor c (OR: 0.24, 95%CI: 0.089-0.63; P = 0.0037), tumor f (OR: 39.12, 95%CI: 2.72-561.94; P=0.007), liver c (OR: 0.12, 95%CI: 0.027- 0.54; P = 0.0056), liver f (OR: 540.64, 95%CI:6.72 - 43521.86; P = 0.0049) and rim APHE (OR: 15.32, 95%CI: 2.87- 81.87; P=0.0014) were independent predictors of proliferative HCC. Combining these variables yielded an AUC of 0.77 (95%CI: 0.69-0.84), sensitivity of 73.02% (95%CI: 0.64-0.86), specificity of 68.85% (95%CI: 0.54-0.79), and accuracy of 70.97% (95%CI: 0.62-0.79), respectively, for predicting proliferative HCC. The C-index of the corresponding nomogram was 0.77 (95%CI: 0.69-0.84).

CONCLUSION

s Proliferative HCC reveals decreased stiffness and increased fluidity for both tumor and liver. Combining biomechanical signature and viscoelasticity could predicate proliferative HCC.

CLINICAL RELEVANCE/APPLICATION

The proliferation class accounts for about 50% of HCCs,which has strong invasiveness and poor prognosis. Therefore, predicting proliferative HCC was urgent and importantto characterize morpho-molecular subtypes for the prediction of prognosis and therapeutic response in clinical practice. We investigated the diagnostic ability of the biomechanical parameters quantified by in vivo tomoelastography for predicting proliferative HCC subtypes. To our knowledge, this is the first study to connect biomechanical properties with the proliferative nature of HCCs. Based on our data, Proliferative HCC may be softer, more liquid like and more bioinvasive than non-proliferative HCC. Additionally, proliferative HCC could be predicted with good accuracy by combing stiffness and fluidity of both the tumor and the liver.

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - GU DPS

Sub-Events

T5A-SPGU-1 MRI guided focused ultrasound ablation (MRgFUS) for localized intermediate-risk prostate cancer - results of a phase II trial

Participants
Sangeet Ghai, MD, Toronto, ON (*Presenter*) Research Grant, INSIGHTEC Ltd

PURPOSE

To explore oncologic and functional outcomes at 2 years following targeted focal therapy performed under MRI guided focused ultrasound (MRgFUS) for intermediate-risk csPCa

METHODS AND MATERIALS

In this prospective phase II trial, between February 2016 and July 2019 , men with MRI visible unifocal csPCa were treated by transrectal MRgFUS. Real time ablation monitoring was performed by MR thermography. Non-perfused volume was measured at treatment completion. Periprocedural complications were recorded. Follow-up included International Prostate Symptom Score (IPSS) and International Index of Erectile Function (IIEF-15) at 24 months, and mpMRI and biopsy at 6 and 24 months. LQMM models were used to model median change from baseline.

RESULTS

Treatment was successfully completed in all 44 men, 36 with Grade Group (GG) 2 and 8 with GG3 disease (median age [IQR]: 67 years [62-70]]. Median (IQR) prostate volume and tumor length 40cc (31.5-50.8) and 9mm (7-12.5) respectively. 17 PCa sites were in peripheral zone and 6 in transition zone. Median (IQR) non perfused volumes were 6.1cc (3.5-8.0). No major treatment-related adverse events occurred. 40 of 44 (91%) sites of PCa (=6mm GG1 disease or any volume =GG2 disease) were free of disease at treatment site at study conclusion (24 months). Additional 3 of 44 participants (7%) had out of field new site of csPCa at 2 years. 37 men (84%) remained free of disease (=6mm GG1 or any volume GG2) at 2 years. Median (IQR) IPSS and IIEF-15 were similar at baseline and 24 months (3.5 [IQR: 2.0-7.0] vs. 4.5 [IQR: 1.0-8.0], p=0.84; 59.5 [25.2-65.0] vs. 31.5 [IQR: 16.2-61.0], p=0.34, respectively). 3 of 7 men with recurrent disease underwent salvage treatment (2 underwent salvage focal treatment by MRI laser therapy and 1 participant underwent radical prostatectomy with negative margins). The remaining 41 of 44 (93%) men including 4 with small volume MR invisible csPCa remain on active surveillance.

CONCLUSION

s Targeted focal therapy of intermediate-risk prostate cancer performed under MRgFUS is safe with very encouraging 2 year oncological and functional outcomes.

CLINICAL RELEVANCE/APPLICATION

MRI guided targeted focal therapy by MRgFUS is a feasible treatment option in men with localized clinically significant prostate cancer (csPCa).

T5A-SPGU-2 Fat-containing adnexal masses on MRI: solid tissue volume and fat distribution as a guide for O-RADS Score assignment

Participants
Monica Cheng, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the O-RADS MRI scoring system for fat-containing adnexal masses, by investigating the optimal method for quantifying volume of solid tissue and the associations between fat distribution and malignant histology.

METHODS AND MATERIALS

This retrospective single-center study included consecutive patients with fat-containing ovarian masses on MRI during 2008-2021. Two radiologists (R1, R2) independently reviewed MRI for overall size, size of any solid tissue, size of solid tissue that was not a Rokitansky nodule (RN), and distribution of fat (fat only, fat-fluid level, fat balls, focal, scattered). Reference standard was pathology or follow-up >6 months. Wilcoxon rank sum test, Fisher exact test, and ROC curve tests were used for statistical analysis. Data are presented as median (interquartile ranges).

RESULTS

205 women (age 35years; range 25-46) with 180 benign lesions (including 172 mature teratomas) and 25 malignant lesions (10 immature teratomas, 5 teratomas with malignant transformation, 6 mixed germ cell tumors, and 4 others) were included. Overall size

(9.9 cm [8.4-14.8] vs 5.6 cm [3.7-8.1] for R1;12.4 cm [8.5-15.2] vs 5.7 cm [3.8-8.1] for R2), size of any solid tissue (5.1 cm [2-10] vs 1.2 cm [0-2.1] for R1; 3.2 cm [1.5-6.7] vs 0 cm [0-1.5] for R2), size of non-RN solid tissue (5.1 cm [0-10] vs 0 cm [0-0] for R1; 3.1 cm [1.0-6.7] vs 0 cm [0-0] for R2), and distribution of fat were all significantly different between malignant and benign lesions ($p<0.01$). The area under the ROC was greatest for size of non-RN solid tissue (0.84 [95%CI 0.74-0.93] for R1; 0.86 [95%CI 0.77-0.95] for R2) compared to overall size of mass (0.80 [95%CI 0.69-0.91] for R1; 0.83 [95%CI 0.73-0.92] for R2) and size of any solid tissue (0.80 [0.69-0.91] for R1; 0.81 [95% CI, 0.71-0.92] for R2). Optimal cutoffs using non-RN solid tissue were =1.2 cm (R1) and =1.0 cm (R2), yielding sensitivities and specificities of 0.72 (95%CI 0.51-0.88) and 0.93 (95%CI 0.89-0.97) for R1 and 0.76 (95%CI 0.55-0.91) and 0.95 (95%CI 0.91-0.98) for R2. Scattered fat was present in most (9/10) immature teratomas and mixed germ cell tumors for both R1 and R2.

CONCLUSION

s In patients with fat-containing ovarian masses, size of overall mass, size of solid tissue, and distribution of fat were significantly different between benign and malignant lesions.

CLINICAL RELEVANCE/APPLICATION

To refine O-RADS, a simple approach assessing size of solid tissue that is not a Rokitansky nodule and scattered fat may be useful for determining ovarian malignancy.

T5A-SPGU-3 Investigationof multiparametric magnetic resonance imaging applied in evaluating bladder cancer pathological response after neoadjuvant immunotherapy.

Participants
Lingmin Kong, Guangdong, China (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the diagnostic performance of T2WI,dynamic contrast-enhanced(DCE) and diffusion-weighted(DW) MRI in discriminating bladder cancer(BCa) pathological changes after neoadjuvant chemotherapy(NAC) plus immunotherapy.

METHODS AND MATERIALS

This prospective study included 13 patients with pathologically confirmed BCa, who underwent both pre- and post treatment (at least two cycles of NAC plus immunotherapy that is Cisplatin-based NAC in combination with immunotherapy,including Tislelizumab,Toripalimab or Sintilimab Injection) MR imaging and subsequent cystectomy or transurethral resection. MRI examinations included conventional MRI sequences(T1 weighted, T2 weighted imaing) and functional MRI sequences(DCE, DW imaging) on a 3.0T scanner (Signa Pioneer, GE, Milwaukee, WI, USA). The tumor response was assessed by two senior radiologists through three steps(figure 1). The results(table 1) were compared with the findings at histopathology specimens obtained after NAC.

RESULTS

On post neoadjuvant immunotherapy cystectomy or transurethral resection specimens, pathological complete response(pCR) was confirmed in 7 patients (53.8%, 7/13). The diagnostic accuracy of multiparametric magnetic resonance imaging(mp MRI) in distinguishing complete response(CR) from non-CR was 100%.

CONCLUSION

s Mp MRI can be a potential noninvasive technique for evaluating BCa pathological response after NAC plus immunotherapy.

CLINICAL RELEVANCE/APPLICATION

Immune checkpoint inhibitors (ICIs), especially PD-1/PD-L1 inhibitors, emerged as an important treatment strategy in muscle invasive bladder cancer and cisplatin-based NAC plus immunotherapy becomes research focus recently. This study first investigate the diagnostic potential of multiparametric magnetic resonance imaging(mp MRI) in evaluating BCa pathological response after NAC plus immunotherapy and showed that the combination of T2WI,dynamic contrast-enhanced MR(DCE-MR) and diffusion-weighted MR(DW-MR) had significant advantages in discriminating pathological changes. The results indicated that mp MRI may be a useful non-invasive imaging biomarker that can not only evaluate pathological response but also select BCa patients who are suitable for conservative therapy,to further salvage unnecessary operation and improve patients' life quality.

T5A-SPGU-1

MRI guided focused ultrasound ablation (MRgFUS) for localized intermediate-risk prostate cancer -results of a phase II trial

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - GU DPS

Participants
Sangeet Ghai, MD, Toronto, ON (*Presenter*) Research Grant, INSIGHTEC Ltd

PURPOSE

To explore oncologic and functional outcomes at 2 years following targeted focal therapy performed under MRI guided focused ultrasound (MRgFUS) for intermediate-risk csPCa

METHODS AND MATERIALS

In this prospective phase II trial, between February 2016 and July 2019 , men with MRI visible unifocal csPCa were treated by transrectal MRgFUS. Real time ablation monitoring was performed by MR thermography. Non-perfused volume was measured at treatment completion. Periprocedural complications were recorded. Follow-up included International Prostate Symptom Score (IPSS) and International Index of Erectile Function (IIEF-15) at 24 months, and mpMRI and biopsy at 6 and 24 months. LQMM models were used to model median change from baseline.

RESULTS

Treatment was successfully completed in all 44 men, 36 with Grade Group (GG) 2 and 8 with GG3 disease (median age [IQR]: 67 years [62-70]]. Median (IQR) prostate volume and tumor length 40cc (31.5-50.8) and 9mm (7-12.5) respectively. 17 PCa sites were in peripheral zone and 6 in transition zone. Median (IQR) non perfused volumes were 6.1cc (3.5-8.0). No major treatment-related adverse events occurred. 40 of 44 (91%) sites of PCa (=6mm GG1 disease or any volume =GG2 disease) were free of disease at treatment site at study conclusion (24 months). Additional 3 of 44 participants (7%) had out of field new site of csPCa at 2 years. 37 men (84%) remained free of disease (=6mm GG1 or any volume GG2) at 2 years. Median (IQR) IPSS and IIEF-15 were similar at baseline and 24 months (3.5 [IQR: 2.0-7.0] vs. 4.5 [IQR: 1.0-8.0], p=0.84; 59.5 [25.2-65.0] vs. 31.5 [IQR: 16.2-61.0], p=0.34, respectively). 3 of 7 men with recurrent disease underwent salvage treatment (2 underwent salvage focal treatment by MRI laser therapy and 1 participant underwent radical prostatectomy with negative margins). The remaining 41 of 44 (93%) men including 4 with small volume MR invisible csPCa remain on active surveillance.

CONCLUSION

s Targeted focal therapy of intermediate-risk prostate cancer performed under MRgFUS is safe with very encouraging 2 year oncological and functional outcomes.

CLINICAL RELEVANCE/APPLICATION

MRI guided targeted focal therapy by MRgFUS is a feasible treatment option in men with localized clinically significant prostate cancer (csPCa).

Head and Neck Tuesday Poster Discussions - A

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - HN DPS

Sub-Events

T5A-SPHN-1 Application Value of Radiomic Nomogram Based on Preoperative HRCT in Predicting Fallopian Canal Involvement in Cholesteatoma

Participants
Xiaoxue Fan, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

Cholesteatoma growth pattern predicts frequent involvement of the tympanic segment of the fallopian canal, and fallopian canal dehiscence is a major risk factor for facial nerve injury during middle ear mastoid surgery. The purpose of this study was to establish and validate a non-contrast HRCT based radiomic nomogram for predicting fallopian canal involvement in patients with cholesteatoma.

METHODS AND MATERIALS

214 consecutive patients (157 in the training set and 57 in the test set) who underwent surgery and had pathologically confirmed cholesteatoma were retrospectively included. Open-source radiomics software was used to select and extract features on the HRCT. A radiomics signature model was constructed to fallopian canal involvement using the least absolute shrinkage and selection operator (LASSO). Radiomic features, clinically independent risk factors were incorporated into multivariate logistic regression analysis and presented in the formation of a nomogram for predicting fallopian canal involvement in both the training and test sets, which were evaluated by its discrimination, calibration, and clinical usefulness.

RESULTS

A radiomics model consisting of seven radiomic features with a good prognostic ability in the training set with the area under the curve (AUC) of 0.85 (95%CI, 0.78-0.90), which was also confirmed in the test set with an AUC of 0.81 (95%CI, 0.68-0.90). Multivariate logistic regression identifies cerebral plate hypoplasia and stapes destruction as independent risk factors for fallopian canal involvement in cholesteatoma. The nomogram consisting of the radiomics scores and cerebral plate hypoplasia and stapes destruction showed good discrimination ability in the training and test sets with an AUC of 0.91 (95%CI, 0.85-0.95) and an AUC of 0.83 (95%CI, 0.71-0.92), respectively. Decision curve analysis showed that the radiomic nomogram was clinically useful.

CONCLUSION

s Radiomic nomogram based on the non-contrast HRCT is a useful tool for the prediction of fallopian canal involvement in patients with cholesteatoma, which can assist clinicians for optimized risk stratification of patients preoperatively and take effective measures to prevent intraoperative facial nerve injury.

CLINICAL RELEVANCE/APPLICATION

This study developed and validated the efficacy of preoperative individualized prediction of fallopian canal involvement in patients with cholesteatoma based on radiomics nomogram of HRCT scans. The radiomics nomogram drawings include the radiomic model, stapes involvement, and low cerebral plate. The easy-to-use radiomics nomogram showed good discrimination in both the training set (AUC, 0.910) and the test set (AUC, 0.828), outperforming traditional clinical factors.

T5A-SPHN-3 Otomastoiditis: A Potentially Overused and Unnecessarily Alarmist Term in the Reporting of Non-contrast Head CT

Participants
Jimmy Swanson, MD, Winston Salem, NC (*Presenter*) Nothing to Disclose

PURPOSE

Otomastoiditis is a rare, clinically diagnosed infection with potential for life-threatening intracranial complications. Middle ear and mastoid opacification are common, nonspecific imaging findings. Some radiologists attribute middle ear and mastoid opacification to otomastoiditis, even in the absence of supportive clinical features. This approach is potentially problematic and may result in unnecessary antibiotic use and otolaryngology consults. Among inpatients and emergency department (ED) patients undergoing noncontrast head CT for reasons unrelated to suspected temporal bone pathology whose radiology report includes the term "otomastoiditis," we hypothesize a low prevalence of true, clinically diagnosed otomastoiditis. Our purpose is to determine the true otomastoiditis prevalence in this population and to characterize downstream effects of radiologist "otomastoiditis" usage.

METHODS AND MATERIALS

Inpatients and ED patients undergoing noncontrast head CT between February 2018 and August 2021 were retrospectively reviewed. The following inclusion criteria were applied: 1) age 18+ years, 2) indication unrelated to temporal bone pathology, 3) no known temporal bone pathology or prior surgery, 4) "otomastoiditis" used in the radiology report. Patient demographics and relevant

clinical information were collected from the electronic health record. Among patients with clinically diagnosed otomastoiditis, CT imaging was reviewed to assess for imaging features specific for otomastoiditis (e.g., coalescence, epidural abscess).

RESULTS

A total of 92 patients (54 male, 38 female, mean age 63 years) formed the study cohort. Otolaryngology was consulted to evaluate possible otomastoiditis in 7 (8%), antibiotics were initiated prior to consultation in 3 (3%), and a clinical diagnosis of otomastoiditis was established in 1 (1%) patient whose head CT demonstrated mastoid erosion, pneumocephalus, and temporal lobe edema.

CONCLUSION

s Although the term "otomastoiditis" was used in 100% of our cohort's radiology reports, the true prevalence was only 1%. Importantly, no patients with sole imaging findings of middle ear and mastoid opacification received a clinical diagnosis of otomastoiditis. Absent clinical suspicion for infection or imaging evidence of an infectious complication, we recommend the descriptive term "opacification" over "otomastoiditis" to minimize the risk of unwarranted otolaryngology consults and unnecessary antibiotic usage.

CLINICAL RELEVANCE/APPLICATION

The clinical relevance of this study is that the data provide justification for using the term "opacification" over "otomastoiditis" in the absence of clinical suspicion for infection or imaging evidence of an infectious complication.

T5A-SPIN

Informatics Tuesday Poster Discussions - A

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - IN DPS

Sub-Events

T5A-SPIN-1 Intelligent Denoising

Participants
Marina Manso Jimeno, New York, NY (*Presenter*) Nothing to Disclose

PURPOSE

To accelerate the Alzheimer's disease (AD) screening MRI protocol employed at our institution by trading off signal-to-noise ratio (SNR) for faster acquisition time. SNR is recovered post-acquisition via image denoising using deep learning (DL). We aim to (i) improve imaging throughput; (ii) guarantee image quality using DL denoising, measured by peak SNR (PSNR, dB) and structural similarity index (SSIM) compared to the unaccelerated acquisitions.

METHODS AND MATERIALS

Intelligent protocolling The routine protocol (gold standard, GS) consisted of two T1 sagittal sequences and five axial sequences: T2, DWI, T2 FLAIR, T2*, and T1, totaling 19:47 (minutes: seconds). The accelerated protocol (Fastest) was constructed by consulting sequence-specific Look Up Tables similarly to Ravi et al., MRI, 2020, to obtain acquisition parameters yielding the shortest acquisition times and highest relative SNRs. Two experiments were performed to investigate: (1) improvement in throughput (measured by table time; 1 volunteer); (2) repeatability across 5 sessions (5 volunteers). All healthy volunteers were imaged on a GE 3T Premier scanner, and 26 datasets were acquired in total.Image denoising using deep learning Contrast-specific baseline deep learning (DL) models and subject-specific DL (DL-SS) models were trained on publicly available datasets for image denoising. The noise was forward simulated similarly to Geethanath et al., ISMRM, 2021. All models utilized a common network architecture and were trained for 75 epochs. DL-SS were obtained by fine-tuning the DL models on the worst SNR data acquired across all repeats from experiment #2. Additionally, DL-based unsharp masking was performed. The four methods (GS, Fastest, DL, DL-SS) were evaluated on PSNR, SSIM over 5 contrasts, and volumetry values for 99 regions obtained from T1 data using the tool described in Thomas et al., IEEE BIBE, 2020.

RESULTS

The table times measured from experiment 1 were 19:12 and 9:52 for the GS and Fastest protocols, respectively. This was a 1.94x gain in imaging throughput. The mean improvement in PSNR/SSIM across contrasts were 3.943/0.083 (DL) and 5.570/0.100 (DL-SS). The mean RMSE of 12 T1 volumetry measures from GS data were 12.335 (Fastest), 6.607 (DL), and 4.293 (DL-SS), respectively. On-going work involves evaluating these methods on clinically relevant metrics for the remaining contrasts.

CONCLUSION

s The Fastest protocol resulted in a 1.94x gain in imaging throughput. The DL-SS models outperformed the baseline DL models, yielding a mean improvement of 7.1813 dB/0.1256 (PSNR/SSIM).

CLINICAL RELEVANCE/APPLICATION

Intelligent protocolling can improve AD screening throughput and DL-based image denoising can guarantee image quality.

T5A-SPIN-3 Automated AI Pipeline for Brain Lesion Classification using Dual-Energy Computed Tomography

Participants
Colin Schaeffer, MS, (*Presenter*) Nothing to Disclose

PURPOSE

The current protocol for patients presenting with stroke-like symptoms is a CT scan with iodinated contrast. If it is then determined that the patient is having an ischemic stroke, the patient is treated with blood thinners; however, blood thinners put the patient at further risk of hemorrhagic transformation. Therefore, it is hospital protocol to rescan the patient using dual-energy CT (DECT) within 24 hours to monitor for bleeds. The problem with rescanning in such a short period of time is that it is possible for residual iodine contrast to still be present in the brain. Discriminating between hemorrhages and residual contrast is a difficult task for radiologists. What we propose in this study is a form of computer aided diagnosis system that uses a three step A.I. pipeline to identify images with lesions, segment the lesion, and then classify it as either residual contrast or an intracranial hemorrhage. This project presents the first two steps in the pipeline: 1) Lesion identification and 2) Lesion segmentation.

METHODS AND MATERIALS

For our identification model, with IRB approval, we obtained 11,547 head CT scans (10,000 without lesions and 1,547 with lesions). This dataset was filtered and stratified into a training set of 7,490 images and a test set of 1,873 images. We then used a five-fold cross validation method on the training set for hyperparameter tuning and model selection. For our segmentation algorithm, the image volumes were co-registered and skull stripped before training both an unsupervised anomaly detection algorithm and a

supervised U-net architecture for segmentation. These models were tested and compared on a set of manually segmented images.

RESULTS

Our model to identify brain volumes containing lesions obtained an average area under the curve (AUC) of 0.942 when evaluated using a five-fold cross validation method.

CONCLUSION

s We have developed an automated A.I. pipeline that can be used to identify and segment brain lesions in follow-up stroke DECT imaging. This pipeline can be used to extract quantitative information about the lesions from DECT data which can then be used to classify the lesion.

CLINICAL RELEVANCE/APPLICATION

An A.I. pipeline such as the one proposed in this study addresses the clinical problem of residual contrast in follow-up stroke imaging. Residual iodine contrast can hinder diagnosis. While reader studies using DECT iodine maps have been published addressing this problem, no quantitative model to differentiate blood from iodine has been published.

T5A-SPIN-4 Gender Disparity in Developing a Convolutional Neural Network Specific for The Identification of Infrarenal Abdominal Aortic Aneurysms

Participants
Justin Camara, MD, Loma Linda, CA (*Presenter*) Nothing to Disclose

PURPOSE

To determine if gender training and testing factors affect the accuracy of a convolutional neural network (CNN) for infrarenal abdominal aortic aneurysms (AAA) identification on computed tomography angiogram (CTA) scans.

METHODS AND MATERIALS

From 2015 to 2020, a HIPAA-compliant, IRB-approved, retrospective study analyzed 400 abdominopelvic CTA scans. Utilizing a previously reported methodology to develop a foundational AAA-specific trained CNN, 6 new CNN models were created under varying gender training and testing conditions to assess overall accuracy: male-only training/male-only testing, female-only training/female-only testing, male-only training/all testing, female-only training/all testing, all training/male-only testing, all training/female-only testing. Model accuracy and AUC were analyzed and reported. Misjudgments were analyzed by review of heatmaps, via gradient weighted class activation, overlaid on CTA images.

RESULTS

Similar to our previously reported custom CNN model for AAA on CTA images, five of six of the new gender-restricted training/testing CNN models also demonstrated high levels of sensitivities (96.6% - 99.1%), specificities (98.4% - 99.6%), and overall accuracies (98.0% - 99.1%). However, the gender model that was trained with female-only cases and tested on both male and female cases demonstrated a significantly reduced level of specificity (87.7%) and reduced overall accuracy (93.0%). Interestingly, the companion gender model (male-only cases and tested on both male and female cases) maintained a high level of specificity (99.5%) and overall accuracy (98.0%). A preliminary subanalysis of misjudgements in the female-only trained model demonstrates aneurysm size and mural thrombus to be predominant factors in false negative misjudgment cases and errors in segmentation to be the predominant factor in false positive misjudgements.

CONCLUSION

s Preliminary analysis determined that female-only gender training has a reduced accuracy in the development of CNN for AAA identification on CT angiograms. Further investigation is needed to elucidate the reason for the gender disparity to rectify any future AI AAA modeling for real-world application and deployment.

CLINICAL RELEVANCE/APPLICATION

Gender disparity in medicine and radiology needs further investigation. Although not deeply studied in machine learning, such studies are important to reduce any gender bias/disparity in any future AI modeling for real-world application and deployment.

T5A-SPIN-5 Deep Transfer Learning Strategy For Whole-body Aorta Segmentation Using CT Angiography Image of Two Acquisition Protocols

Participants
Seung-Won Yang, MS, (*Presenter*) Nothing to Disclose

PURPOSE

To develop a deep learning algorithm for whole-body aorta segmentation on CT angiography (CTA) images in normal population, utilizing transfer learning strategy across two CT acquisition protocols of coronary and whole-body aorta.

METHODS AND MATERIALS

In order for the whole-body aorta segmentation task to leverage the benefit of coronary CTA (CCTA) with high-resolution features by dedicated acquisition protocol and its relatively lower labeling cost, we enrolled two kinds of CTA scans separately: CT scans of 368 patients who underwent ECG-gated CCTA were included for the pre-training of aortic root and ascending aorta segmentation, and CT scans of 100 patients who underwent ECG-gated aorta CTA using high-pitch helical mode were used for the whole-body aorta segmentation. Non-experts labeled aorta by using a manual toolkit, and an expert radiologist examined its validity before the data were enrolled. The labeled dataset was finally refined by applying preprocessing algorithms of equalization, denoising, interpolation, and normalization (and divided into train and test sets with a ratio of 9:1). The pre-training model adopted U-shape architecture as a backbone network, and is fed with augmented data under the RandAugment strategy of an automated augmentation method. In the whole-body segmentation, we built a Swin-Transformer based encoder-decoder network of which backbone layers are initialized by the pre-trained weights. As for loss function, we used a combo loss that is weighted summation of distribution-based and overlap-based losses.

RESULTS

To assess model performance, we introduced the dice score coefficient (DSC) and the averaged Hausdorff distance (AHD) in mm. The pre-trained model achieved high performance with DSC of 0.969±0.0223 and AHD of 1.80±1.06 for aortic root and ascending aorta segmentation. The proposed model for the whole-body aorta segmentation also showed improvement compared to a non-transferred model, so that the metrics were improved from 0.929±0.0231 and 7.53±4.76 to 0.935±0.0125 and 5.71±2.35. Particularly, we witnessed the knowledge transfer makes the aortic root segmentation in whole-body CTA more accurate, yielding better DSC and AHD from 0.896±0.102 and 13.1±8.82 to 0.921±0.0712 and 11.2±9.15.

CONCLUSION

s Our approach is able to improve performance of the whole-body aorta segmentation model to be comparable to radiologists, utilizing the CCTA that has detail anatomic information and lower labeling cost.

CLINICAL RELEVANCE/APPLICATION

The proposed model can be built with less effort in data collection, and is practical enough to provide geometric parameters of the whole-body aorta that can be used for further medical applications, such as follow-up of aortic aneurysm or planning for catheter treatment.

T5A-SPIN-6 A Deep-learning Method for Intracranial Aneurysm Detection on Computed Tomographic Angiography Images

PURPOSE

Computed tomographic angiography (CTA) is preferred for intracranial aneurysms (IAs) screening. Recently, deep learning-based algorithms show the potential to detect IAs in CTA. However, low diagnostic accuracy and high false-positive results were found in these models. The aim of this study is to develop a deep learning model with improved diagnostic accuracy and validated in real-world data.

METHODS AND MATERIALS

The model consisted of a U-Net based segmentation network and a refine network. It differentiated voxels being potential IAs on 3D patches of CTA images. Only the patches that contained positive voxels were proceeded by the refine network, and the possibilities of these patches having IAs were computed. By focusing on the positive patches from the segmentation results, the refine network screened discriminative features and reduced false-positive results. The model was trained and validated using a public dataset with 1338 CTA scans. Then, the model was tested in a dataset of 38 patients with IAs who have both CTA and DSA results. Finally, two radiologists with more than 10 years' experience reviewed the dataset with and without the assistance of AI.

RESULTS

For the public dataset, after applying the refine network, the precision on lesion level surged from 45.5% to 69.4% without sacrificing the diagnostic sensitivity (96% vs. 95.2%) (Figure 1-A). On the patient level, the precision increased from 89.5% to 94.8% with a similar diagnostic sensitivity of (97.3% versus 96.7%). For the real-world dataset, with the assistance of AI, radiologists obtained higher diagnostic accuracy compared to without AI (Figure 1-B). In detail, diagnostic sensitivity increased from 64.9% to 91% and precision increased from 83.8% to 97.3%).

CONCLUSION

s The refine network improved the diagnostic precision for CTA detection of IAs. With the assistance of this model, radiologists improved diagnostic accuracy for IAs.

CLINICAL RELEVANCE/APPLICATION

The proposed deep learning method may help make clinical diagnoses of IAs. It may improve the diagnostic accuracy for IAs screening in CTA.

Intelligent Denoising

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - IN DPS

Participants
Marina Manso Jimeno, New York, NY (*Presenter*) Nothing to Disclose

PURPOSE

To accelerate the Alzheimer's disease (AD) screening MRI protocol employed at our institution by trading off signal-to-noise ratio (SNR) for faster acquisition time. SNR is recovered post-acquisition via image denoising using deep learning (DL). We aim to (i) improve imaging throughput; (ii) guarantee image quality using DL denoising, measured by peak SNR (PSNR, dB) and structural similarity index (SSIM) compared to the unaccelerated acquisitions.

METHODS AND MATERIALS

Intelligent protocolling The routine protocol (gold standard, GS) consisted of two T1 sagittal sequences and five axial sequences: T2, DWI, T2 FLAIR, T2*, and T1, totaling 19:47 (minutes: seconds). The accelerated protocol (Fastest) was constructed by consulting sequence-specific Look Up Tables similarly to Ravi et al., MRI, 2020, to obtain acquisition parameters yielding the shortest acquisition times and highest relative SNRs. Two experiments were performed to investigate: (1) improvement in throughput (measured by table time; 1 volunteer); (2) repeatability across 5 sessions (5 volunteers). All healthy volunteers were imaged on a GE 3T Premier scanner, and 26 datasets were acquired in total.Image denoising using deep learning Contrast-specific baseline deep learning (DL) models and subject-specific DL (DL-SS) models were trained on publicly available datasets for image denoising. The noise was forward simulated similarly to Geethanath et al., ISMRM, 2021. All models utilized a common network architecture and were trained for 75 epochs. DL-SS were obtained by fine-tuning the DL models on the worst SNR data acquired across all repeats from experiment #2. Additionally, DL-based unsharp masking was performed. The four methods (GS, Fastest, DL, DL-SS) were evaluated on PSNR, SSIM over 5 contrasts, and volumetry values for 99 regions obtained from T1 data using the tool described in Thomas et al., IEEE BIBE, 2020.

RESULTS

The table times measured from experiment 1 were 19:12 and 9:52 for the GS and Fastest protocols, respectively. This was a 1.94x gain in imaging throughput. The mean improvement in PSNR/SSIM across contrasts were 3.943/0.083 (DL) and 5.570/0.100 (DL-SS). The mean RMSE of 12 T1 volumetry measures from GS data were 12.335 (Fastest), 6.607 (DL), and 4.293 (DL-SS), respectively. On-going work involves evaluating these methods on clinically relevant metrics for the remaining contrasts.

CONCLUSION

s The Fastest protocol resulted in a 1.94x gain in imaging throughput. The DL-SS models outperformed the baseline DL models, yielding a mean improvement of 7.1813 dB/0.1256 (PSNR/SSIM).

CLINICAL RELEVANCE/APPLICATION

Intelligent protocolling can improve AD screening throughput and DL-based image denoising can guarantee image quality.

T5A-SPIN-3

Automated AI Pipeline for Brain Lesion Classification using Dual-Energy Computed Tomography

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - IN DPS

Participants
Colin Schaeffer, MS, (*Presenter*) Nothing to Disclose

PURPOSE

The current protocol for patients presenting with stroke-like symptoms is a CT scan with iodinated contrast. If it is then determined that the patient is having an ischemic stroke, the patient is treated with blood thinners; however, blood thinners put the patient at further risk of hemorrhagic transformation. Therefore, it is hospital protocol to rescan the patient using dual-energy CT (DECT) within 24 hours to monitor for bleeds. The problem with rescanning in such a short period of time is that it is possible for residual iodine contrast to still be present in the brain. Discriminating between hemorrhages and residual contrast is a difficult task for radiologists. What we propose in this study is a form of computer aided diagnosis system that uses a three step A.I. pipeline to identify images with lesions, segment the lesion, and then classify it as either residual contrast or an intracranial hemorrhage. This project presents the first two steps in the pipeline: 1) Lesion identification and 2) Lesion segmentation.

METHODS AND MATERIALS

For our identification model, with IRB approval, we obtained 11,547 head CT scans (10,000 without lesions and 1,547 with lesions). This dataset was filtered and stratified into a training set of 7,490 images and a test set of 1,873 images. We then used a five-fold cross validation method on the training set for hyperparameter tuning and model selection. For our segmentation algorithm, the image volumes were co-registered and skull stripped before training both an unsupervised anomaly detection algorithm and a supervised U-net architecture for segmentation. These models were tested and compared on a set of manually segmented images.

RESULTS

Our model to identify brain volumes containing lesions obtained an average area under the curve (AUC) of 0.942 when evaluated using a five-fold cross validation method.

CONCLUSION

s We have developed an automated A.I. pipeline that can be used to identify and segment brain lesions in follow-up stroke DECT imaging. This pipeline can be used to extract quantitative information about the lesions from DECT data which can then be used to classify the lesion.

CLINICAL RELEVANCE/APPLICATION

An A.I. pipeline such as the one proposed in this study addresses the clinical problem of residual contrast in follow-up stroke imaging. Residual iodine contrast can hinder diagnosis. While reader studies using DECT iodine maps have been published addressing this problem, no quantitative model to differentiate blood from iodine has been published.

T5A-SPIN-4

Gender Disparity in Developing a Convolutional Neural Network Specific for The Identification of Infrarenal Abdominal Aortic Aneurysms

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - IN DPS

Participants
Justin Camara, MD, Loma Linda, CA (*Presenter*) Nothing to Disclose

PURPOSE

To determine if gender training and testing factors affect the accuracy of a convolutional neural network (CNN) for infrarenal abdominal aortic aneurysms (AAA) identification on computed tomography angiogram (CTA) scans.

METHODS AND MATERIALS

From 2015 to 2020, a HIPAA-compliant, IRB-approved, retrospective study analyzed 400 abdominopelvic CTA scans. Utilizing a previously reported methodology to develop a foundational AAA-specific trained CNN, 6 new CNN models were created under varying gender training and testing conditions to assess overall accuracy: male-only training/male-only testing, female-only training/female-only testing, male-only training/all testing, female-only training/all testing, all training/male-only testing, all training/female-only testing. Model accuracy and AUC were analyzed and reported. Misjudgments were analyzed by review of heatmaps, via gradient weighted class activation, overlaid on CTA images.

RESULTS

Similar to our previously reported custom CNN model for AAA on CTA images, five of six of the new gender-restricted training/testing CNN models also demonstrated high levels of sensitivities (96.6% - 99.1%), specificities (98.4% - 99.6%), and overall accuracies (98.0% - 99.1%). However, the gender model that was trained with female-only cases and tested on both male and female cases demonstrated a significantly reduced level of specificity (87.7%) and reduced overall accuracy (93.0%). Interestingly, the companion gender model (male-only cases and tested on both male and female cases) maintained a high level of specificity (99.5%) and overall accuracy (98.0%). A preliminary subanalysis of misjudgements in the female-only trained model demonstrates aneurysm size and mural thrombus to be predominant factors in false negative misjudgment cases and errors in segmentation to be the predominant factor in false positive misjudgements.

CONCLUSION

s Preliminary analysis determined that female-only gender training has a reduced accuracy in the development of CNN for AAA identification on CT angiograms. Further investigation is needed to elucidate the reason for the gender disparity to rectify any future AI AAA modeling for real-world application and deployment.

CLINICAL RELEVANCE/APPLICATION

Gender disparity in medicine and radiology needs further investigation. Although not deeply studied in machine learning, such studies are important to reduce any gender bias/disparity in any future AI modeling for real-world application and deployment.

T5A-SPIN-5

Deep Transfer Learning Strategy For Whole-body Aorta Segmentation Using CT Angiography Image of Two Acquisition Protocols

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - IN DPS

Participants
Seung-Won Yang, MS, (*Presenter*) Nothing to Disclose

PURPOSE

To develop a deep learning algorithm for whole-body aorta segmentation on CT angiography (CTA) images in normal population, utilizing transfer learning strategy across two CT acquisition protocols of coronary and whole-body aorta.

METHODS AND MATERIALS

In order for the whole-body aorta segmentation task to leverage the benefit of coronary CTA (CCTA) with high-resolution features by dedicated acquisition protocol and its relatively lower labeling cost, we enrolled two kinds of CTA scans separately: CT scans of 368 patients who underwent ECG-gated CCTA were included for the pre-training of aortic root and ascending aorta segmentation, and CT scans of 100 patients who underwent ECG-gated aorta CTA using high-pitch helical mode were used for the whole-body aorta segmentation. Non-experts labeled aorta by using a manual toolkit, and an expert radiologist examined its validity before the data were enrolled. The labeled dataset was finally refined by applying preprocessing algorithms of equalization, denoising, interpolation, and normalization (and divided into train and test sets with a ratio of 9:1). The pre-training model adopted U-shape architecture as a backbone network, and is fed with augmented data under the RandAugment strategy of an automated augmentation method. In the whole-body segmentation, we built a Swin-Transformer based encoder-decoder network of which backbone layers are initialized by the pre-trained weights. As for loss function, we used a combo loss that is weighted summation of distribution-based and overlap-based losses.

RESULTS

To assess model performance, we introduced the dice score coefficient (DSC) and the averaged Hausdorff distance (AHD) in mm. The pre-trained model achieved high performance with DSC of 0.969±0.0223 and AHD of 1.80±1.06 for aortic root and ascending aorta segmentation. The proposed model for the whole-body aorta segmentation also showed improvement compared to a non-transferred model, so that the metrics were improved from 0.929±0.0231 and 7.53±4.76 to 0.935±0.0125 and 5.71±2.35. Particularly, we witnessed the knowledge transfer makes the aortic root segmentation in whole-body CTA more accurate, yielding better DSC and AHD from 0.896±0.102 and 13.1±8.82 to 0.921±0.0712 and 11.2±9.15.

CONCLUSION

s Our approach is able to improve performance of the whole-body aorta segmentation model to be comparable to radiologists, utilizing the CCTA that has detail anatomic information and lower labeling cost.

CLINICAL RELEVANCE/APPLICATION

The proposed model can be built with less effort in data collection, and is practical enough to provide geometric parameters of the whole-body aorta that can be used for further medical applications, such as follow-up of aortic aneurysm or planning for catheter treatment.

T5A-SPIR

Interventional Tuesday Poster Discussions - A

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - IR DPS

Sub-Events

T5A-SPIR-1 Cryoablation of Breast Cancer in Metastatic Patients. A Single Institutional Experience

Participants
Claudio Pusceddu, MD, (*Presenter*) Nothing to Disclose

PURPOSE

to evaluate the safety and efficacy of breast cryoablation (CRA) as local therapy for patient with metastatic breast cancer.

METHODS AND MATERIALS

thirty-nine breast lesions, mean size 2,1 (range 1 - 6,7 cm) in twenty-nine consecutive patients, mean age 51 (36-81) with core-needle biopsy-proven breast carcinoma and metastases were included in this study. Twenty-three patients had one lesion, 4 patients two lesions, 1 patient three lesions and 1 patient five lesions. Under local anaesthesia and mild conscious sedation, the tumour and surrounding breast tissue were ablated with percutaneous CT-guided CRA. Cryoablation consisted of 2 cycles each of 10 minutes of freezing followed by a 4-min active and 4-min passive thawing phase for each one. Twenty-four patients underwent one CRA session, four patients 2 CRA sessions and one patient underwent 3 CRA sessions.

RESULTS

all CRA sessions were successfully completed and all breast tumours were ablated. Morbidity consisted in transient and mild ecchymotic changes and post-procedural oedema seen in ten cases. The therapeutic outcomes were evaluated by contrast-enhanced TC or MRI at 2-, 6-, 12-, and 18-month intervals. The absence of tumour enhancement TC or MR image was considered as indicating complete tumour necrosis. During the mean follow-up of 15 months (6- 28 months) 26 patients had shown complete response to the treatment. Only 3 patients out 29 (10%) showed relapse close to the treated lesion.

CONCLUSION

s CRA of metastatic breast cancer is a safe and effective method which allows local control of the disease.

CLINICAL RELEVANCE/APPLICATION

This method can effectively be used with good local control of the disease in patients who present with metastases at the beginning of the illness.

T5A-SPIR-2 Outcomes of Percutaneous Cholangioscopy Directed Biopsies for Suspicious Biliary Lesions

Participants
Tushar Garg, MD, Baltimore, MD (*Presenter*) Conference Travel, Siemens Healthineers

PURPOSE

To evaluate the safety and effectiveness of percutaneous cholangioscopy (PC)-directed biopsies for the evaluation of biliary pathology.

METHODS AND MATERIALS

This was an IRB-approved, retrospective study evaluating patients who underwent PC-directed biopsy for biliary pathology from July 2013 and January 2022. Fifteen patients (10 male; mean age 61 [range 48-84] years) underwent 15 PC-directed biopsies for various indications. The technical success was defined as successful access with endoscope and visualization of the biliary system, while procedural success was defined as successful biopsy of the lesion if present.

RESULTS

Out of the 15 PC-directed biopsies, 8 (53.3%) were performed to rule out recurrence of malignancy, 3 (20%) to evaluate a mass lesion, 2 (13.3%) to evaluate a filling defect, and 1(6.6%) to evaluate the extent of malignancy. The technical and procedural success rate for the procedure was 100% (15/15), however, there was failure to obtain a clamshell biopsy in one procedure for which successful brush biopsy was performed. Clamshell biopsy (1.6 mm forceps) was done in 86.6% (13/15) of procedures with a median of 3 samples per procedure and brush biopsy (1.72 mm or 3 mm cytology brush) was taken in 6 (40%) procedures with a median of 2.5 samples per procedure. All samples obtained were adequate to make a pathological diagnosis and led to change in patient management. No complications were seen during the procedure and up to 30-days post-procedure.

CONCLUSION

s This study supports the safety and effectiveness of PC-directed biopsies in patients with suspicious biliary pathologies.

CLINICAL RELEVANCE/APPLICATION

PC-directed biopsies can be used for the diagnostic evaluation of patients with biliary lesions which otherwise cannot be evaluated with the help of non-invasive imaging techniques or laboratory evaluation.

T5A-SPIR-3 Biodegradable Stents in The Management of Biliary Strictures After Pediatric Split Liver Transplantation

Participants
Paolo Marra, Bergamo, Italy (*Presenter*) Nothing to Disclose

PURPOSE

To present the preliminary experience with biodegradable biliary stents as adjuvant treatment to percutaneous transhepatic cholangiography (PTC), bilioplasty and internal-external biliary drainage (IEBD), in the management of biliary strictures after split liver transplantation (SLT).

METHODS AND MATERIALS

In addition to the standard treatment, 10 pediatric patients (6 males; median age 8 years) with SLT underwent percutaneous transhepatic implantation of an innovative 10F helical-shaped biodegradable biliary stent, featuring a slow degradation profile of 11 weeks. To our knowledge the device is unique and the first to be CE-marked for the use in this indication. Feasibility of percutaneous implantation and short-term clinical outcomes were assessed.

RESULTS

Percutaneous stent implantation was technically successful in all 10 patients. In 6 patients a single stent was placed across the anastomotic stricture; in 3 patients two stents were used in parallel to achieve larger sizes. In the first performed case early stent dislodgement and migration in the bowel was demonstrated with X-rays after 72 hours, without sequelae. In the other cases correct stent position and progressive degradation was confirmed by serial X-rays. No complications occurred during a median follow up of 6 months. Two patients presented stricture relapse 8 months after treatment.

CONCLUSION

s Preliminary data suggest that implantation of biodegradable biliary stents is feasible and safe, to be considered in the management of post SLT cholestasis in pediatric patients. This device may prolong biliary drainage and may relieve discomfort of long-term IEBD.

CLINICAL RELEVANCE/APPLICATION

Pediatric split liver transplantation is burdened by a relatively high rate of biliary complications and biodegradable biliary stents may improve the interventional radiological management.

T5A-SPIR-4 Effect of Transarterial Chemoembolization Selectivity Treatment Modality in Hepatocellular Carcinoma Patients over 12 Months Follow Up

Participants
Shin Yin Ooi, MBBS, MRCS, (*Presenter*) Nothing to Disclose

PURPOSE

Transarterial chemoembolization (TACE) is a widely used palliative treatment for liver cancer worldwide. However, it is commonly associated with post embolization syndrome which causes fever, nausea, lethargy and pain. The purpose of this study is to assess the effect of TACE selectivity treatment modality on quality of life in palliative hepatocellular carcinoma patients.

METHODS AND MATERIALS

This is a prospective study carried out in Vascular and Interventional Radiology Department of Singapore General Hospital from September 2018 till February 2019. Patients who were diagnosed with hepatocellular carcinoma based on American Association for the Study of Liver Diseases (AASLD) imaging criteria or histology were included. The patients' quality of life (QOL) were assessed at pre-treatment, 2 weeks, 4 weeks, 3 months, 6 months and 12 months post-treatment using Functional Assessment of Cancer Therapy-Hepatobiliary (FACT-Hep) questionnaire.

RESULTS

Twenty-six patients (male:20, female: 6) with primary hepatocellular carcinoma, good ECOG performance status (ECOG 0 or 1) and preserved liver function (84.6% Child A, 15.4% Child B) were enrolled in the study. Majority of the study population has multiple liver tumours (57.7%) compared to single large liver tumour (42.3%). The FACT-G scores were different in selectivity treatment modality group at 6 months (p-value: 0.040) and 12 months (p-value: 0.038). Patients who underwent superselective and ultraselective TACE were reported to have better QOL compared to the selective group.

CONCLUSION

s In this prospective study, patients who received superselective and ultraselective TACE treatment were reported having statistically significant improvement in QOL composite scores at 6 months and 12 months. Patients without hepatitis have better liver function and QOL scores compared to Hepatitis C patients. The limitation of this study is the small sample size, but the strength is it reflects the actual clinical practice in local population.

CLINICAL RELEVANCE/APPLICATION

Increase use of superselectivity and ultraselectivity treatment modality in TACE can improve the quality of life in palliative hepatocellular cancer patients.

T5A-SPIR-5 Prediction of Future Remnant Liver Hypertrophy After Portal Vein Embolization

Participants
Max Masthoff, MD, Muenster, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the predictive value of baseline computed-tomography (CT) data for future remnant liver (FRL) hypertrophy after portal vein embolization (PVE) prior to major hepatectomy.

METHODS AND MATERIALS

In this retrospective study all consecutive patients undergoing right-sided PVE with or without liver vein embolization (LVE) between 2018 and 2021 were included. CT-volumetry was performed before and 2-5 weeks after PVE to assess standardized FRL volume (sFRLV). Radiomic features (RF) were extracted from baseline CT after segmenting liver and spleen volume and a standardized region of interest (ROI) from the L1 vertebra, representing bone marrow. For selecting features that allow classification of response (hypertrophy=1.33), a stepwise dimension reduction was performed. Logistic regression models were fitted and selected features were tested for their predictive value.

RESULTS

A total of n=53 patients (f= 21, m=32; mean age 64±10.5y (range 22-82y)) with primary or secondary liver cancer were included in this study. sFRLV increased significantly from 20.8±7.7% to 30.4±8.7% after PVE (p<0.001), resulting in a mean hypertrophy of FRL by 1.5 ± 0.3 fold. There was no significant difference in hypertrophy after PVE with or without LVE. sFRLV hypertrophy =1.33 was reached in n=35 (66%) patients. Three independent radiomic features, one each liver-, spleen- and bone-associated, differentiated well between responders and non-responders. A logistic regression model including the features MaximumProbability_liver, Skewness_spleen and TotalEnergy_bone revealed highest accuracy (AUC=0.875) for the prediction of response.

CONCLUSION

s This proof-of-concept study provides first evidence on a potential predictive value of baseline CT imaging data for FRL hypertrophy after portal vein embolization.

CLINICAL RELEVANCE/APPLICATION

Baseline imaging data may allow for early prediction of future remnant liver hypertrophy after portal vein embolization and may thus enable individualized patient selection and avoidance of ineffective interventions to optimize treatment strategies in liver cancer.

T5A-SPIR-6 Reduction in 30 Day Readmissions by Initial Insertion of Larger Bore Biliary Drainage Catheters

Participants
Muhammad Malik, MD, Boston, MA (*Presenter*) Nothing to Disclose

PURPOSE

Prior data has shown that 30-day readmissions after biliary drainage (PTBD) is common (46%) when initial drainage is performed with 8 Fr drains. The current study evaluated for differences in readmissions when initial drainage was performed with a larger bore drainage catheter.

METHODS AND MATERIALS

In an IRB approved, retrospective, single center study all PTBD procedures between 01-2014 to 11-2021 (n=3015) were analyzed. Procedures through pre-existing access (n=2430), multiple initial access biliary procedures (n=211), and patients dying during the index admission (n=44) were excluded. For each patient, the first 30-day readmission was used to determine cause of readmission. Readmissions were categorized as planned or unplanned, and unplanned causes as related to or unrelated to interventional radiology.

RESULTS

Patients (n=330, age: 66 (IQR: 26-98) years; 52% men) fit criteria and underwent 330 PTBD. PTBD was performed for malignant obstruction in 161/330 (48%), benign obstruction in 136/330 (41%), and biliary leakage in 33/330 (10%). Catheters were placed in the right duct (170/330 [52%]), in the left duct (79/330 [24%]), bilaterally (65/330 [20%]), trilaterally (13/330 [4%]) and via trans-cholecystic approach (3/330 [1%]. Mean length of index hospitalization was 14±15 days (1-115). After discharge, 30-day readmission was 118/330 (36%) and 30-day death was 29/330 (9%). Of all readmissions, 25/118 (21%) were planned and 93/118 (79%) were unplanned. A majority of unplanned readmissions (65/93; 70%) were related to interventional radiology. Overall, initial access used 8 Fr catheters in 79/330 (24%) and gt;8 Fr catheters in 251/330 (76%) procedures. In years when 8 Fr catheters were more commonly used (25/38; 66% vs 13/38; 34% for gt;8 Fr) the readmission rate was 20/38 (53%). In years when gt;8 Fr were used more commonly (223/292; 76% vs 54/292; 18% for 8 Fr) the readmission rates was 98/292 (33%). 30-day readmission was more common in 8 Fr years compared to gt;8 Fr years (53% vs. 33%, p=0.02).

CONCLUSION

s Increased usage of gt;8 Fr initial PTBD catheters for initial access was associated with lower 30-day readmission rates compared to 8 Fr initial PTBD catheters.

CLINICAL RELEVANCE/APPLICATION

Thirty day readmissions after percutaneous biliary drainage procedures can be reduced by using larger bore (gt;8 Fr) catheters during initial access.

T5A-SPIR-7 Complications in 2290 Percutaneous Biliary Procedures: Single Institution Experience

Participants
Ahsun Riaz, MD, Chicago, IL (*Presenter*) Consultant, Boston Scientific Corporation

PURPOSE

Examine complication rates of percutaneous biliary interventions performed by Interventional Radiology (IR) in 452 patients.

METHODS AND MATERIALS

We analysed retrospective data from 452 consecutive patients that underwent 2290 percutaneous biliary procedures at our center

from January 2010 to April 2020. The procedures included drain placement/exchange, cholangioplasty, and stent placement. Data regarding peri-catheter leak, catheter malposition, catheter occlusion, bleeding, perforation, sepsis requiring intensive care treatment (ICU), sepsis not requiring ICU treatment and death were collected.

RESULTS

Complications were observed in 707 procedures (31%), of which 75% were minor complications; peri-catheter leak (47%), catheter occlusion (15%) and drain malposition (13%). The mean duration of drain was 79 days (range:1-2404 days). The mean number of exchanges per drain was 3.9 (range: 1-32). On sub-stratification analysis, complications occurred more frequently in cases with malignant indications; 22% vs 9.7% (p<.00001). Intraprocedural bleeding was observed in 7 cases and post-procedural bleeding secondary to pseudoaneurysm formation in 30; 1% and 4.2% of all complications, respectively. 63% of all bleeds were managed by embolization. Sepsis occurred in 5.4% of cases, of which 1.1% required ICU treatment. Two percent of patients undergoing biliary drainage for a malignant indication developed sepsis compared to one in benign. Bowel perforation was a rare observation noted in only 2 cases. Death within 30 days occurred in 4 patients; three of these patients had a malignant etiology.

CONCLUSION

s Over 10 years, an overall complication rate of 31% was observed in 2290 consecutive biliary procedures. Most were minor with peri-catheter leak, drain malposition, and catheter occlusion accounting for 47%, 13% and 15% of complications, respectively. Sepsis was the most frequent major complication occurring in 5.4% of cases, followed by bleeding in 5.2%. IR should make efforts to internalize drains as soon as clinically possible to minimize minor complications.

CLINICAL RELEVANCE/APPLICATION

Percutaneous management of biliary pathologies is routinely performed by Interventional Radiology. The majority of post-procedural complications are minor which can be decreased by an effort to internalize biliary drains as soon as clinically possible.

T5A-SPIR-9 Development of A Three-Dimensional Multi-Modal Perfusion-Thermal Electrode System for Complete Tumor Eradication

Participants
Hui Zheng, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To develop a novel three-dimensional (3D) multi-modal perfusion-thermal electrode system for complete eradication of medium-to-large malignancies.

METHODS AND MATERIALS

This study included five steps: (i) design of the new system; (ii) production of the new system; (iii) ex-vivo evaluation of the perfusion-thermal functions; (iv) mathematic simulation to confirm its accurate temperature profiles; and (iv) in-vivo technical validation using living animal models with orthotopic liver tumors.

RESULTS

In ex-vivo experiments, gross pathology and optical imaging demonstrated the successful distribution/deposition of the motexafin gadolinium (MGd) at a sphere shape through the new electrode, with a temperature gradient from the electrode core at 80? to its periphery at 42 ?. An excellent consistence of temperature profiles at varying spots, from center to periphery of the liver tumor, was found between the mathematic simulation and actual animal tumor models (Pearson coefficient=0.977). For in-vivo technical validation, indocyanine green (ICG) was directly delivered into the peritumoral zones while simultaneous generation of central tumoral lethal radiofrequency (RF) heat (> 60 ?) with peritumoral sublethal RF hyperthermia (< 60 ?). Both optical imaging and fluorescent microscopy confirmed successful peritumoral ICG distribution/deposition with increased heat shock protein 70 expression.

CONCLUSION

s This new 3D perfusion-thermal electrode system enabled simultaneously delivery of agents and RF hyperthermia into the difficult-to-treat peritumoral zones, which may open the new avenues to solve the critical clinical problems, the incomplete eradication of medium-to-larger tumors with current image-guided percutaneous thermal ablation techniques.

CLINICAL RELEVANCE/APPLICATION

This study has established ground works for developing a new 3D perfusion-thermal electrode system, to solve the clinical problem on incomplete eradication of medium-to-larger tumors with current thermal ablations.

T5A-SPIR-1

Cryoablation of Breast Cancer in Metastatic Patients. A Single Institutional Experience

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - IR DPS

Participants
Claudio Pusceddu, MD, (*Presenter*) Nothing to Disclose

PURPOSE

to evaluate the safety and efficacy of breast cryoablation (CRA) as local therapy for patient with metastatic breast cancer.

METHODS AND MATERIALS

thirty-nine breast lesions, mean size 2,1 (range 1 - 6,7 cm) in twenty-nine consecutive patients, mean age 51 (36-81) with core-needle biopsy-proven breast carcinoma and metastases were included in this study. Twenty-three patients had one lesion, 4 patients two lesions, 1 patient three lesions and 1 patient five lesions. Under local anaesthesia and mild conscious sedation, the tumour and surrounding breast tissue were ablated with percutaneous CT-guided CRA. Cryoablation consisted of 2 cycles each of 10 minutes of freezing followed by a 4-min active and 4-min passive thawing phase for each one. Twenty-four patients underwent one CRA session, four patients 2 CRA sessions and one patient underwent 3 CRA sessions.

RESULTS

all CRA sessions were successfully completed and all breast tumours were ablated. Morbidity consisted in transient and mild ecchymotic changes and post-procedural oedema seen in ten cases. The therapeutic outcomes were evaluated by contrast-enhanced TC or MRI at 2-, 6-, 12-, and 18-month intervals. The absence of tumour enhancement TC or MR image was considered as indicating complete tumour necrosis. During the mean follow-up of 15 months (6- 28 months) 26 patients had shown complete response to the treatment. Only 3 patients out 29 (10%) showed relapse close to the treated lesion.

CONCLUSION

s CRA of metastatic breast cancer is a safe and effective method which allows local control of the disease.

CLINICAL RELEVANCE/APPLICATION

This method can effectively be used with good local control of the disease in patients who present with metastases at the beginning of the illness.

Outcomes of Percutaneous Cholangioscopy Directed Biopsies for Suspicious Biliary Lesions

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - IR DPS

Participants
Tushar Garg, MD, Baltimore, MD (*Presenter*) Conference Travel, Siemens Healthineers

PURPOSE

To evaluate the safety and effectiveness of percutaneous cholangioscopy (PC)-directed biopsies for the evaluation of biliary pathology.

METHODS AND MATERIALS

This was an IRB-approved, retrospective study evaluating patients who underwent PC-directed biopsy for biliary pathology from July 2013 and January 2022. Fifteen patients (10 male; mean age 61 [range 48-84] years) underwent 15 PC-directed biopsies for various indications. The technical success was defined as successful access with endoscope and visualization of the biliary system, while procedural success was defined as successful biopsy of the lesion if present.

RESULTS

Out of the 15 PC-directed biopsies, 8 (53.3%) were performed to rule out recurrence of malignancy, 3 (20%) to evaluate a mass lesion, 2 (13.3%) to evaluate a filling defect, and 1(6.6%) to evaluate the extent of malignancy. The technical and procedural success rate for the procedure was 100% (15/15), however, there was failure to obtain a clamshell biopsy in one procedure for which successful brush biopsy was performed. Clamshell biopsy (1.6 mm forceps) was done in 86.6% (13/15) of procedures with a median of 3 samples per procedure and brush biopsy (1.72 mm or 3 mm cytology brush) was taken in 6 (40%) procedures with a median of 2.5 samples per procedure. All samples obtained were adequate to make a pathological diagnosis and led to change in patient management. No complications were seen during the procedure and up to 30-days post-procedure.

CONCLUSION

s This study supports the safety and effectiveness of PC-directed biopsies in patients with suspicious biliary pathologies.

CLINICAL RELEVANCE/APPLICATION

PC-directed biopsies can be used for the diagnostic evaluation of patients with biliary lesions which otherwise cannot be evaluated with the help of non-invasive imaging techniques or laboratory evaluation.

T5A-SPIR-3

Biodegradable Stents in The Management of Biliary Strictures After Pediatric Split Liver Transplantation

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - IR DPS

Participants
Paolo Marra, Bergamo, Italy (*Presenter*) Nothing to Disclose

PURPOSE

To present the preliminary experience with biodegradable biliary stents as adjuvant treatment to percutaneous transhepatic cholangiography (PTC), bilioplasty and internal-external biliary drainage (IEBD), in the management of biliary strictures after split liver transplantation (SLT).

METHODS AND MATERIALS

In addition to the standard treatment, 10 pediatric patients (6 males; median age 8 years) with SLT underwent percutaneous transhepatic implantation of an innovative 10F helical-shaped biodegradable biliary stent, featuring a slow degradation profile of 11 weeks. To our knowledge the device is unique and the first to be CE-marked for the use in this indication. Feasibility of percutaneous implantation and short-term clinical outcomes were assessed.

RESULTS

Percutaneous stent implantation was technically successful in all 10 patients. In 6 patients a single stent was placed across the anastomotic stricture; in 3 patients two stents were used in parallel to achieve larger sizes. In the first performed case early stent dislodgement and migration in the bowel was demonstrated with X-rays after 72 hours, without sequelae. In the other cases correct stent position and progressive degradation was confirmed by serial X-rays. No complications occurred during a median follow up of 6 months. Two patients presented stricture relapse 8 months after treatment.

CONCLUSION

s Preliminary data suggest that implantation of biodegradable biliary stents is feasible and safe, to be considered in the management of post SLT cholestasis in pediatric patients. This device may prolong biliary drainage and may relieve discomfort of long-term IEBD.

CLINICAL RELEVANCE/APPLICATION

Pediatric split liver transplantation is burdened by a relatively high rate of biliary complications and biodegradable biliary stents may improve the interventional radiological management.

T5A-SPIR-4

Effect of Transarterial Chemoembolization Selectivity Treatment Modality in Hepatocellular Carcinoma Patients over 12 Months Follow Up

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - IR DPS

Participants
Shin Yin Ooi, MBBS, MRCS, (*Presenter*) Nothing to Disclose

PURPOSE

Transarterial chemoembolization (TACE) is a widely used palliative treatment for liver cancer worldwide. However, it is commonly associated with post embolization syndrome which causes fever, nausea, lethargy and pain. The purpose of this study is to assess the effect of TACE selectivity treatment modality on quality of life in palliative hepatocellular carcinoma patients.

METHODS AND MATERIALS

This is a prospective study carried out in Vascular and Interventional Radiology Department of Singapore General Hospital from September 2018 till February 2019. Patients who were diagnosed with hepatocellular carcinoma based on American Association for the Study of Liver Diseases (AASLD) imaging criteria or histology were included. The patients' quality of life (QOL) were assessed at pre-treatment, 2 weeks, 4 weeks, 3 months, 6 months and 12 months post-treatment using Functional Assessment of Cancer Therapy-Hepatobiliary (FACT-Hep) questionnaire.

RESULTS

Twenty-six patients (male:20, female: 6) with primary hepatocellular carcinoma, good ECOG performance status (ECOG 0 or 1) and preserved liver function (84.6% Child A, 15.4% Child B) were enrolled in the study. Majority of the study population has multiple liver tumours (57.7%) compared to single large liver tumour (42.3%). The FACT-G scores were different in selectivity treatment modality group at 6 months (p-value: 0.040) and 12 months (p-value: 0.038). Patients who underwent superselective and ultraselective TACE were reported to have better QOL compared to the selective group.

CONCLUSION

s In this prospective study, patients who received superselective and ultraselective TACE treatment were reported having statistically significant improvement in QOL composite scores at 6 months and 12 months. Patients without hepatitis have better liver function and QOL scores compared to Hepatitis C patients. The limitation of this study is the small sample size, but the strength is it reflects the actual clinical practice in local population.

CLINICAL RELEVANCE/APPLICATION

Increase use of superselectivity and ultraselectivity treatment modality in TACE can improve the quality of life in palliative hepatocellular cancer patients.

T5A-SPIR-5

Prediction of Future Remnant Liver Hypertrophy After Portal Vein Embolization

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - IR DPS

Participants
Max Masthoff, MD, Muenster, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the predictive value of baseline computed-tomography (CT) data for future remnant liver (FRL) hypertrophy after portal vein embolization (PVE) prior to major hepatectomy.

METHODS AND MATERIALS

In this retrospective study all consecutive patients undergoing right-sided PVE with or without liver vein embolization (LVE) between 2018 and 2021 were included. CT-volumetry was performed before and 2-5 weeks after PVE to assess standardized FRL volume (sFRLV). Radiomic features (RF) were extracted from baseline CT after segmenting liver and spleen volume and a standardized region of interest (ROI) from the L1 vertebra, representing bone marrow. For selecting features that allow classification of response (hypertrophy=1.33), a stepwise dimension reduction was performed. Logistic regression models were fitted and selected features were tested for their predictive value.

RESULTS

A total of n=53 patients (f= 21, m=32; mean age 64±10.5y (range 22-82y)) with primary or secondary liver cancer were included in this study. sFRLV increased significantly from 20.8±7.7% to 30.4±8.7% after PVE ($p<0.001$), resulting in a mean hypertrophy of FRL by 1.5 ± 0.3 fold. There was no significant difference in hypertrophy after PVE with or without LVE. sFRLV hypertrophy =1.33 was reached in n=35 (66%) patients. Three independent radiomic features, one each liver-, spleen- and bone-associated, differentiated well between responders and non-responders. A logistic regression model including the features MaximumProbability_liver, Skewness_spleen and TotalEnergy_bone revealed highest accuracy (AUC=0.875) for the prediction of response.

CONCLUSION

s This proof-of-concept study provides first evidence on a potential predictive value of baseline CT imaging data for FRL hypertrophy after portal vein embolization.

CLINICAL RELEVANCE/APPLICATION

Baseline imaging data may allow for early prediction of future remnant liver hypertrophy after portal vein embolization and may thus enable individualized patient selection and avoidance of ineffective interventions to optimize treatment strategies in liver cancer.

T5A-SPIR-6

Reduction in 30 Day Readmissions by Initial Insertion of Larger Bore Biliary Drainage Catheters

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - IR DPS

Participants
Muhammad Malik, MD, Boston, MA (*Presenter*) Nothing to Disclose

PURPOSE

Prior data has shown that 30-day readmissions after biliary drainage (PTBD) is common (46%) when initial drainage is performed with 8 Fr drains. The current study evaluated for differences in readmissions when initial drainage was performed with a larger bore drainage catheter.

METHODS AND MATERIALS

In an IRB approved, retrospective, single center study all PTBD procedures between 01-2014 to 11-2021 (n=3015) were analyzed. Procedures through pre-existing access (n=2430), multiple initial access biliary procedures (n=211), and patients dying during the index admission (n=44) were excluded. For each patient, the first 30-day readmission was used to determine cause of readmission. Readmissions were categorized as planned or unplanned, and unplanned causes as related to or unrelated to interventional radiology.

RESULTS

Patients (n=330, age: 66 (IQR: 26-98) years; 52% men) fit criteria and underwent 330 PTBD. PTBD was performed for malignant obstruction in 161/330 (48%), benign obstruction in 136/330 (41%), and biliary leakage in 33/330 (10%). Catheters were placed in the right duct (170/330 [52%]), in the left duct (79/330 [24%]), bilaterally (65/330 [20%]), trilaterally (13/330 [4%]) and via trans-cholecystic approach (3/330 [1%]. Mean length of index hospitalization was 14±15 days (1-115). After discharge, 30-day readmission was 118/330 (36%) and 30-day death was 29/330 (9%). Of all readmissions, 25/118 (21%) were planned and 93/118 (79%) were unplanned. A majority of unplanned readmissions (65/93; 70%) were related to interventional radiology. Overall, initial access used 8 Fr catheters in 79/330 (24%) and gt;8 Fr catheters in 251/330 (76%) procedures. In years when 8 Fr catheters were more commonly used (25/38; 66% vs 13/38; 34% for gt;8 Fr) the readmission rate was 20/38 (53%). In years when gt;8 Fr were used more commonly (223/292; 76% vs 54/292; 18% for 8 Fr) the readmission rates was 98/292 (33%). 30-day readmission was more common in 8 Fr years compared to gt;8 Fr years (53% vs. 33%, p=0.02).

CONCLUSION

s Increased usage of gt;8 Fr initial PTBD catheters for initial access was associated with lower 30-day readmission rates compared to 8 Fr initial PTBD catheters.

CLINICAL RELEVANCE/APPLICATION

Thirty day readmissions after percutaneous biliary drainage procedures can be reduced by using larger bore (gt;8 Fr) catheters during initial access.

Complications in 2290 Percutaneous Biliary Procedures: Single Institution Experience

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - IR DPS

Participants
Ahsun Riaz, MD, Chicago, IL (*Presenter*) Consultant, Boston Scientific Corporation

PURPOSE

Examine complication rates of percutaneous biliary interventions performed by Interventional Radiology (IR) in 452 patients.

METHODS AND MATERIALS

We analysed retrospective data from 452 consecutive patients that underwent 2290 percutaneous biliary procedures at our center from January 2010 to April 2020. The procedures included drain placement/exchange, cholangioplasty, and stent placement. Data regarding peri-catheter leak, catheter malposition, catheter occlusion, bleeding, perforation, sepsis requiring intensive care treatment (ICU), sepsis not requiring ICU treatment and death were collected.

RESULTS

Complications were observed in 707 procedures (31%), of which 75% were minor complications; peri-catheter leak (47%), catheter occlusion (15%) and drain malposition (13%). The mean duration of drain was 79 days (range:1-2404 days). The mean number of exchanges per drain was 3.9 (range: 1-32). On sub-stratification analysis, complications occurred more frequently in cases with malignant indications; 22% vs 9.7% (p<.00001). Intraprocedural bleeding was observed in 7 cases and post-procedural bleeding secondary to pseudoaneurysm formation in 30; 1% and 4.2% of all complications, respectively. 63% of all bleeds were managed by embolization. Sepsis occurred in 5.4% of cases, of which 1.1% required ICU treatment. Two percent of patients undergoing biliary drainage for a malignant indication developed sepsis compared to one in benign. Bowel perforation was a rare observation noted in only 2 cases. Death within 30 days occurred in 4 patients; three of these patients had a malignant etiology.

CONCLUSION

s Over 10 years, an overall complication rate of 31% was observed in 2290 consecutive biliary procedures. Most were minor with peri-catheter leak, drain malposition, and catheter occlusion accounting for 47%, 13% and 15% of complications, respectively. Sepsis was the most frequent major complication occurring in 5.4% of cases, followed by bleeding in 5.2%. IR should make efforts to internalize drains as soon as clinically possible to minimize minor complications.

CLINICAL RELEVANCE/APPLICATION

Percutaneous management of biliary pathologies is routinely performed by Interventional Radiology. The majority of post-procedural complications are minor which can be decreased by an effort to internalize biliary drains as soon as clinically possible.

T5A-SPIR-9

Development of A Three-Dimensional Multi-Modal Perfusion-Thermal Electrode System for Complete Tumor Eradication

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - IR DPS

Participants
Hui Zheng, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To develop a novel three-dimensional (3D) multi-modal perfusion-thermal electrode system for complete eradication of medium-to-large malignancies.

METHODS AND MATERIALS

This study included five steps: (i) design of the new system; (ii) production of the new system; (iii) ex-vivo evaluation of the perfusion-thermal functions; (iv) mathematic simulation to confirm its accurate temperature profiles; and (iv) in-vivo technical validation using living animal models with orthotopic liver tumors.

RESULTS

In ex-vivo experiments, gross pathology and optical imaging demonstrated the successful distribution/deposition of the motexafin gadolinium (MGd) at a sphere shape through the new electrode, with a temperature gradient from the electrode core at 80? to its periphery at 42 ?. An excellent consistence of temperature profiles at varying spots, from center to periphery of the liver tumor, was found between the mathematic simulation and actual animal tumor models (Pearson coefficient=0.977). For in-vivo technical validation, indocyanine green (ICG) was directly delivered into the peritumoral zones while simultaneous generation of central tumoral lethal radiofrequency (RF) heat (> 60 ?) with peritumoral sublethal RF hyperthermia (< 60 ?). Both optical imaging and fluorescent microscopy confirmed successful peritumoral ICG distribution/deposition with increased heat shock protein 70 expression.

CONCLUSION

s This new 3D perfusion-thermal electrode system enabled simultaneously delivery of agents and RF hyperthermia into the difficult-to-treat peritumoral zones, which may open the new avenues to solve the critical clinical problems, the incomplete eradication of medium-to-larger tumors with current image-guided percutaneous thermal ablation techniques.

CLINICAL RELEVANCE/APPLICATION

This study has established ground works for developing a new 3D perfusion-thermal electrode system, to solve the clinical problem on incomplete eradication of medium-to-larger tumors with current thermal ablations.

Musculoskeletal Tuesday Poster Discussions - A

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - MK DPS

Sub-Events

T5A-SPMK-1 Comparison of Isotropic MAVRIC-SL and Conventional MAVRIC-SL in the Evaluation of Symptomatic Hip Arthroplasties at 3T

Participants
Kathryn Stevens, MBBS, FRCR, Stanford, CA (*Presenter*) Nothing to Disclose

PURPOSE

To compare isotropic MAVRIC-SL with conventional MAVRIC-SL in patients with symptomatic hip implants at 3T.

METHODS AND MATERIALS

39 symptomatic patients with 59 total hip implants were imaged on a 3T MRI scanner including conventional proton density-weighted coronal MAVRIC-SL (6m58s scan time, 1.25x1.6x4mm resolution) and isotropic coronal MAVRIC-SL (4m10s scan time,1.6x1.6x1.6mm resolution) employing robust principal component analysis for accelerated scanning. Two MSK radiologists graded overall image quality on acquired coronal images, as well as reformatted axial and sagittal images, overall metal artifact, and visualization around the femoral and acetabular components using a 3-point scale (3: diagnostic, 2: moderately diagnostic, 1: non-diagnostic). Images were examined for different pathologies, including effusion, synovitis, osteolysis, loosening, pseudotumor, fracture, gluteal tendon abnormalities, with degree of confidence. Reformatted images were evaluated to see if they lead to a change in diagnostic confidence or diagnosis of new pathology that could potentially contribute to hip pain.

RESULTS

No significant difference was demonstrated between coronal MAVRIC-SL and isotropic MAVRIC-SL for overall image quality, metal artifact suppression, or visualization around the acetabular or femoral components, but image quality on axial and sagittal reformats was significantly higher with the isotropic sequence ($p<0.01$). Interobserver agreement for was substantial ($k=0.798$). Isotropic MAVRIC-SL achieved a comparable degree of diagnostic confidence for most types of pathology ($p < 0.05$). Inclusion of axial and sagittal reformats changed the diagnosis or increased diagnostic confidence in 7.6% cases on conventional imaging, compared to 42.4% on isotropic imaging ($p<0.01$). A new diagnosis based on reformatted images that may contribute to hip symptoms was made in 22.9% cases on conventional imaging, compared to 50.8% on isotropic imaging ($p<0.01$).

CONCLUSION

s Coronal isotropic and conventional MAVRIC-SL images were comparable, with similar degrees of diagnostic confidence for most types of pathology. However, image quality of isotropic reformatted images was significantly better and revealed abnormalities that were either obscured or not as well seen in the coronal acquisition plane, as well as other findings that could contribute to hip pain.

CLINICAL RELEVANCE/APPLICATION

This fast RPCA MAVRIC-SL isotropic acquisition shows promise for improved visualization of hardware complications with diagnostically acceptable image quality and has the potential to significantly decrease overall clinical scan time, both by eliminating the need to scan in multiple planes and through use of accelerated scanning.

T5A-SPMK-2 Hip Impingement in Flexion Did Not Involve Cam-deformity and Is Located on Anterior-inferior Proximal Femur in Cam and Pincer FAI Patients with Decreased Femoral Version

Participants
Till Lerch, MD, PhD, Bern, Switzerland (*Presenter*) Nothing to Disclose

PURPOSE

Symptomatic FAI patients have limitations in daily activities and sports and report exacerbation of hip pain in deep flexion or while sitting. But exact impingement location in deep flexion is unknown. Hypothesis/Purpose We aimed to investigate impingement-free maximal flexion, location of hip impingement and if cam-deformity causes impingement in flexion in symptomatic cam and pincer FAI patients with decreased femoral version(FV).

METHODS AND MATERIALS

An IRB-approved retrospective study involving 24 patients (37 hips) with decreased femoral version(FV<5°) was performed. All FAI patients were symptomatic(mean age 33±10 years) and had anterior hip/groin pain and a positive anterior-impingement-test. Subgroups of patients with cam-type deformity(16 hips), patients with pincer-type deformity(7 hips) and patients with mixed-type FAI(6 hips) were compared. All patients underwent pelvic CT scans and were evaluated with individual CT-based 3D-models and validated software for patient-specific impingement-simulation using equidistant-method.

RESULTS

(1)Mean impingement-free flexion of patients with pincer-type FAI(113±10°) and patients with mixed-type FAI(114±11°) was significantly($p<0.001$) lower compared to patients with cam-type FAI(122±13°). (2)Patients with mixed-type FAI(67%) and patients with pincer-type FAI(57%) had significantly($p<0.001$) increased prevalence of intraarticular impingement compared to cam-type FAI(33%) in 115° of flexion. Patients with pincer-type FAI (57%) had significantly($p<0.001$) higher prevalence of extraarticular subspine hip impingement compared to cam-type FAI(22%)in 125° of flexion. (3)Femoral impingement in maximal flexion was located anterior-inferior at 4 o'clock(71% of pincer-type FAI, 50% of mixed-type FAI) and 5 o'clock (61% of cam-type FAI). Cam-deformity was not involved in maximal flexion (0% 1-3 o'clock). Acetabular impingement in maximal flexion was located anterior-superior(2 o'clock) of all patients.

CONCLUSION

s Femoral impingement conflict in flexion was located anterior-inferior and did not involve the cam-deformity. This is different compared to previous studies that reported anterior-superior femoral impingement location during the anterior-impingement-test.

CLINICAL RELEVANCE/APPLICATION

This could be important for FAI patients to avoid exacerbation of hip pain in deep flexion. This could be important for radiologists to better understand FAI and the cam-deformity.

T5A-SPMK-3 3D Printed Model and Guide for Decompression and Stem-Cell Treatment of Avascular Necrosis of the Femoral Head

Participants
Alborz Feizi, New Haven, CT (*Presenter*) Nothing to Disclose

PURPOSE

Avascular necrosis (AVN) is a condition characterized by bone tissue necrosis as a result of poor blood supply. The disease progresses in stages, and the treatment depends on the stage and location of AVN. One of the most common locations of AVN is at the femoral head. During the early stages of the disease, treatment options such as core decompression and cellular therapies can diminish further necrosis and avoid hip collapse. However, current treatment protocols lack the means to accurately guide a therapeutic device to the precise location of necrotic tissue. Furthermore, existing modes of treatment delivery can be complicated by postoperative infection and fracture. Here, we present a technique and device that has the potential to improve therapy outcomes by precisely targeting lesions, and placing stem cells in the optimal environment to induce revascularization.

METHODS AND MATERIALS

A foam cortical shell femur was scanned using computed tomography (CT) and segmented in Synopsys Simpleware ScanIP software to create a 3D femur model. From the model, a femur-specific drill-guide was designed based on a preoperatively planned ideal drill trajectory for the placement of the decompression device and for the delivery of stem-cells to the core of the necrotic region. A delivery cannula and a needle were drilled into the foam cortical shell femur using the 3D-printed drill-guide. After placement of the delivery cannula and needle using the custom guide, a second CT scan was performed to evaluate the accuracy and precision of the 3D-printed guide in delivering treatment to the ideal drill tip location.

RESULTS

In our model, the post-drilling 3D reconstruction showed a maximum of 2-degree deviation from the theoretical model. The needle tip was also between 0.257 and 2.149 mm away from the theoretical needle tip.

CONCLUSION

s 3D printed devices have the potential to improve positioning of treatment instruments. Consequently, this technique can allow for more precise localized decompression and stem-cell treatment of necrotic tissue.

CLINICAL RELEVANCE/APPLICATION

Approximately 50% percent of patients with femoral AVN experience hip collapse. This procedure has the potential to improve outcomes of decompression and stem-cell treatment and reduce the need for hip replacement surgery.

T5A-SPMK-1

Comparison of Isotropic MAVRIC-SL and Conventional MAVRIC-SL in the Evaluation of Symptomatic Hip Arthroplasties at 3T

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - MK DPS

Participants
Kathryn Stevens, MBBS, FRCR, Stanford, CA (*Presenter*) Nothing to Disclose

PURPOSE

To compare isotropic MAVRIC-SL with conventional MAVRIC-SL in patients with symptomatic hip implants at 3T.

METHODS AND MATERIALS

39 symptomatic patients with 59 total hip implants were imaged on a 3T MRI scanner including conventional proton density-weighted coronal MAVRIC-SL (6m58s scan time, 1.25x1.6x4mm resolution) and isotropic coronal MAVRIC-SL (4m10s scan time,1.6x1.6x1.6mm resolution) employing robust principal component analysis for accelerated scanning. Two MSK radiologists graded overall image quality on acquired coronal images, as well as reformatted axial and sagittal images, overall metal artifact, and visualization around the femoral and acetabular components using a 3-point scale (3: diagnostic, 2: moderately diagnostic, 1: non-diagnostic). Images were examined for different pathologies, including effusion, synovitis, osteolysis, loosening, pseudotumor, fracture, gluteal tendon abnormalities, with degree of confidence. Reformatted images were evaluated to see if they lead to a change in diagnostic confidence or diagnosis of new pathology that could potentially contribute to hip pain.

RESULTS

No significant difference was demonstrated between coronal MAVRIC-SL and isotropic MAVRIC-SL for overall image quality, metal artifact suppression, or visualization around the acetabular or femoral components, but image quality on axial and sagittal reformats was significantly higher with the isotropic sequence ($p<0.01$). Interobserver agreement for was substantial ($k=0.798$). Isotropic MAVRIC-SL achieved a comparable degree of diagnostic confidence for most types of pathology ($p < 0.05$). Inclusion of axial and sagittal reformats changed the diagnosis or increased diagnostic confidence in 7.6% cases on conventional imaging, compared to 42.4% on isotropic imaging ($p<0.01$). A new diagnosis based on reformatted images that may contribute to hip symptoms was made in 22.9% cases on conventional imaging, compared to 50.8% on isotropic imaging ($p<0.01$).

CONCLUSION

s Coronal isotropic and conventional MAVRIC-SL images were comparable, with similar degrees of diagnostic confidence for most types of pathology. However, image quality of isotropic reformatted images was significantly better and revealed abnormalities that were either obscured or not as well seen in the coronal acquisition plane, as well as other findings that could contribute to hip pain.

CLINICAL RELEVANCE/APPLICATION

This fast RPCA MAVRIC-SL isotropic acquisition shows promise for improved visualization of hardware complications with diagnostically acceptable image quality and has the potential to significantly decrease overall clinical scan time, both by eliminating the need to scan in multiple planes and through use of accelerated scanning.

Multisystem Tuesday Poster Discussion - A

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - MS DPS

Sub-Events

T5A-SPMS-1 The Changes of Brain Function and Psychological Activity in Patients with Crohn's Disease: A Prospective Case-control Study

Participants
Ruonan Zhang, Guangzhou, China (*Presenter*) Nothing to Disclose

PURPOSE

Recent studies point to the brain-gut axis dysfunction as a key player in the occurrence and development of Crohn’s disease (CD). Disclosing neuropsychological characteristics of CD patients may help shed light on its pathogenesis and provide potential therapeutic target. However, little is known about neuropsychological changes in CD patients. The aim of this study is to investigate the alterations in brain function in CD patients and to explore the relationship between psychological changes and CD activity.

METHODS AND MATERIALS

43 CD patients who underwent brain functional MRI-bold (fMRI-bold) , Diffusion Tensor Imaging (DTI) , 3D T1 MPRAG and intestinal MRI and 22 matched healthy controls (HCs) who only received brain fMRI and 3D T1 MPRAG were prospectively recruited. Psychological activities (depression, anxiety, stress) and CD bowel activity (simplified Magnetic Resonance Index of Activity(MaRIAs) and Crohn's Disease Activity Index (CDAI)) were evaluated. Differences in brain function and psychological activity between CD patients and HCs were analyzed. The correlation between psychological activities and both CDAI and MaRIAs were investigated.

RESULTS

CD patients had significantly higher amplitude of low frequency fluctuations in thalamus, higher regional homogeneity in cerebellar, higher fractional anisotropy in seven fiber bundles (eg, body of corpus callosum, and inferior fronto-occipital fasciculus, etc), but lower gray matter signal in right orbitofrontal cortex than those of HCs (all $P<0.05$). Moreover, there were significant differences in psychological activities between HCs and CD patients ($P<0.05$). We found a positive and statistically significant correlation between MaRIAs and CDAI in CD patients ($n = 43$, $r = 0.397$, $p < 0.05$). However, no significant association was found between bowel activity (MaRIAs and CDAI) and psychological activities (all $P>0.05$).

CONCLUSION

s CD patients demonstrated abnormal neural activity that associated with emotional, pain and cognitive-related functions, which may relate to their poor psychological activities.

CLINICAL RELEVANCE/APPLICATION

Although our preliminary results are not yet sufficient to support a close relationship between psychological status and bowel activity, clinicians still should pay more attention to these neuropsychological changes of CD patients as they might be potential therapeutic targets.

T5A-SPNMMI-1 A Pilot Study of68Ga-PSMA11 and68Ga-RM2 PET/MRI for Evaluation of Prostate Cancer Response to High Intensity Focused Ultrasound (HIFU) Therapy

Participants
Heying Duan, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Focal therapy for localized prostate cancer (PC) using high intensity focused ultrasound (HIFU) is gaining in popularity as it is non-invasive and associated with fewer side effects than standard whole-gland treatments. However, better methods to evaluate response to HIFU are an unmet need. Prostate specific membrane antigen (PSMA) and gastrin-releasing peptide receptors (GRPR) are both overexpressed in PC. In this study, we evaluated a novel approach of using both 68Ga-RM2 and 68Ga-PSMA11 PET/MRI in each patient before and after HIFU treatment to assess accuracy of target tumor localization and response to treatment.

METHODS AND MATERIALS

Fourteen men, 64.5±8.0 (range 48 - 78) years-old, with newly diagnosed PC were prospectively enrolled. Pre-HIFU, patients underwent prostate biopsy, multiparametric MRI (mpMRI), 68Ga-PSMA11 and 68Ga-RM2 PET/MRI. Response to treatment was assessed at a minimum of 6 months after HIFU with prostate biopsy (n=9), as well as 68Ga-PSMA11 and 68Ga-RM2 PET/MRI (n=14). Maximum and peak standardized uptake values (SUVmax and SUVpeak) of known or suspected PC lesions were collected.

RESULTS

Pre-HIFU biopsy revealed 17 cancers of which 14 were clinically significant (Gleason score =3+4). mpMRI identified 18 lesions, 14 of them =PI-RADS 4. 68Ga-PSMA11 and 68Ga-RM2 PET/MRI each showed 23 positive intraprostatic lesions, of which 21 were congruent in 13 patients and 5 were incongruent in 5 patients. In the pre-HIFU workup, 68Ga-PSMA11 identified all target tumors while 68Ga-RM2 PET/MRI missed 2 tumors. Post-HIFU,68Ga-RM2 PET/MRI was negative in the treatment zones, whereas 68Ga-PSMA11 showed persistent uptake in one lesion which proved to be non-clinically significant cancer on biopsy. Three new ipsilateral lesions were seen with both radiopharmaceuticals, which were verified by prostate biopsy and patients were subsequently treated with a repeat HIFU. Pre-treatment prostate specific antigen (PSA) decreased significantly after HIFU by 66%. Concordantly, SUVmax decreased significantly after HIFU for 68Ga-PSMA11 (P=0.003) and 68Ga-RM2 (P=0.000).

CONCLUSION

s Our results show that 68Ga-PSMA11 and 68Ga-RM2 PET/MRI identified the target tumor for HIFU in 100% and 86%, respectively, and accurately verified response to treatment. This suggests that PET might be a useful tool in the guidance and monitoring of treatment success in patients receiving focal therapy for PC.

CLINICAL RELEVANCE/APPLICATION

68Ga-PSMA11 and 68Ga-RM2 PET/MRI were feasible for monitoring HIFU treatment success and might avoid re-biopsies for treatment verification with its associated risks.

T5A-SPNMMI-2 Impact of 18F-fluciclovine PET/CT on Failure-free Survival in Biochemical Recurrence of Prostate Cancer Following Salvage Radiation Therapy

Participants
Charles Marcus, MD, Altanta, GA (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the correlation between 18F-fluciclovine PET/CT findings and failure-free survival (FFS) in patients with biochemical recurrence of prostate cancer, status post radical prostatectomy who underwent salvage radiation therapy (RT)

METHODS AND MATERIALS

79 prostate cancer patients enrolled in the study arm of a single center, randomized controlled trial (NCT01666808) in which salvage RT guided by fluciclovine PET/CT findings (including radiotherapy target volume design) were included. 4 patients with extrapelvic disease (M1) were excluded. Treatment failure was defined as a serum prostate specific antigen (PSA) level of =0.2ng/mL above the nadir after salvage RT, confirmed with an additional measurement, requiring systemic treatment or clinical progression. All patients were followed at regular intervals up to 48 months. Kaplan-Meier plot was generated and FFS were compared between patients with no uptake, prostate bed only and/or pelvic nodal uptake using the Z test at 3 years and 4

years.Funding Information: National Institutes of Health/National Cancer Institute, Blue Earth Diagnostics

RESULTS

80% (60/75) of patients had a positive M0 fluciclovine PET/CT, of which 57% (34/60) of the patients had prostate bed only uptake, while 43% (26/60) had pelvic nodal ± bed uptake. RT planning decision was changed in 32% of patients. Following RT, disease failure was detected in 36% (27/75) patients. There was a significant difference in FFS between patients who had a positive vs negative scan (62% vs 93%; $p<0.001$) at 36 months and (59% vs 93%; $p<0.001$) at 48 months. Similarly, there was a significant difference in FFS between patients with uptake in pelvic nodes ± bed vs prostate bed only at 36 months (50% vs 71%; $p=0.003$) and at 48 months (50% vs 66%; $p=0.040$) (Figures 1-3),

CONCLUSION

s 18F-fluciclovine PET/CT findings are predictive of failure-free survival in post-prostatectomy patients with biochemical recurrence status post salvage radiation therapy. Difference in failure-free survival despite targeted salvage radiotherapy based on the PET/CT findings may indicate the complex biology of these tumors and its relationship to metabolic tumor burden.

CLINICAL RELEVANCE/APPLICATION

18F-fluciclovine PET/CT findings can predict failure-free survival outcomes in patients with biochemical recurrence of prostate cancer.

T5A-SPNPM-1 Efficacy of Low-Cost Gelatin Models to Teach Vascular Anatomy and Intravascular Access Techniques

Participants
Kenneth Richardson, Miami, FL (*Presenter*) Nothing to Disclose

PURPOSE

Ultrasound (US) guided vascular access has become increasingly popular due to its reduced complications and higher success rates. Commercial training phantoms have grown in popularity due to their advantage in allowing providers to develop tactile skills in a low risk setting. However, such models are expensive and thus poorly accessible. This study analyzes the efficacy of homemade, low-cost reusable gelatin-based central line vascular models to teach vascular anatomy and intravascular access techniques in training physicians.

METHODS AND MATERIALS

Medical students from all years were recruited from the University of Miami to participate in a 90-minute simulation workshop led by Interventional Radiology residents. Participants completed pre- and post-surveys that assessed knowledge acquisition and subjective confidence levels related to the procedure. After a brief orientation, participants practiced US guided central line access using two different homemade gelatin models that simulated the anatomical positioning of the internal jugular (IJ) and femoral veins. The sternocleidomastoid muscle and femoral nerve were simulated using tofu and a cord of hotdog, respectively. Balloons and latex tubing injected with red food coloring simulated veins and arteries, respectively. The mold was created using a mixture of 90 mg gelatin, 500 mL water, 2 tbsp Metamucil, 30 mL rubbing alcohol, and food coloring. Statistical analysis was performed using IBM SPSS statistics.

RESULTS

A total of 20 medical students were recruited, with a 100% response rate in both the pre- and post-surveys. There was a statistically significant increase in self-reported confidence in basic US use (adjusting gain, depth, probe manipulation), localizing major anatomical structures, using ultrasound for vessel access ($p=0.013$, $p<0.001$, $p<0.001$), and reported ease in identifying muscle, nerves, and major blood vessels under US ($p<0.001$, $p<0.001$, $p<0.001$). There was also a significant increase in correctly identified anatomical landmarks following the workshop, including the sternocleidomastoid muscle, IJ, carotid artery, femoral nerve, femoral artery, and femoral vein ($p<0.001$, $p=0.008$, $p=0.004$, $p<0.001$, $p<0.001$, $p<0.001$).

CONCLUSION

s Our findings suggest our homemade low-cost reusable gelatin-based models were effective in teaching vascular anatomy and US guided vascular access techniques to training physicians. Limitations include a small sample size from a single institution, and quantitative survey research design.

CLINICAL RELEVANCE/APPLICATION

Low-cost gelatin models represent an alternative to expensive commercial US phantoms to teach vascular anatomy and access techniques. These models have the potential to be adapted to many US guided procedures.

T5A-SPNPM-2 Motivations of Canadian Medical Students, Resident Physicians, and Fellows to Participate in a National Radiology Mentorship Program: Potential for Mutual Benefit?

Participants
Mohamed Abu-Nada, (*Presenter*) Nothing to Disclose

PURPOSE

To determine the reasons why mentees (medical students) and mentors (radiology residents and fellows) believe participating in a radiology mentorship program will be beneficial.

METHODS AND MATERIALS

A pan-Canadian survey was distributed to Canadian medical students and radiology trainees as a needs assessment to launch a longitudinal radiology mentorship program. The survey was shared through the Canadian Association of Radiologists and radiology residency programs. Medical students were categorized as mentees and trainees as mentors.

RESULTS

161 participants (67 mentors and 94 mentees) responded from Canadian medical schools. Despite being underrepresented in radiology, most mentors were women (55%). Women also represented 47% of mentees. Additionally, 26% of mentors and 37% of mentees identified as visible minorities. Mentors' top reasons for participating in mentorship were to aid in the development of future radiologists (85%) and to enhance their own mentoring/teaching skills (84%). Additionally, 42% of mentors who previously had a mentor themselves believed it positively influenced their radiology application and 95% believed mentoring was beneficial to trainees. Mentees' top reasons for participating were to learn more about radiology (82%), they were considering applying to radiology (82%), or were looking to get involved in radiology research projects (79%).

CONCLUSION

s This data can be used to inform the creation of a targeted radiology mentorship program since mentors and mentees have either benefitted or believe they can benefit from such a program. This data also shows the motivation of radiology trainees to improve their mentoring skills, which could also be acquired by creating intentional mentoring training.

CLINICAL RELEVANCE/APPLICATION

Due to the lack of exposure to radiology in the medical teaching curricula, radiology is often poorly understood by medical students. Currently, no Canadian radiology-specific mentorship program exists for medical students. Literature suggests that students with mentors have an increased sense of personal accomplishment, feel more confident in their careers, and have reduced burnout rates. Mentors benefit from mentorship programs with internal gratification, personal enrichment, and job satisfaction. Also, being a mentor provides the opportunity to develop leadership, communication, and collaboration skills. Additionally, in Canada, there exists a gender gap in radiology where women are under-represented and visible minorities also seem less represented. Studies have also shown that females and minorities are less likely to have mentors in radiology. Hence, a Canadian radiology mentorship program offered to all medical students could help increase diversity in radiology.

T5A-SPNPM-3 Formal Wellness Training of Academic Radiology Leaders Raises Awareness and Improved Teamwork Scores of Their Faculty

Participants
Jay R. Parikh, MD, West University Place, TX (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the effect of formal leadership training of academic radiology leaders within an academic center on their faculty burnout and professional fulfillment.

METHODS AND MATERIALS

The study cohort were academic radiologists within one of the largest academic organizations of academic radiologists within the United States. All academic radiologists within the organization were electronically mailed a weblink to a confidential IRB-approved survey in April 2021. The survey included validated questions from the Stanford Professional Fulfillment Index (PFI), values alignment, teamwork, overload, and work family conflict. Academic leaders were invited in May 2021 to participate in instructor-led formal training on leading wellness focusing on 5 core leadership skills - emotional intelligence, self-care, resilience support, demonstrating care, and managing burnout. An identical follow-up survey was electronically mailed to their faculty 6 months after initial training in November 2021.

RESULTS

The overall response rate of academic radiologists was 13 % (24/178). There was high internal consistency (Cronbach's a = 0.88 for work exhaustion and a = 0.93 for fulfillment). The inverse association between professional fulfillment and work exhaustion was significant ($r = -0.83$, $p < 0.01$). There was statistically significant improvement in one aspect of teamwork scores; assuming positive intent (5.36 vs 4.64; $p=0.03$). No statistically significant differences were identified for fulfillment, work exhaustion, alignment, work overload and work family conflict scores after training.

CONCLUSION

s Formal instruction of academic radiology leaders in leading wellness improved teamwork scores in their academic faculty. There was no significant change in work exhaustion, fulfillment nor organizational alignment of the faculty.

CLINICAL RELEVANCE/APPLICATION

Formal instruction of academic radiology leaders in leading wellness raised awareness and improved teamwork scores of their faculty.

T5A-SPNR-1 MRI Radiogenomics Analysis Predicts KRAS, EGFR and MET Mutational Status in Non-Small Cell Lung Carcinoma Brain Metastasis

Participants
Murat AK, MD, Pittsburgh, PA (*Presenter*) Nothing to Disclose

PURPOSE

Non-small cell lung cancer (NSCLC) has the highest incidence of metastases to the brain. Targetable alterations are often present in brain metastasis (BM) not found in the primary tumor. A non-invasive strategy is needed to detect brain-specific alterations. This study was conducted to assess the potential of radiogenomics to predict KRAS, EGFR and MET mutation status in BM from NSCLC patients.

METHODS AND MATERIALS

We retrospectively identified 159 NSCLC with BM both imaging and genomic annotation available. For each lesion, we segmented edema, contrast enhancement, and necrosis volume of interest (VOI) on both T2 FLAIR and T1 post-contrast sequences. Additionally, contralateral white matter (cWM) was also segmented for feature normalization. 10 histogram based first-order features and 195 second-order gray level co-occurrence matrix features were extracted from each VOI. After normalization, we divided the 195 second order features by the volumes of each VOI to produce another 195 volume-independent features per VOI for a total of 2,400 extracted features per lesions. We performed feature selection with Least Absolute Shrinkage and Selection Operator (LASSO). We split the cohort into 70% training and 30% testing sets for KRAS and EGFR and 80% training and 20% testing sets for MET models. We report the area under the curve (AUC) for classifying mutation status of each lesion and XGBoost was used to generate radiomics model.

RESULTS

Out of the 2,400 total features, LASSO identified 32 features for the EGFR mutant (mt) prediction model; of which the 20 most relevant were used for model building. The model achieved 78% accuracy, 77% sensitivity and 100% specificity. For the KRAS mt prediction model, LASSO defined 91 features and the model was generated with the top 30 features attaining 71% accuracy, 82% sensitivity and 60% specificity. Similarly, LASSO determined 90 features for MET mt prediction model, of which the top 15 features were used for the model demonstrating 77% accuracy, 76% sensitivity and 83% specificity.

CONCLUSION

s This study demonstrates that radiomics-based signatures can predict brain-specific molecular alterations including KRAS, EGFR and MET mutations.

CLINICAL RELEVANCE/APPLICATION

While further validation is warranted in a larger cohort, the proposed predictive radiomics-based approach is cost-effective, non-invasive and will help identify NSCLC patients with BM that are likely to respond to targeted treatments.

T5A-SPNR-10 The Role of Susceptibility-Weighted Imaging as an Accessory Diagnostic Tool of Global Cerebral Anoxia in the Post Cardiac Arrest Setting

Participants
Alyssa Ionno, Syracuse, NY (*Presenter*) Nothing to Disclose

PURPOSE

To examine the utility of Susceptibility-Weighted Imaging (SWI) in patients with concern for acute hypoxic-ischemic injury (HII) to the brain in the post cardiac arrest setting. It is well known that Diffusion-Weighted Imaging is our most sensitive MR sequence to detect a hypoxic-ischemic event, however it is our goal to demonstrate SWI as an effective accessory tool that should be utilized to assist in qualifying the degree of ischemic injury.

METHODS AND MATERIALS

Retrospective chart review was conducted in our tertiary care center. A total of 50 adult patients were selected at random with a history of acute cardiac arrest and MRI evaluation with concern for anoxic brain injury. With an independent review from a board-certified Neuroradiologist, SWI sequences were evaluated with an emphasis on the appearance of the superficial cortical veins. The great cerebral vein along with visualized arterial vasculature was also evaluated. The appearance of these vessels was quantified

using a scale of 0 - 3, 0 for absent or not seen, 1 for diminished appearance, 2 for present and normal, 3 for dilated. These findings were correlated with DWI results.

RESULTS

Of the 50 patients initially chart reviewed 37 demonstrated MR findings consistent with anoxic brain injury on either T2-weighted or DWI imaging. Within those 37 cases 26 had DWI findings consistent with acute anoxic brain injury (70%). SWI was unavailable or suboptimal in 6 cases leaving a total of 44 cases for complete analysis. Within the SWI subset, 34 of the 44 available cases demonstrated absent (0) or diminished (1) superficial cortical veins (77%). Importantly, only 5 of the 37 patients (14%) with any MRI findings characteristic of anoxic brain injury did not show any form of diminished superficial venous vasculature on SWI. Additionally, the great cerebral vein was absent or diminished in 30 of the 44 available cases (68%). In comparison to DWI, only 5 of the 26 (19%) cases with DWI findings consistent with HII did not show any form of diminished superficial or great venous vasculature on SWI. Interestingly, of the 13 available cases with no additional MR findings to suggest anoxic brain injury 4 demonstrated diminished or absent superficial cortical veins.

CONCLUSION

s In SWI, the amount of deoxy-hemoglobin content within the cortical veins directly correlates with their prominence. This can therefore be applied to episodes HII, which is secondary to a decrease in overall cerebral oxygen metabolism. Our data demonstrates a significant correlation with decreased vascular prominence on SWI in this setting.

CLINICAL RELEVANCE/APPLICATION

To further reinforce the use and addition of susceptibility weighted imaging in protocols for acute anoxic brain injury.

T5A-SPNR-11 Predictors of Intracranial Aneurysm Wall Enhancement on High Resolution MR Vessel Wall Imaging

Participants
Abhinav Patel, MBBS, Chicago, IL (*Presenter*) Nothing to Disclose

PURPOSE

MR Vessel Wall Imaging (VWI) is an increasingly utilized modality for evaluation of neurovascular pathologies like Intracranial aneurysms (IAs) and atherosclerotic plaques. Multiple studies have evaluated the associations between intracranial aneurysm wall enhancement (AWE), risk of rupture, and aneurysm growth on follow-up. In our study, we aim to identify predictors for AWE.

METHODS AND MATERIALS

IRB approval was obtained for a retrospective study. Patients with IAs greater or equal to 2mm and VWI imaging were included. AWE was evaluated qualitatively, and a quantitative assessment of the percentage increase in signal intensity (SI) was also performed using means of three point ROIs placed on aneurysm wall on pre and post-contrast axial T1-SPACE sequences. The increase in SI was normalized to white matter SI on pre and post-contrast images. Patient demographics, risk factors and IA size and morphology were recorded. IAs were grouped into small (<3.9mm), medium (4-7mm), and large (>7.1mm) sizes. Spearman rank test, linear regression, and one way ANOVA were used to assess statistical associations between an increase in signal intensity, size, and other variables using SPSS v28.

RESULTS

A total of 174 patients (Mean age = 62.5 (24-87), 74% females) with 214 IAs (Mean size = 5.149 mm (2-30 mm) were assessed. 18/174 (10.34%) patients presented with subarachnoid hemorrhage. On qualitative evaluation, AWE was observed in 112/214 ICAs (52.3%). IA size demonstrated a moderate correlation (r = 0.5, p<0.001, 95% CI, 0.372-0.609) to percentage increase in SI. There was a statistically significant (p<0.001) increase in percentage SI, 24.75%, 46.35%, and 79.69%, in small (n = 78) , medium (n = 96) , and large (n = 40) aneurysm groups. Thrombosis of the aneurysm sac (r = 0.238, p = 0.002, 95% CI, 0.085-0.381) and SAH demonstrated a statistically significant albeit weak correlation (r = 0.188, p = 0.015, 95% CI, 0.032-0.0335) with AWE. There was no correlation between demographics, risk factors (HTN, HLD, family history, smoking) and AWE.

CONCLUSION

s Destabilizing IA factors that may increase permeability appear to be associated with AWE or uptake, including large size, mural thrombus, and rupture.

CLINICAL RELEVANCE/APPLICATION

VWI holds an advantage over traditional vascular imaging techniques that are restricted to visualizing the vessel lumen. This study supports the hypothesis that AWE on MR VWI could be an indicator of aneurysm wall instability while lack of enhancement could correlate to wall stability.

T5A-SPNR-12 Characterization of Normal-Appearing White Matter Over 1-2 Years in Small Vessel Disease Using Quantitative Susceptibility Mapping and Free-Water Mapping

Participants
Yawen Sun, Shanghai, China (*Presenter*) Nothing to Disclose

PURPOSE

The aim of this study was to investigate alterations in the normal-appearing white matter (NAWM) with small vessel disease (SVD) over 1-2 years using quantitative susceptibility mapping and free-water (FW) mapping.

METHODS AND MATERIALS

Fifty-one SVD patients were included in this prospective study. Clinical testing and brain MRI scans were performed both at baseline and follow-up. Quantitative susceptibility (QS), fractional anisotropy (FA), mean diffusivity (MD), FW, FW-corrected FA (FAT), and FW-corrected MD (MDT) maps within white matter lesions (WMLs) and NAWM were generated for comparison. We also used the Johns Hopkins University Inventory of Cognitive Bias in Medicine (ICBM)-DTI-81 white matter (WM) label atlas as an anatomic guide and calculated the NAWM part in each of the WM tracts. The average regional values were extracted and paired t-test was used to analyze the longitudinal change. Partial correlations were used to assess the relationship between the MRI indices changes (e.g.?QSfollowup-baseline/QSbaseline) and Montreal Cognitive Assessment (MoCA) scores changes (?MoCAfollowup-

baseline/MoCAbaseline) which represent the cognitive function.

RESULTS

Over 1-2 years, no significant difference was found in these MRI indices between baseline and follow-up in the WMLs region. In contrast, the QS values (index of demyelination) increased significantly in the NAWM at follow-up. Among WM tracts, we found the QS values in the NAWM part of the left superior frontal blade (SF), left occipital blade, right uncinate fasciculus, and right corticospinal tract (CST) were higher at follow-up than those at baseline. Results of FW (index of neuroinflammation/edema) analysis revealed that SVD patients at follow-up had increased FW in the NAWM part of the right CST and decreased FW in the NAWM part of the right inferior frontal blade (IF). The right SF and the right IF demonstrated significantly decreased FAT (indices of axonal loss) at follow-up compared to baseline. The degree of FAT changes in the NAWM part of the right IF were positively correlated with MoCA scores changes.

CONCLUSION

s Our study revealed how WMLs and NAWM may change over the years. The results supported that SVD is a dynamic chronic disease and the NAWM in SVD is still in the progressive injury process. Distinguishing among demyelination, neuronal degeneration, and neuroinflammation in the NAWM in vivo may provide a better understanding of the progression of SVD.

CLINICAL RELEVANCE/APPLICATION

QSM and FW mapping can provide complementary information in the NAWM of SVD patients.

T5A-SPNR-13 Structural Disconnection Is Associated With Disease Severity in Neuromyelitis Optica Spectrum Disorder

Participants
Ji Young Woo, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Neuromyelitis optica spectrum disorder (NMOSD) is an autoimmune inflammatory and demyelinating disorder of the central nervous system (CNS). Accumulating evidence suggest that distinct pattern of MRI lesions characteristic of NMOSD exists and the brain MRI have potential prognostic implications. However, we do not fully understand how this brain lesions in NMOSD is associated to its rather severe and distinct clinical course. Here, we tried to investigate the association via brain structural disconnection.

METHODS AND MATERIALS

20 patients diagnosed with NMOSD with AQP4-IgG according to the 2015 International Panel for NMO Diagnosis (IPND) criteria. The white matter lesion ROIs were manually drawn section by section on the 3D FLAIR sequence. Structural disconnection was estimated using the Lesion Quantification Toolkit. Connectome-based predictive modeling (CPM) was used to predict patient's EDSS (Expanded Disability Status Scale) from their disconnection severity matrix. In addition, correlational tractography using 32 direction diffusion weighted image was conducted to reveal local connection associated with disease severity.

RESULTS

CPM successfully predicted the EDSS using the disconnection severity matrix ($r = 0.506$, $p = 0.028$; $q2 = 0.274$). Among important edges in the prediction process, 19 edges were connecting the Motor - frontoparietal network, followed by 16 edges connecting the nodes within motor network and 15 edges connecting within frontoparietal network. Correlational tractography revealed local connectome in the periependymal area is associated with EDSS score.

CONCLUSION

s The structural disconnection within and between the motor and frontoparietal networks emerged as being most informative in predictions. In other words, the more severe disconnections involving these networks is predictive of severe EDSS score. Also, local disconnectome in the periependymal region is associated with EDSS score

CLINICAL RELEVANCE/APPLICATION

Using state-of the art imaging techniques and multivariate machine learning approach, we show that structural disconnection due to brain lesions, especially motor and fronto-parietal network, is predictive of disease severity in NMOSD.

T5A-SPNR-14 Spatial Similarity of MRI-Visible Perivascular Spaces in Healthy Young Adult Twins

Participants
Boeun Lee, (*Presenter*) Nothing to Disclose

PURPOSE

This study aims to determine whether genetic factors affect the location of dilated perivascular spaces (dPVS) by comparing healthy young twins and non-twin (NT) siblings.

METHODS AND MATERIALS

A total of 700 healthy young adult twins and NT siblings (138 monozygotic (MZ) twin pairs, 79 dizygotic (DZ) twin pairs, and 133 NT sibling pairs) were collected from the Human Connectome Project dataset. dPVS was automatically segmented and normalized to standard space. Then, spatial similarity indices (mean squared error [MSE], structural similarity [SSIM], and dice similarity [DS]) were calculated for dPVS in the basal ganglia (BGdPVS) and white matter (WMdPVS) between paired subjects before and after propensity score matching of dPVS volumes between groups. Within-pair correlations for the regional volumes of dVPS were also assessed using the intraclass correlation coefficient (ICC).

RESULTS

The spatial similarity of dPVS was significantly higher in MZ twins (higher DS [median, 0.382 and 0.310] and SSIM [0.963 and 0.887] and lower MSE [0.005 and 0.005] for BGdPVS and WMdPVS, respectively) than DZ twins (DS [0.121 and 0.119], SSIM [0.941 and 0.868], and MSE [0.010 and 0.011]) and NT siblings (DS [0.106 and 0.097], SSIM [0.924 and 0.848], and MSE [0.016 and 0.017]). No significant difference was found between DZ twins and NT siblings. Similar results were found even after subjects were matched

according to dPVS volume. Regional dPVS volumes were also more correlated within pairs in MZ twins than DZ twins and NT siblings.

CONCLUSION

s Our results suggest that genetic factors affect the location of dPVS.

CLINICAL RELEVANCE/APPLICATION

We demonstrated that location of dPVS as well as its overall burden might be genetically determined to some extent using high quality images of healthy young twins and NT siblings from a large dataset.

T5A-SPNR-15 Characterization of White Matter Microstructural Abnormalities Associated With Cognitive Dysfunction in Cerebral Small Vessel Disease With Cerebral Microbleeds

Participants
Haotian Xin, Jinan, China (*Presenter*) Nothing to Disclose

PURPOSE

To characterize white matter (WM) microstructural abnormalities with diffusion tensor imaging (DTI) and their relationship with cognitive dysfunction in cerebral small vessel disease (CSVD) patients with cerebral microbleeds (CMBs) at the group and individual levels.

METHODS AND MATERIALS

Fractional anisotropy (FA), mean diffusivity (MD), axial diffusivity (AD) and radial diffusivity (RD) images from 49 CSVD patients with CMBs (CSVD-c), 114 CSVD patients without CMBs (CSVD-n), and 83 controls were analyzed using DTI-derived tract-based spatial statistics (TBSS) to detect WM diffusion changes among groups. Pearson's correlations between regional diffusion changes and cognitive performance were investigated for all groups. Furthermore, machine learning and multivariate pattern analysis (MVPA) were applied for group classification and identifying the discriminative WM diffusion features for predicting CSVD patients with CMBs.

RESULTS

The CSVD-c group showed significant FA decrease, AD, RD and MD increases mainly in the bilateral superior longitudinal fasciculus (SLF), inferior fronto-occipital fasciculus (IFOF), anterior thalamic radiation (ATR), inferior longitudinal fasciculus (ILF), corticospinal tract (CST), corpus callosum, external capsule and right anterior limb of internal capsule (ALIC) compared with the CSVD-n and control groups. There was no significant difference in any diffusion metric between the CSVD-n and control groups. In addition, the widespread regional diffusion alterations among groups were significantly correlated with cognitive parameters in both the CSVD-c and CSVD-n groups. Notably, we applied the multiple kernel learning (MKL) technique in MVPA to combine regional diffusion features, yielding an average of >77% accuracy for three binary classifications, which shows a considerable improvement over the individual modality approach.

CONCLUSION

s Our findings revealed that CSVD patients with CMBs have extensive WM microstructural deterioration and suggested a key role of CMBs in causing vascular cognitive impairment involved in auditory verbal, symbol digit and executive control. Combining DTI-derived diffusivity and anisotropy metrics can provide complementary information for assessing WM alterations associated with cognitive dysfunction and serve as a potential discriminative pattern to detect CSVD at the individual level.

CLINICAL RELEVANCE/APPLICATION

Our study may help to understand the pathology of CSVD and develop new objective neuroimaging biomarkers for diagnosis, monitoring the progression of disease or evaluating treatment efficacy.

T5A-SPNR-16 Quantitative Evaluation of White Matter Injury after Acute Carbon Monoxide Poisoning by Diffusion Tensor Imaging

Participants
Wenxuan Han, XI'AN, China (*Presenter*) Nothing to Disclose

PURPOSE

Carbon monoxide (CO) poisoning is one of the leading causes of poisoning death worldwide. At present, the brain injury mechanism of CO poisoning is still unclear, which may be related to ischemic brain tissue injury and white matter (WM) demyelination. Still, there is no consistent conclusion in existing studies. Therefore, DTI was used in this study to evaluate the microstructural integrity of white matter in patients with acute CO poisoning, and to provide evidence for the characteristics of early DTI in patients with acute CO poisoning.

METHODS AND MATERIALS

Twenty-four patients with acute CO poisoning were received MRI within 7 days after CO poisoning. Meanwhile, 25 age- and sex-matched healthy subjects were enrolled as controls for the study. MRI was performed using a 3.0-T scanner with a 24 channels head coil. MRI sequences included T1-weighted image (T1WI), T2WI and DTI were acquired. DTI data were processed using the FMRI Software Library (FSL) Diffusion Toolkit. Tract-Based Spatial Statistics (TBSS) was used to perform voxel-wise analysis. The differences between the two groups of demographic data were analyzed. Statistical analysis of DTI data was implemented using the permutation-based (non-parametric) randomize tool within FSL. A restrictive statistical threshold was used (Threshold-Free Cluster Enhancement threshold, $p < 0.05$, corrected for multiple comparisons).

RESULTS

Of the 24 analyzed patients, the median age was 53.4±16.2 years, and there were 5 male patients (20.8%). The median age of healthy controls was 53.4±14.2 years and there were 9 males (36.0%). There were no significant differences in sex or age between patients and controls ($p=0.24$, $p=0.99$). Fractional anisotropy (FA) value of genu, body and splenium of corpus callosum, bilateral frontal corona radiata and bilateral posterior WM in acute CO poisoning patients was significantly lower than that in the control group, while mean diffusivity (MD), axial diffusivity (AD), radial diffusivity (RD) was significantly higher than that in the control group. The spatial extents were relatively similar in all 4 DTI statistical maps.

CONCLUSION

s This study suggests that DTI can provide a basis for quantitative assessment of brain injury after acute CO poisoning.

CLINICAL RELEVANCE/APPLICATION

DTI may be a biomarker for varying injury severity in acute CO poisoning.

T5A-SPNR-17 Interaction Effect Between White Matter Hyperintensity Burden and Cognitive Status on the Grey Matter Volume: A Large Scale Cross-Sectional T1 and T2 Multi-Modal Study Using Automated Segmentation Tool

Participants
Regina Ey Kim, (*Presenter*) Researcher, NEUROPHET, Inc

PURPOSE

The correlation between the white matter hyperintensity (WMH) and brain atrophy has been increasingly recognized as the biomarker of conversion from mild cognitive impairment (MCI) to Alzheimer's disease (AD). However, due to the studies with limited subject (n < 100), the related findings are debatable. In addition, the detailed WMH analysis, such as periventricular hyperintensity (PWMH) and deep white matter hyperintensity (DWMH), has not been investigated previously. To better understand the association between WM burden and grey matter (GM) atrophy, the interaction effect between WMH burden (both PWMH and DWMH) and cognitive status on the GM volume was investigated.

METHODS AND MATERIALS

A total of 3060 paired images of T1-weighted (T1w) MRI and T2- Fluid Attenuated Inversion Recovery (T2-FLAIR) MRI were utilized from seven research or clinical sites in Korea. Participants were categorized into cognitively normal (N=1540), mild cognitive impairment (MCI, N=1099), and dementia (N=421) group based on their clinical assessments. T1w and T2-FLAIR images were processed and extracted their outcomes (seven GM volumes and three WMH ratio to WM) using previously developed tools. Multivariate linear regression analysis was then performed to identify interaction effect between WMH ratio to WM and cognitive status after adjusting for corresponding WMH ratio, GM volume, age, and sex.

RESULTS

Our results indicated the higher WMH burden was associated with the lower cingulate volume in MCI (-9.5mL, p=0.022) when compared to the control groups . This interaction effect was mainly driven by the PWMH (-9.6mL, p=0.039) rather than the DWMH (-0.1mL, p=0.248). For the dementia group, the larger GMV with increased WMH was observed for frontal (+69.9mL, p=0.022) and parietal GM (+55.7mL, p=0.018). The parietal result was mostly driven by the PWMH (80.2mL, p=0.018) too.

CONCLUSION

s Our research demonstrated the significant interaction effect between the WMH burden and the cognitive type, highlighting the importance of observing WMH burden in details (e.g., PWMH vs. DWMH) for cognitive decline status.

CLINICAL RELEVANCE/APPLICATION

The WMH burden in association with cognitive decline, including MCI and dementia, should be closely monitored for their effect on brain atrophy.

T5A-SPNR-18 What Causes Us to Fail and What Happens Afterwards? A Retrospective Analysis of Failed Fluoroscopic Guided Lumbar Punctures at a Large Tertiary Medical Center

Participants
Myroslav Gerasymchuk, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Fluoroscopic guided lumbar punctures (FGLP) is an image guided procedure performed to obtain cerebrospinal fluid (CSF). Rarely, FGLPs can be unsuccessful for variety of reasons including inability to enter the spinal canal or inability to collect CSF, even though the needle tip is seen in the spinal canal on fluoroscopy. To our knowledge, no published data on FGLP failure rates, causes of failures, and immediate outcomes of patients with failed FGLPs exists. We hypothesize that FGLPs have a high success rate, majority of failed FGLPs are due to inadequate egress of CSF through the needle, and majority of patients with failed FGLPs return and undergo a successful FGLP.

METHODS AND MATERIALS

We retrospectively reviewed charts of patients with failed FGLPs from 6/1/2018-3/31/2022 to collect demographic data and determine cause of FGLP failure (inability to collect CSF), if patient had a successful repeat FGLP, and if no further FGLP attempt was made, if the patient was successfully discharged.

RESULTS

From 6/1/2018-3/31/2022, n=922 FGLPs were performed on inpatient/ER patients. 46/922 (5.0%) of patients had failed initial attempts by 30 trainees at obtaining CSF. 23/46 (50%) of failures were due to lack of egress of CSF through the LP needle, though the needle tip was within the spinal canal. 10/23 patients (43%) returned to undergo FGLP on another date (mean 6.3 days (range 1-28 days) after 1st attempt) of which 70% underwent documented IV hydration prior to the FGLP and 90% were successful. 14/46 (30%) of failures were due to inability to access the spinal canal either due to degenerative changes (n=10), high BMI (>35) (n=3), or postsurgical scarring (n=1). 3/14 of patients returned to undergo another FGLP of which 2 were successful and 1 failed again. 17/46 (35%) of patients did not undergo further FGLP attempt as they improved clinically or other reasons for symptomatology were revealed and 100% of these patients were successfully discharged.

CONCLUSION

s In our large sample, FGLPs had a success rate of 95%. Majority of the FGLPs failures were due to inability to collect CSF presumably due to low CSF pressure. Majority of these patients subsequently underwent a successful FGLP after hydration. Of patients who returned for a repeat FGLP after an initial FGLP failure due to degenerative bony changes or high BMI, 66% were

successful. Few patients did not return for a repeat FGLP and were successfully discharged.

CLINICAL RELEVANCE/APPLICATION

FGLPs have a high success rate in obtaining CSF and majority of the FGLP failures are due to presumed low CSF pressure. Assurance of proper hydration may obviate a need for repeat FGLP. Physicians should also be aware that FGLPs can still fail and some patients will eventually be discharged without requiring CSF sampling.

T5A-SPNR-19 In Vitro and In Vivo Evaluation of US-Triggered Release from Novel Spinal Device

Participants
Flemming Forsberg, PhD, Philadelphia, PA (*Presenter*) Research Grant, Canon Medical Systems Corporation;Research support, Canon Medical Systems Corporation;Research support, General Electric Company;Speaker, General Electric Company;Research support, Siemens AG;Research Grant, Butterfly Network, Inc;Research support, Lantheus Medical Imaging, Inc;Research support, Bracco Group

PURPOSE

Bacterial infection following spinal fusion is a major clinical concern, with up to 15% incidence, despite aggressive peri-operative antibiotic treatments. To serve this need, we have designed and evaluated an US-activated bulk release system to combat post-surgical bacterial survival.

METHODS AND MATERIALS

Polylactic acid (PLA) clips with a 0.79 cm3 drug-loading reservoir were 3D printed, loaded with the appropriate payload, and sealed with a PLA film (0.05 ± 0.01 mm thick). Clips evaluated in vitro were loaded with 150 µL vancomycin (VAN, 400 mg/mL, Athenex) and 50 µL Sonazoid (GE Healthcare), and those tested in vivo with 150 µL methylene blue (MeB) solution and 50 µL Sonazoid. Long-term stability of Sonazoid in distilled water and VAN was determined over a 14-day incubation at 4°C. Microbubble counts were obtained via flow cytometry. Contrast enhancement was visualized with a Logiq E10 scanner (GE). VAN-loaded clips were submerged in 37°C water and insonated for 10 minutes using a curvilinear C6 probe. Power Doppler imaging (1.8 MHz, 6.5 kHz PRF, ISPTA 146.2 ± 1.4 mW/cm2) induced VAN release, quantified using spectrophotometry. MeB-loaded clips were implanted into a rabbit along the spinal midline at L2 and L5, as well as a pig at L1 and L3, then insonated in Doppler mode at 1.7 MHz for 20 minutes using the C6 probe (5.4 kHz PRF, ISPTA < 146 mW/cm2). Animals were sacrificed 2 hours post-insonation for evaluation.

RESULTS

VAN had a conservatory effect on Sonazoid ($p = 0.007$) over the 14 days, since the number of Sonazoid microbubbles in distilled water had reduced by ~90% (from 7.3 ± 1.4x107/mL to 7.3 ± 1.6x106/mL), while those incubated in the VAN solution reduced by ~60% (from 8.9 ± 6.7x106/mL to 3.3 ± 9.3x106/mL). Contrast enhancement was observed from both solutions at 14 days, indicating retained cavitation ability. Insonated clips had an average cumulative VAN release of 81.4 ± 2.8 mg at 72 hours. Uninsonated clips had only 0.3 ± 0.1 mg average cumulative VAN release ($p < 0.0001$). Clips retrieved from the rabbit showed no signs of PLA film rupture nor MeB staining on surrounding tissues. Following physical puncture of the PLA film, release of MeB solution was visible. The pig clip PLA film was visibly ruptured, and demonstrated some MeB staining of the overlying tissues.

CONCLUSION

s These results demonstrate the ability to produce US-triggered release of an encapsulated prophylactic solution, and an important proof of concept for continuing large animal model in vivo evaluations.

CLINICAL RELEVANCE/APPLICATION

Existing methods are only partially successful in preventing infection after spinal fusion surgery. We designed an US-activated system for release of prophylactics to combat post-surgical infection.

T5A-SPNR-2 Intraorbital Findings in Giant Cell Arteritis on Black Blood MRI

Participants
Konstanze Guggenberger, MD, Wuerzburg, Germany (*Presenter*) Nothing to Disclose

PURPOSE

An expedient and accurate diagnosis of giant cell arteritis (GCA) is critical as blindness is an irreversible complication. Little is known about the spectrum of orbital imaging findings in GCA. We determined the prevalence of inflammatory changes of the intraorbital structures using high-resolution black blood MRI (BB-MRI) in patients with GCA compared to age-matched controls.

METHODS AND MATERIALS

A retrospective multicenter case-control study was performed screening for patients who underwent a BB-MRI on a 3 Tesla MR scanner, a clinical or histologic diagnosis of GCA, as well as age-matched controls. The BB-MRI pulse sequence was a post-contrast compressed-sensing (CS) T1-weighted sampling perfection with application-optimized contrasts using different flip angle evolution sequence. Two radiologists, blinded to clinical history, independently assessed for enhancement of the optic nerve, optic nerve sheath, ophthalmic artery vessel wall, optic chiasm, intraconal fat and extraocular muscle. Descriptive statistics were used to report percentages. Association of intraorbital BB-MRI findings with orbital symptoms was tested by Chi-Square analysis

RESULTS

56 patients (N=41 females; mean age 74 years) with GCA and 50 age-matched controls (17 female; mean age 70) met inclusion criteria. At the time of BB-MRI, 20 patients were steroid-naïve and 36 patients received a mean of 70 days (SD 133 days) of steroids. 32% of GCA patients showed inflammatory changes of at least one intraorbital structure. In GCA patients, optic nerve sheath enhancement (23%) was the most common BB-MRI finding, followed by ophthalmic artery vessel wall enhancement (OA-VWE) (14%). OA-VWE was unilateral in 9% and bilateral in 5%. Optic nerve enhancement was observed in one GCA patient. There was no significant correlation between patient reported orbital symptoms and pathologic enhancement of an intraorbital structure ($p=0.10$). None of the age-matched control patients showed any inflammatory changes of intraorbital structures.

CONCLUSION

s BB-MRI revealed inflammatory findings in the orbits in up to 32% of patients with GCA independent of patient reported orbital

symptoms. Optic nerve sheath enhancement was the most common intraorbital inflammatory change.

CLINICAL RELEVANCE/APPLICATION

BB-MRI is a promising imaging technique to assess early inflammatory orbital changes in patients with GCA and may have a diagnostic and prognostic role for ophthalmologic complications.

T5A-SPNR-3 Multimodal Imaging of Lateral Branch Circulation and Cerebral Hemodynamic Correlation in Moyamoya Disease

Participants
Yao Lu, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the relationship between collateral circulation and cerebral hemodynamics in patients with moyamoya disease and moyamoya syndrome using 4D CTA-CTP imaging.

METHODS AND MATERIALS

The clinical and imaging data of 32 patients with moyamoya disease and moyamoya syndrome in Beijing Hospital from January 2017 to January 2022 were retrospectively analyzed.4D-CTA images were scored by ASPECTS multi-phases scoring system, and DSA images were scored by ASITN/SIR score. The patients were divided into good collateral circulation group, medium collateral circulation group and poor collateral circulation group based on collateral circulation score. The consistency and correlation of the two collateral scores were compared. The perfusion parameters including cerebral blood volume (CBV), cerebral blood flow (CBF), mean transit time (MTT), mean transit time (TTP) and delay time (DLY) were obtained at basal ganglia level. The regions of interest (ROI) were plotted in the frontal, temporal and occipital lobes of both hemispheres respectively. Total of 192 measurements were obtained for each perfusion parameter. The differences of perfusion parameters among the three groups were compared.

RESULTS

1. The consistency of the two collateral circulation scores was moderate (Kappa=0.693, P<0.001). Spearman correlation analysis showed the correlation was good (r=0.805, P<0.001). 2. There were statistically significant differences in CBF, MTT and TTP among the three groups [CBF (38.2 ml /100g/min vs 40.6 ml /100g/min vs 42.1 ml /100g/min, P=0.019), MTT (4.9s vs 4.9s vs 4.5s), TTP (20.0s vs 18.3s vs 16.4s, P =0.012)].The CBF value of the poor collateral circulation group was lower than that of the good collateral circulation group (P =0.015 after Bonferroni correction). The MTT value of the moderate collateral circulation group was higher than that of the good collateral circulation group (P =0.005 after Bonferroni correction). The TTP value of the poor collateral circulation group was higher than that of the good collateral circulation group (P=0.015 after Bonferroni correction).

CONCLUSION

s 4D CTA-CTP is equivalent to DSA in evaluating collateral circulation in patients with moyamoya disease and moyamoya syndrome, and the cerebral hemodynamics can be assessed simutaneously, which has high clinical significance for disease monitoring.

CLINICAL RELEVANCE/APPLICATION

Multi-modal imaging can be used to monitor the cerebral hemodynamics of patients with moyamoya disease in a non-invasive manner, provide effective guidance for treatment, and observe the disease progression in real time.

T5A-SPNR-5 To Achieve Dramatic Radiation Dose and Contrast Dose Reduction with 70kVp Tube Voltage and Iterative Reconstruction for Head and Neck CT Angiographyon Wide-detector CT: Comparison with Conventional CT Using 120kVp

Participants
Yanan Zhu, Ankang, China (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the clinical value of using 70kVp and new generation adaptive statistical iterative reconstruction (ASIR-V) for reducing radiation dose and contrast dose in head and neck computed tomographic angiography (CTA) on a 16cm wide-detector CT.

METHODS AND MATERIALS

Sixteen patients (Group A) were prospectively enrolled to undergo low radiation and contrast dose head and neck CTA using 70 kVp tube voltage and 25 mL contrast medium (CM) on a 16cm wide-detector CT system. Images were reconstructed using ASIR-V at 80% level. These images were compared with the historic data of 16 consecutive patients (Group B) who were scanned on a 64 slices CT scanner using conventional doses with 120 kVp and 50 mL CM. CT values and noise of the internal carotid artery (ICA), basilar artery (BA), middle cerebral artery (MCA), left thalamus, left centrum ovale and left cerebellar hemisphere were measured. The signal-to-noise ratio (SNR) and the contrast-to-noise ratio (CNR) for targeted arteries and brain parenchyma were calculated. Subjective image quality in terms of bone-brain interface, beam hardening artifact and gray matter and white matter contrast was evaluated. The volumetric CT dose index (CTDIvol) was recorded. Measurements from the two groups were statistically compared.

RESULTS

Group A reduced radiation dose by 94% (1.94±0.0mGy vs. 33.16±4.92mGy, p<0.001) and used half the contrast medium dose (25mL vs. 50mL) compared with Group B. There was no difference in the mean CT values of ICA, BA and MCA between Group A (507.95±171.06HU, 430.43±169.20HU, 431.06±152.85HU, respectively) and Group B (427.09±97.01HU, 341.88±79.17HU, 328.40±84.74HU, respectively) There were no differences in SNR and the CNR for the targeted arteries and brain parenchyma and no difference in subjective image quality between the two groups (all P > 0.05).

CONCLUSION

s The use of 70kVp and ASIR-V in head and neck CTA on a wide-detector CT system significantly reduces both radiation dose and contrast dose while providing excellent image quality, compared to the use of conventional protocols .

CLINICAL RELEVANCE/APPLICATION

Image quality of the head and neck CTA were not impaired at the low dose of 70kvp and 25ml iodinated contrast agent on wide

Image quality of the head and neck CTA were not impaired at the low dose of 70kVp and 25ml iodinated contrast agent on wide-detector CT, allowing for radiation and contrast medium reduction.

T5A-SPNR-6 Positive Correlation Between Cerebral Amyloid Angiopathy (CAA) And Transverse Relaxation Rate (R2): An Analysis of Ex-vivo MRI and Neuropathology

Participants
Md Tahmid Yasar, (*Presenter*) Nothing to Disclose

PURPOSE

Cerebral amyloid angiopathy (CAA) is identified by deposition of amyloid in the cortical and meningeal vessel walls. In this work, the association of CAA with the transverse relaxation rate R2 values in a large community-based cohort of older adults was investigated.

METHODS AND MATERIALS

Cerebral hemispheres from 797 older adult participants of three cohort studies, the Rush Memory and Aging Project, the Minority Aging Research Study, and the Religious Orders Study were utilized in this work. All hemispheres were imaged ex-vivo at approximately 30 days postmortem using 3T clinical MRI scanners. Each scan included a multi-echo spin-echo sequence. The signals from different echoes were used to fit a mono-exponential T2 decay function (R2 is the reciprocal of T2) in each voxel. The obtained R2 maps were registered to an ex-vivo hemisphere template using ANTS. Following the MRI scan, each hemisphere underwent thorough neuropathologic evaluation. The assessed pathologies were: CAA, Alzheimer's pathology, LATE-NC, hippocampal sclerosis, Lewy bodies, arteriolosclerosis, atherosclerosis, gross and microscopic infarcts. Voxel-wise linear regression was carried out to determine the association of CAA with R2, controlling for all other pathologies listed above, demographics (age at death, sex, education), postmortem interval to fixation and imaging and scanner covariates. Statistical analysis was done using PALM with tail-accelerated 1000 permutations, threshold-free cluster enhancement, and family-wise error rate correction. Statistical significance was set at $p<0.05$.

RESULTS

The analysis showed a spatial pattern of higher R2 values for elevated CAA scores. The pattern comprised of structures such as the caudate, putamen, nucleus accumbens, hippocampus, insula, anterior cingulate cortex, orbitofrontal cortex, and superior frontal cortex. Negative association between R2 values and CAA scores were not found.

CONCLUSION

s Our work showed that CAA is associated with higher R2 among older adults, independent of demographic covariates and other neuropathologies. The spatial pattern included basal ganglia and frontal lobe structures.

CLINICAL RELEVANCE/APPLICATION

Our work demonstrates the association of CAA with relaxation rate R2 in older adults. The findings can be used to generate features for MRI-based classifier that can detect the CAA pathology.

T5A-SPNR-7 Migraine-Associated Vascular Changes on Structural 7T-MRI

Awards
Trainee Research Prize - Medical Student

Participants
Wilson Xu, Los Angeles, CA (*Presenter*) Nothing to Disclose

PURPOSE

Migraine is a complex medical disorder which might be associated with vascular-related changes in the brain, such as white matter hyperintensities (WMH), and in some cases cerebral microbleeds (CMB). The association between migraine and enlarged perivascular spaces (EPVS) has not been thoroughly investigated. Our study utilizes ultra-high field 7T MRI to compare structural microvascular changes in different types of migraine, comparing them for the first time to headache-free healthy controls (HC).

METHODS AND MATERIALS

Participants included 10 chronic migraine (CM), 10 episodic migraine without aura (EMWoA), and 5 age-matched HC. Inclusion criteria were ages 25-60 years and ongoing CM/EMWoA. Exclusion criteria were overt cognitive impairment, brain tumor, prior intracranial surgery, contraindications to MRI, and claustrophobia.Neuroimaging data were collected using 7T MRI scans utilizing T1, T2, FLAIR, and SWI/QSM sequences. We calculated EPVS in centrum semiovale (CSO) and basal ganglia (BG), WMH using the Fazekas scale, and CMB using the microbleed anatomical rating scale. We also collected clinical data such as disease duration and severity, symptoms at time of scan, presence of aura, and side of headache. Regression analysis compared neuroimaging data among CM, EMWoA, and HC.

RESULTS

Preliminary statistical analysis reveals that the number of EPVS in the CSO, but not in the BG, was significantly higher with migraine compared to HC ($p=0.04$). Frequency of WMH and CMB in migraine did not differ significantly from that of HC. However, migraine patients showed a significant correlation between EPVS quantity in CSO and deep WMH severity ($p=0.04$).

CONCLUSION

s Significant differences in the EPVS in migraine compared to HC might be suggestive of glymphatic disruption within the brain, but whether such changes affect migraine development or result from migraine is unknown. EPVS may influence other vascular-related changes in migraine, suggesting a pathophysiological mechanism or possible use as an early imaging biomarker. Continued study with larger case populations and longitudinal follow-up will better establish the relationship between structural changes and migraine development and type.

CLINICAL RELEVANCE/APPLICATION

7T MRI allows us to measure EPVS in migraine more accurately, advancing our knowledge on the effect of vascular/glymphatic

changes on various types of migraine for future disease-specific therapy.

T5A-SPNR-8 Migraine-Associated Perfusion Changes on 7T MRI

Participants
Brendon Chou, Arcadia, CA (*Presenter*) Nothing to Disclose

PURPOSE

Perfusion studies using Arterial Spin Labeling (ASL) in migraines have had conflicting results. However, these studies were limited by image resolution of 1.5 and 3T MRI scanners. Our study utilizes ultra-high field 7T MRI to investigate perfusion changes in different types of migraine with comparison to healthy controls (HC) for the first time to improve our understanding of migraine pathophysiology and guide diagnosis and treatment.

METHODS AND MATERIALS

Participants were recruited as 10 chronic migraine (CM), 10 episodic migraine without aura (EMWoA), and 5 age-matched HC. Inclusion criteria were ages 25-60 years and ongoing CM/EMWoA. Exclusion criteria were overt cognitive impairment, brain tumor, prior intracranial surgery, contraindications to MRI, and claustrophobia.Neuroimaging data were acquired using the Human Connectome Project protocol implemented on a 7T MRI scanner. For the quantification of cerebral blood flow, we adopted a 3D gradient and spin-echo (GRASE) pseudo-continuous ASL (pCASL) sequence with background suppression. We also collected clinical data such as disease duration and severity, symptoms at time of scan, presence of aura, and side of headache. Cerebral blood flow (CBF) maps were generated by performing pairwise subtraction of motion-corrected label and control images from pCASL data, which were subsequently averaged across the time series.

RESULTS

We observed a trend for higher cerebral blood flow (CBF) in the cortex and white matter of CM patients compared with HC or EMWoA patients (p=0.07).

CONCLUSION

s This study is novel in its usage of 7T MRI pCASL to assess perfusion changes in migraine patients. CBF increase within the cortex and white matter may reflect the lasting effects of cerebral hyperperfusion in chronic migraine or can be secondary to repetitive and frequent cortical hyperactivity. In order to understand the underlying mechanism of these changes, further studies are required to investigate the relationship between CBF and functional connectivity changes in different migraine types and phases.

CLINICAL RELEVANCE/APPLICATION

Increase in CBF in CM migraine compared to EMWoA or HC can be suggestive of more extensive vascular dysregulation in this group, which may help us understand the underlying mechanism, differentiate specific types of migraine and guide further treatment.

MRI Radiogenomics Analysis Predicts KRAS, EGFR and MET Mutational Status in Non-Small Cell Lung Carcinoma Brain Metastasis

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Murat AK, MD, Pittsburgh, PA (*Presenter*) Nothing to Disclose

PURPOSE

Non-small cell lung cancer (NSCLC) has the highest incidence of metastases to the brain. Targetable alterations are often present in brain metastasis (BM) not found in the primary tumor. A non-invasive strategy is needed to detect brain-specific alterations. This study was conducted to assess the potential of radiogenomics to predict KRAS, EGFR and MET mutation status in BM from NSCLC patients.

METHODS AND MATERIALS

We retrospectively identified 159 NSCLC with BM both imaging and genomic annotation available. For each lesion, we segmented edema, contrast enhancement, and necrosis volume of interest (VOI) on both T2 FLAIR and T1 post-contrast sequences. Additionally, contralateral white matter (cWM) was also segmented for feature normalization. 10 histogram based first-order features and 195 second-order gray level co-occurrence matrix features were extracted from each VOI. After normalization, we divided the 195 second order features by the volumes of each VOI to produce another 195 volume-independent features per VOI for a total of 2,400 extracted features per lesions. We performed feature selection with Least Absolute Shrinkage and Selection Operator (LASSO). We split the cohort into 70% training and 30% testing sets for KRAS and EGFR and 80% training and 20% testing sets for MET models. We report the area under the curve (AUC) for classifying mutation status of each lesion and XGBoost was used to generate radiomics model.

RESULTS

Out of the 2,400 total features, LASSO identified 32 features for the EGFR mutant (mt) prediction model; of which the 20 most relevant were used for model building. The model achieved 78% accuracy, 77% sensitivity and 100% specificity. For the KRAS mt prediction model, LASSO defined 91 features and the model was generated with the top 30 features attaining 71% accuracy, 82% sensitivity and 60% specificity. Similarly, LASSO determined 90 features for MET mt prediction model, of which the top 15 features were used for the model demonstrating 77% accuracy, 76% sensitivity and 83% specificity.

CONCLUSION

s This study demonstrates that radiomics-based signatures can predict brain-specific molecular alterations including KRAS, EGFR and MET mutations.

CLINICAL RELEVANCE/APPLICATION

While further validation is warranted in a larger cohort, the proposed predictive radiomics-based approach is cost-effective, non-invasive and will help identify NSCLC patients with BM that are likely to respond to targeted treatments.

T5A-SPNR-10

The Role of Susceptibility-Weighted Imaging as an Accessory Diagnostic Tool of Global Cerebral Anoxia in the Post Cardiac Arrest Setting

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Alyssa Ionno, Syracuse, NY (*Presenter*) Nothing to Disclose

PURPOSE

To examine the utility of Susceptibility-Weighted Imaging (SWI) in patients with concern for acute hypoxic-ischemic injury (HII) to the brain in the post cardiac arrest setting. It is well known that Diffusion-Weighted Imaging is our most sensitive MR sequence to detect a hypoxic-ischemic event, however it is our goal to demonstrate SWI as an effective accessory tool that should be utilized to assist in qualifying the degree of ischemic injury.

METHODS AND MATERIALS

Retrospective chart review was conducted in our tertiary care center. A total of 50 adult patients were selected at random with a history of acute cardiac arrest and MRI evaluation with concern for anoxic brain injury. With an independent review from a board-certified Neuroradiologist, SWI sequences were evaluated with an emphasis on the appearance of the superficial cortical veins. The great cerebral vein along with visualized arterial vasculature was also evaluated. The appearance of these vessels was quantified using a scale of 0 - 3, 0 for absent or not seen, 1 for diminished appearance, 2 for present and normal, 3 for dilated. These findings were correlated with DWI results.

RESULTS

Of the 50 patients initially chart reviewed 37 demonstrated MR findings consistent with anoxic brain injury on either T2-weighted or DWI imaging. Within those 37 cases 26 had DWI findings consistent with acute anoxic brain injury (70%). SWI was unavailable or suboptimal in 6 cases leaving a total of 44 cases for complete analysis. Within the SWI subset, 34 of the 44 available cases demonstrated absent (0) or diminished (1) superficial cortical veins (77%). Importantly, only 5 of the 37 patients (14%) with any MRI findings characteristic of anoxic brain injury did not show any form of diminished superficial venous vasculature on SWI. Additionally, the great cerebral vein was absent or diminished in 30 of the 44 available cases (68%). In comparison to DWI, only 5 of the 26 (19%) cases with DWI findings consistent with HII did not show any form of diminished superficial or great venous vasculature on SWI. Interestingly, of the 13 available cases with no additional MR findings to suggest anoxic brain injury 4 demonstrated diminished or absent superficial cortical veins.

CONCLUSION

s In SWI, the amount of deoxy-hemoglobin content within the cortical veins directly correlates with their prominence. This can therefore be applied to episodes HII, which is secondary to a decrease in overall cerebral oxygen metabolism. Our data demonstrates a significant correlation with decreased vascular prominence on SWI in this setting.

CLINICAL RELEVANCE/APPLICATION

To further reinforce the use and addition of susceptibility weighted imaging in protocols for acute anoxic brain injury.

T5A-SPNR-11

Predictors of Intracranial Aneurysm Wall Enhancement on High Resolution MR Vessel Wall Imaging

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Abhinav Patel, MBBS, Chicago, IL (*Presenter*) Nothing to Disclose

PURPOSE

MR Vessel Wall Imaging (VWI) is an increasingly utilized modality for evaluation of neurovascular pathologies like Intracranial aneurysms (IAs) and atherosclerotic plaques. Multiple studies have evaluated the associations between intracranial aneurysm wall enhancement (AWE), risk of rupture, and aneurysm growth on follow-up. In our study, we aim to identify predictors for AWE.

METHODS AND MATERIALS

IRB approval was obtained for a retrospective study. Patients with IAs greater or equal to 2mm and VWI imaging were included. AWE was evaluated qualitatively, and a quantitative assessment of the percentage increase in signal intensity (SI) was also performed using means of three point ROIs placed on aneurysm wall on pre and post-contrast axial T1-SPACE sequences. The increase in SI was normalized to white matter SI on pre and post-contrast images. Patient demographics, risk factors and IA size and morphology were recorded. IAs were grouped into small (<3.9mm), medium (4-7mm), and large (>7.1mm) sizes. Spearman rank test, linear regression, and one way ANOVA were used to assess statistical associations between an increase in signal intensity, size, and other variables using SPSS v28.

RESULTS

A total of 174 patients (Mean age = 62.5 (24-87), 74% females) with 214 IAs (Mean size = 5.149 mm (2-30 mm) were assessed. 18/174 (10.34%) patients presented with subarachnoid hemorrhage. On qualitative evaluation, AWE was observed in 112/214 ICAs (52.3%). IA size demonstrated a moderate correlation ($r = 0.5$, $p<0.001$, 95% CI, 0.372-0.609) to percentage increase in SI. There was a statistically significant ($p<0.001$) increase in percentage SI, 24.75%, 46.35%, and 79.69%, in small (n = 78) , medium (n = 96) , and large (n = 40) aneurysm groups. Thrombosis of the aneurysm sac ($r = 0.238$, $p = 0.002$, 95% CI, 0.085-0.381) and SAH demonstrated a statistically significant albeit weak correlation ($r = 0.188$, $p = 0.015$, 95% CI, 0.032-0.0335) with AWE. There was no correlation between demographics, risk factors (HTN, HLD, family history, smoking) and AWE.

CONCLUSION

s Destabilizing IA factors that may increase permeability appear to be associated with AWE or uptake, including large size, mural thrombus, and rupture.

CLINICAL RELEVANCE/APPLICATION

VWI holds an advantage over traditional vascular imaging techniques that are restricted to visualizing the vessel lumen. This study supports the hypothesis that AWE on MR VWI could be an indicator of aneurysm wall instability while lack of enhancement could correlate to wall stability.

T5A-SPNR-12

Characterization of Normal-Appearing White Matter Over 1-2 Years in Small Vessel Disease Using Quantitative Susceptibility Mapping and Free-Water Mapping

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Yawen Sun, Shanghai, China (*Presenter*) Nothing to Disclose

PURPOSE

The aim of this study was to investigate alterations in the normal-appearing white matter (NAWM) with small vessel disease (SVD) over 1-2 years using quantitative susceptibility mapping and free-water (FW) mapping.

METHODS AND MATERIALS

Fifty-one SVD patients were included in this prospective study. Clinical testing and brain MRI scans were performed both at baseline and follow-up. Quantitative susceptibility (QS), fractional anisotropy (FA), mean diffusivity (MD), FW, FW-corrected FA (FAT), and FW-corrected MD (MDT) maps within white matter lesions (WMLs) and NAWM were generated for comparison. We also used the Johns Hopkins University Inventory of Cognitive Bias in Medicine (ICBM)-DTI-81 white matter (WM) label atlas as an anatomic guide and calculated the NAWM part in each of the WM tracts. The average regional values were extracted and paired t-test was used to analyze the longitudinal change. Partial correlations were used to assess the relationship between the MRI indices changes (e.g.?QSfollowup-baseline/QSbaseline) and Montreal Cognitive Assessment (MoCA) scores changes (?MoCAfollowup-baseline/MoCAbaseline) which represent the cognitive function.

RESULTS

Over 1-2 years, no significant difference was found in these MRI indices between baseline and follow-up in the WMLs region. In contrast, the QS values (index of demyelination) increased significantly in the NAWM at follow-up. Among WM tracts, we found the QS values in the NAWM part of the left superior frontal blade (SF), left occipital blade, right uncinate fasciculus, and right corticospinal tract (CST) were higher at follow-up than those at baseline. Results of FW (index of neuroinflammation/edema) analysis revealed that SVD patients at follow-up had increased FW in the NAWM part of the right CST and decreased FW in the NAWM part of the right inferior frontal blade (IF). The right SF and the right IF demonstrated significantly decreased FAT (indices of axonal loss) at follow-up compared to baseline. The degree of FAT changes in the NAWM part of the right IF were positively correlated with MoCA scores changes.

CONCLUSION

s Our study revealed how WMLs and NAWM may change over the years. The results supported that SVD is a dynamic chronic disease and the NAWM in SVD is still in the progressive injury process. Distinguishing among demyelination, neuronal degeneration, and neuroinflammation in the NAWM in vivo may provide a better understanding of the progression of SVD.

CLINICAL RELEVANCE/APPLICATION

QSM and FW mapping can provide complementary information in the NAWM of SVD patients.

Structural Disconnection Is Associated With Disease Severity in Neuromyelitis Optica Spectrum Disorder

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Ji Young Woo, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Neuromyelitis optica spectrum disorder (NMOSD) is an autoimmune inflammatory and demyelinating disorder of the central nervous system (CNS). Accumulating evidence suggest that distinct pattern of MRI lesions characteristic of NMOSD exists and the brain MRI have potential prognostic implications. However, we do not fully understand how this brain lesions in NMOSD is associated to its rather severe and distinct clinical course. Here, we tried to investigate the association via brain structural disconnection.

METHODS AND MATERIALS

20 patients diagnosed with NMOSD with AQP4-IgG according to the 2015 International Panel for NMO Diagnosis (IPND) criteria. The white matter lesion ROIs were manually drawn section by section on the 3D FLAIR sequence. Structural disconnection was estimated using the Lesion Quantification Toolkit. Connectome-based predictive modeling (CPM) was used to predict patient's EDSS (Expanded Disability Status Scale) from their disconnection severity matrix. In addition, correlational tractography using 32 direction diffusion weighted image was conducted to reveal local connection associated with disease severity.

RESULTS

CPM successfully predicted the EDSS using the disconnection severity matrix ($r = 0.506$, $p = 0.028$; $q2 = 0.274$). Among important edges in the prediction process, 19 edges were connecting the Motor - frontoparietal network, followed by 16 edges connecting the nodes within motor network and 15 edges connecting within frontoparietal network. Correlational tractography revealed local connectome in the periependymal area is associated with EDSS score.

CONCLUSION

s The structural disconnection within and between the motor and frontoparietal networks emerged as being most informative in predictions. In other words, the more severe disconnections involving these networks is predictive of severe EDSS score. Also, local disconnectome in the periependymal region is associated with EDSS score

CLINICAL RELEVANCE/APPLICATION

Using state-of the art imaging techniques and multivariate machine learning approach, we show that structural disconnection due to brain lesions, especially motor and fronto-parietal network, is predictive of disease severity in NMOSD.

Spatial Similarity of MRI-Visible Perivascular Spaces in Healthy Young Adult Twins

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Boeun Lee, (*Presenter*) Nothing to Disclose

PURPOSE

This study aims to determine whether genetic factors affect the location of dilated perivascular spaces (dPVS) by comparing healthy young twins and non-twin (NT) siblings.

METHODS AND MATERIALS

A total of 700 healthy young adult twins and NT siblings (138 monozygotic (MZ) twin pairs, 79 dizygotic (DZ) twin pairs, and 133 NT sibling pairs) were collected from the Human Connectome Project dataset. dPVS was automatically segmented and normalized to standard space. Then, spatial similarity indices (mean squared error [MSE], structural similarity [SSIM], and dice similarity [DS]) were calculated for dPVS in the basal ganglia (BGdPVS) and white matter (WMdPVS) between paired subjects before and after propensity score matching of dPVS volumes between groups. Within-pair correlations for the regional volumes of dVPS were also assessed using the intraclass correlation coefficient (ICC).

RESULTS

The spatial similarity of dPVS was significantly higher in MZ twins (higher DS [median, 0.382 and 0.310] and SSIM [0.963 and 0.887] and lower MSE [0.005 and 0.005] for BGdPVS and WMdPVS, respectively) than DZ twins (DS [0.121 and 0.119], SSIM [0.941 and 0.868], and MSE [0.010 and 0.011]) and NT siblings (DS [0.106 and 0.097], SSIM [0.924 and 0.848], and MSE [0.016 and 0.017]). No significant difference was found between DZ twins and NT siblings. Similar results were found even after subjects were matched according to dPVS volume. Regional dPVS volumes were also more correlated within pairs in MZ twins than DZ twins and NT siblings.

CONCLUSION

s Our results suggest that genetic factors affect the location of dPVS.

CLINICAL RELEVANCE/APPLICATION

We demonstrated that location of dPVS as well as its overall burden might be genetically determined to some extent using high quality images of healthy young twins and NT siblings from a large dataset.

T5A-SPNR-15

Characterization of White Matter Microstructural Abnormalities Associated With Cognitive Dysfunction in Cerebral Small Vessel Disease With Cerebral Microbleeds

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Haotian Xin, Jinan, China (*Presenter*) Nothing to Disclose

PURPOSE

To characterize white matter (WM) microstructural abnormalities with diffusion tensor imaging (DTI) and their relationship with cognitive dysfunction in cerebral small vessel disease (CSVD) patients with cerebral microbleeds (CMBs) at the group and individual levels.

METHODS AND MATERIALS

Fractional anisotropy (FA), mean diffusivity (MD), axial diffusivity (AD) and radial diffusivity (RD) images from 49 CSVD patients with CMBs (CSVD-c), 114 CSVD patients without CMBs (CSVD-n), and 83 controls were analyzed using DTI-derived tract-based spatial statistics (TBSS) to detect WM diffusion changes among groups. Pearson's correlations between regional diffusion changes and cognitive performance were investigated for all groups. Furthermore, machine learning and multivariate pattern analysis (MVPA) were applied for group classification and identifying the discriminative WM diffusion features for predicting CSVD patients with CMBs.

RESULTS

The CSVD-c group showed significant FA decrease, AD, RD and MD increases mainly in the bilateral superior longitudinal fasciculus (SLF), inferior fronto-occipital fasciculus (IFOF), anterior thalamic radiation (ATR), inferior longitudinal fasciculus (ILF), corticospinal tract (CST), corpus callosum, external capsule and right anterior limb of internal capsule (ALIC) compared with the CSVD-n and control groups. There was no significant difference in any diffusion metric between the CSVD-n and control groups. In addition, the widespread regional diffusion alterations among groups were significantly correlated with cognitive parameters in both the CSVD-c and CSVD-n groups. Notably, we applied the multiple kernel learning (MKL) technique in MVPA to combine regional diffusion features, yielding an average of >77% accuracy for three binary classifications, which shows a considerable improvement over the individual modality approach.

CONCLUSION

s Our findings revealed that CSVD patients with CMBs have extensive WM microstructural deterioration and suggested a key role of CMBs in causing vascular cognitive impairment involved in auditory verbal, symbol digit and executive control. Combining DTI-derived diffusivity and anisotropy metrics can provide complementary information for assessing WM alterations associated with cognitive dysfunction and serve as a potential discriminative pattern to detect CSVD at the individual level.

CLINICAL RELEVANCE/APPLICATION

Our study may help to understand the pathology of CSVD and develop new objective neuroimaging biomarkers for diagnosis, monitoring the progression of disease or evaluating treatment efficacy.

T5A-SPNR-16

Quantitative Evaluation of White Matter Injury after Acute Carbon Monoxide Poisoning by Diffusion Tensor Imaging

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Wenxuan Han, XI'AN, China (*Presenter*) Nothing to Disclose

PURPOSE

Carbon monoxide (CO) poisoning is one of the leading causes of poisoning death worldwide. At present, the brain injury mechanism of CO poisoning is still unclear, which may be related to ischemic brain tissue injury and white matter (WM) demyelination. Still, there is no consistent conclusion in existing studies. Therefore, DTI was used in this study to evaluate the microstructural integrity of white matter in patients with acute CO poisoning, and to provide evidence for the characteristics of early DTI in patients with acute CO poisoning.

METHODS AND MATERIALS

Twenty-four patients with acute CO poisoning were received MRI within 7 days after CO poisoning. Meanwhile, 25 age- and sex-matched healthy subjects were enrolled as controls for the study. MRI was performed using a 3.0-T scanner with a 24 channels head coil. MRI sequences included T1-weighted image (T1WI), T2WI and DTI were acquired. DTI data were processed using the FMRI Software Library (FSL) Diffusion Toolkit. Tract-Based Spatial Statistics (TBSS) was used to perform voxel-wise analysis. The differences between the two groups of demographic data were analyzed. Statistical analysis of DTI data was implemented using the permutation-based (non-parametric) randomize tool within FSL. A restrictive statistical threshold was used (Threshold-Free Cluster Enhancement threshold, $p < 0.05$, corrected for multiple comparisons).

RESULTS

Of the 24 analyzed patients, the median age was 53.4±16.2 years, and there were 5 male patients (20.8%). The median age of healthy controls was 53.4±14.2 years and there were 9 males (36.0%). There were no significant differences in sex or age between patients and controls ($p=0.24$, $p=0.99$). Fractional anisotropy (FA) value of genu, body and splenium of corpus callosum, bilateral frontal corona radiata and bilateral posterior WM in acute CO poisoning patients was significantly lower than that in the control group, while mean diffusivity (MD), axial diffusivity (AD), radial diffusivity (RD) was significantly higher than that in the control group. The spatial extents were relatively similar in all 4 DTI statistical maps.

CONCLUSION

s This study suggests that DTI can provide a basis for quantitative assessment of brain injury after acute CO poisoning.

CLINICAL RELEVANCE/APPLICATION

DTI may be a biomarker for varying injury severity in acute CO poisoning.

T5A-SPNR-17

Interaction Effect Between White Matter Hyperintensity Burden and Cognitive Status on the Grey Matter Volume: A Large Scale Cross-Sectional T1 and T2 Multi-Modal Study Using Automated Segmentation Tool

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Regina Ey Kim, (*Presenter*) Researcher, NEUROPHET, Inc

PURPOSE

The correlation between the white matter hyperintensity (WMH) and brain atrophy has been increasingly recognized as the biomarker of conversion from mild cognitive impairment (MCI) to Alzheimer's disease (AD). However, due to the studies with limited subject (n < 100), the related findings are debatable. In addition, the detailed WMH analysis, such as periventricular hyperintensity (PWMH) and deep white matter hyperintensity (DWMH), has not been investigated previously. To better understand the association between WM burden and grey matter (GM) atrophy, the interaction effect between WMH burden (both PWMH and DWMH) and cognitive status on the GM volume was investigated.

METHODS AND MATERIALS

A total of 3060 paired images of T1-weighted (T1w) MRI and T2- Fluid Attenuated Inversion Recovery (T2-FLAIR) MRI were utilized from seven research or clinical sites in Korea. Participants were categorized into cognitively normal (N=1540), mild cognitive impairment (MCI, N=1099), and dementia (N=421) group based on their clinical assessments. T1w and T2-FLAIR images were processed and extracted their outcomes (seven GM volumes and three WMH ratio to WM) using previously developed tools. Multivariate linear regression analysis was then performed to identify interaction effect between WMH ratio to WM and cognitive status after adjusting for corresponding WMH ratio, GM volume, age, and sex.

RESULTS

Our results indicated the higher WMH burden was associated with the lower cingulate volume in MCI (-9.5mL, p=0.022) when compared to the control groups . This interaction effect was mainly driven by the PWMH (-9.6mL, p=0.039) rather than the DWMH (-0.1mL, p=0.248). For the dementia group, the larger GMV with increased WMH was observed for frontal (+69.9mL, p=0.022) and parietal GM (+55.7mL, p=0.018). The parietal result was mostly driven by the PWMH (80.2mL, p=0.018) too.

CONCLUSION

s Our research demonstrated the significant interaction effect between the WMH burden and the cognitive type, highlighting the importance of observing WMH burden in details (e.g., PWMH vs. DWMH) for cognitive decline status.

CLINICAL RELEVANCE/APPLICATION

The WMH burden in association with cognitive decline, including MCI and dementia, should be closely monitored for their effect on brain atrophy.

What Causes Us to Fail and What Happens Afterwards? A Retrospective Analysis of Failed Fluoroscopic Guided Lumbar Punctures at a Large Tertiary Medical Center

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Myroslav Gerasymchuk, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Fluoroscopic guided lumbar punctures (FGLP) is an image guided procedure performed to obtain cerebrospinal fluid (CSF). Rarely, FGLPs can be unsuccessful for variety of reasons including inability to enter the spinal canal or inability to collect CSF, even though the needle tip is seen in the spinal canal on fluoroscopy. To our knowledge, no published data on FGLP failure rates, causes of failures, and immediate outcomes of patients with failed FGLPs exists. We hypothesize that FGLPs have a high success rate, majority of failed FGLPs are due to inadequate egress of CSF through the needle, and majority of patients with failed FGLPs return and undergo a successful FGLP.

METHODS AND MATERIALS

We retrospectively reviewed charts of patients with failed FGLPs from 6/1/2018-3/31/2022 to collect demographic data and determine cause of FGLP failure (inability to collect CSF), if patient had a successful repeat FGLP, and if no further FGLP attempt was made, if the patient was successfully discharged.

RESULTS

From 6/1/2018-3/31/2022, n=922 FGLPs were performed on inpatient/ER patients. 46/922 (5.0%) of patients had failed initial attempts by 30 trainees at obtaining CSF. 23/46 (50%) of failures were due to lack of egress of CSF through the LP needle, though the needle tip was within the spinal canal. 10/23 patients (43%) returned to undergo FGLP on another date (mean 6.3 days (range 1-28 days) after 1st attempt) of which 70% underwent documented IV hydration prior to the FGLP and 90% were successful. 14/46 (30%) of failures were due to inability to access the spinal canal either due to degenerative changes (n=10), high BMI (>35) (n=3), or postsurgical scarring (n=1). 3/14 of patients returned to undergo another FGLP of which 2 were successful and 1 failed again. 17/46 (35%) of patients did not undergo further FGLP attempt as they improved clinically or other reasons for symptomatology were revealed and 100% of these patients were successfully discharged.

CONCLUSION

s In our large sample, FGLPs had a success rate of 95%. Majority of the FGLPs failures were due to inability to collect CSF presumably due to low CSF pressure. Majority of these patients subsequently underwent a successful FGLP after hydration. Of patients who returned for a repeat FGLP after an initial FGLP failure due to degenerative bony changes or high BMI, 66% were successful. Few patients did not return for a repeat FGLP and were successfully discharged.

CLINICAL RELEVANCE/APPLICATION

FGLPs have a high success rate in obtaining CSF and majority of the FGLP failures are due to presumed low CSF pressure. Assurance of proper hydration may obviate a need for repeat FGLP. Physicians should also be aware that FGLPs can still fail and some patients will eventually be discharged without requiring CSF sampling.

T5A-SPNR-19

In Vitro and In Vivo Evaluation of US-Triggered Release from Novel Spinal Device

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Flemming Forsberg, PhD, Philadelphia, PA (*Presenter*) Research Grant, Canon Medical Systems Corporation;Research support, Canon Medical Systems Corporation;Research support, General Electric Company;Speaker, General Electric Company;Research support, Siemens AG;Research Grant, Butterfly Network, Inc;Research support, Lantheus Medical Imaging, Inc;Research support, Bracco Group

PURPOSE

Bacterial infection following spinal fusion is a major clinical concern, with up to 15% incidence, despite aggressive peri-operative antibiotic treatments. To serve this need, we have designed and evaluated an US-activated bulk release system to combat post-surgical bacterial survival.

METHODS AND MATERIALS

Polylactic acid (PLA) clips with a 0.79 cm3 drug-loading reservoir were 3D printed, loaded with the appropriate payload, and sealed with a PLA film (0.05 ± 0.01 mm thick). Clips evaluated in vitro were loaded with 150 µL vancomycin (VAN, 400 mg/mL, Athenex) and 50 µL Sonazoid (GE Healthcare), and those tested in vivo with 150 µL methylene blue (MeB) solution and 50 µL Sonazoid. Long-term stability of Sonazoid in distilled water and VAN was determined over a 14-day incubation at 4°C. Microbubble counts were obtained via flow cytometry. Contrast enhancement was visualized with a Logiq E10 scanner (GE). VAN-loaded clips were submerged in 37°C water and insonated for 10 minutes using a curvilinear C6 probe. Power Doppler imaging (1.8 MHz, 6.5 kHz PRF, ISPTA 146.2 ± 1.4 mW/cm2) induced VAN release, quantified using spectrophotometry. MeB-loaded clips were implanted into a rabbit along the spinal midline at L2 and L5, as well as a pig at L1 and L3, then insonated in Doppler mode at 1.7 MHz for 20 minutes using the C6 probe (5.4 kHz PRF, ISPTA < 146 mW/cm2). Animals were sacrificed 2 hours post-insonation for evaluation.

RESULTS

VAN had a conservatory effect on Sonazoid ($p = 0.007$) over the 14 days, since the number of Sonazoid microbubbles in distilled water had reduced by ~90% (from 7.3 ± 1.4x107/mL to 7.3 ± 1.6x106/mL), while those incubated in the VAN solution reduced by ~60% (from 8.9 ± 6.7x106/mL to 3.3 ± 9.3x106/mL). Contrast enhancement was observed from both solutions at 14 days, indicating retained cavitation ability. Insonated clips had an average cumulative VAN release of 81.4 ± 2.8 mg at 72 hours. Uninsonated clips had only 0.3 ± 0.1 mg average cumulative VAN release ($p < 0.0001$). Clips retrieved from the rabbit showed no signs of PLA film rupture nor MeB staining on surrounding tissues. Following physical puncture of the PLA film, release of MeB solution was visible. The pig clip PLA film was visibly ruptured, and demonstrated some MeB staining of the overlying tissues.

CONCLUSION

s These results demonstrate the ability to produce US-triggered release of an encapsulated prophylactic solution, and an important proof of concept for continuing large animal model in vivo evaluations.

CLINICAL RELEVANCE/APPLICATION

Existing methods are only partially successful in preventing infection after spinal fusion surgery. We designed an US-activated system for release of prophylactics to combat post-surgical infection.

Intraorbital Findings in Giant Cell Arteritis on Black Blood MRI

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Konstanze Guggenberger, MD, Wuerzburg, Germany (*Presenter*) Nothing to Disclose

PURPOSE

An expedient and accurate diagnosis of giant cell arteritis (GCA) is critical as blindness is an irreversible complication. Little is known about the spectrum of orbital imaging findings in GCA. We determined the prevalence of inflammatory changes of the intraorbital structures using high-resolution black blood MRI (BB-MRI) in patients with GCA compared to age-matched controls.

METHODS AND MATERIALS

A retrospective multicenter case-control study was performed screening for patients who underwent a BB-MRI on a 3 Tesla MR scanner, a clinical or histologic diagnosis of GCA, as well as age-matched controls. The BB-MRI pulse sequence was a post-contrast compressed-sensing (CS) T1-weighted sampling perfection with application-optimized contrasts using different flip angle evolution sequence. Two radiologists, blinded to clinical history, independently assessed for enhancement of the optic nerve, optic nerve sheath, ophthalmic artery vessel wall, optic chiasm, intraconal fat and extraocular muscle. Descriptive statistics were used to report percentages. Association of intraorbital BB-MRI findings with orbital symptoms was tested by Chi-Square analysis

RESULTS

56 patients (N=41 females; mean age 74 years) with GCA and 50 age-matched controls (17 female; mean age 70) met inclusion criteria. At the time of BB-MRI, 20 patients were steroid-naïve and 36 patients received a mean of 70 days (SD 133 days) of steroids. 32% of GCA patients showed inflammatory changes of at least one intraorbital structure. In GCA patients, optic nerve sheath enhancement (23%) was the most common BB-MRI finding, followed by ophthalmic artery vessel wall enhancement (OA-VWE) (14%). OA-VWE was unilateral in 9% and bilateral in 5%. Optic nerve enhancement was observed in one GCA patient. There was no significant correlation between patient reported orbital symptoms and pathologic enhancement of an intraorbital structure (p=0.10). None of the age-matched control patients showed any inflammatory changes of intraorbital structures.

CONCLUSION

s BB-MRI revealed inflammatory findings in the orbits in up to 32% of patients with GCA independent of patient reported orbital symptoms. Optic nerve sheath enhancement was the most common intraorbital inflammatory change.

CLINICAL RELEVANCE/APPLICATION

BB-MRI is a promising imaging technique to assess early inflammatory orbital changes in patients with GCA and may have a diagnostic and prognostic role for ophthalmologic complications.

T5A-SPNR-3

Multimodal Imaging of Lateral Branch Circulation and Cerebral Hemodynamic Correlation in Moyamoya Disease

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Yao Lu, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the relationship between collateral circulation and cerebral hemodynamics in patients with moyamoya disease and moyamoya syndrome using 4D CTA-CTP imaging.

METHODS AND MATERIALS

The clinical and imaging data of 32 patients with moyamoya disease and moyamoya syndrome in Beijing Hospital from January 2017 to January 2022 were retrospectively analyzed.4D-CTA images were scored by ASPECTS multi-phases scoring system, and DSA images were scored by ASITN/SIR score. The patients were divided into good collateral circulation group, medium collateral circulation group and poor collateral circulation group based on collateral circulation score. The consistency and correlation of the two collateral scores were compared. The perfusion parameters including cerebral blood volume (CBV), cerebral blood flow (CBF), mean transit time (MTT), mean transit time (TTP) and delay time (DLY) were obtained at basal ganglia level. The regions of interest (ROI) were plotted in the frontal, temporal and occipital lobes of both hemispheres respectively. Total of 192 measurements were obtained for each perfusion parameter. The differences of perfusion parameters among the three groups were compared.

RESULTS

1. The consistency of the two collateral circulation scores was moderate (Kappa=0.693, P<0.001). Spearman correlation analysis showed the correlation was good (r=0.805, P<0.001). 2. There were statistically significant differences in CBF, MTT and TTP among the three groups [CBF (38.2 ml /100g/min vs 40.6 ml /100g/min vs 42.1 ml /100g/min, P=0.019), MTT (4.9s vs 4.9s vs 4.5s), TTP (20.0s vs 18.3s vs 16.4s, P =0.012)].The CBF value of the poor collateral circulation group was lower than that of the good collateral circulation group (P =0.015 after Bonferroni correction). The MTT value of the moderate collateral circulation group was higher than that of the good collateral circulation group (P =0.005 after Bonferroni correction). The TTP value of the poor collateral circulation group was higher than that of the good collateral circulation group (P=0.015 after Bonferroni correction).

CONCLUSION

s 4D CTA-CTP is equivalent to DSA in evaluating collateral circulation in patients with moyamoya disease and moyamoya syndrome, and the cerebral hemodynamics can be assessed simutaneously, which has high clinical significance for disease monitoring.

CLINICAL RELEVANCE/APPLICATION

Multi-modal imaging can be used to monitor the cerebral hemodynamics of patients with moyamoya disease in a non-invasive manner, provide effective guidance for treatment, and observe the disease progression in real time.

To Achieve Dramatic Radiation Dose and Contrast Dose Reduction with 70kVp Tube Voltage and Iterative Reconstruction for Head and Neck CT Angiographyon Wide-detector CT: Comparison with Conventional CT Using 120kVp

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Yanan Zhu, Ankang, China (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the clinical value of using 70kVp and new generation adaptive statistical iterative reconstruction (ASIR-V) for reducing radiation dose and contrast dose in head and neck computed tomographic angiography (CTA) on a 16cm wide-detector CT.

METHODS AND MATERIALS

Sixteen patients (Group A) were prospectively enrolled to undergo low radiation and contrast dose head and neck CTA using 70 kVp tube voltage and 25 mL contrast medium (CM) on a 16cm wide-detector CT system. Images were reconstructed using ASIR-V at 80% level. These images were compared with the historic data of 16 consecutive patients (Group B) who were scanned on a 64 slices CT scanner using conventional doses with 120 kVp and 50 mL CM. CT values and noise of the internal carotid artery (ICA), basilar artery (BA), middle cerebral artery (MCA), left thalamus, left centrum ovale and left cerebellar hemisphere were measured. The signal-to-noise ratio (SNR) and the contrast-to-noise ratio (CNR) for targeted arteries and brain parenchyma were calculated. Subjective image quality in terms of bone-brain interface, beam hardening artifact and gray matter and white matter contrast was evaluated. The volumetric CT dose index (CTDIvol) was recorded. Measurements from the two groups were statistically compared.

RESULTS

Group A reduced radiation dose by 94% (1.94±0.0mGy vs. 33.16±4.92mGy, $p<0.001$) and used half the contrast medium dose (25mL vs. 50mL) compared with Group B. There was no difference in the mean CT values of ICA, BA and MCA between Group A (507.95±171.06HU, 430.43±169.20HU, 431.06±152.85HU, respectively) and Group B (427.09±97.01HU, 341.88±79.17HU, 328.40±84.74HU, respectively) There were no differences in SNR and the CNR for the targeted arteries and brain parenchyma and no difference in subjective image quality between the two groups (all $P > 0.05$).

CONCLUSION

s The use of 70kVp and ASIR-V in head and neck CTA on a wide-detector CT system significantly reduces both radiation dose and contrast dose while providing excellent image quality, compared to the use of conventional protocols .

CLINICAL RELEVANCE/APPLICATION

Image quality of the head and neck CTA were not impaired at the low dose of 70kvp and 25ml iodinated contrast agent on wide-detector CT, allowing for radiation and contrast medium reduction.

Positive Correlation Between Cerebral Amyloid Angiopathy (CAA) And Transverse Relaxation Rate (R2): An Analysis of Ex-vivo MRI and Neuropathology

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Md Tahmid Yasar, (*Presenter*) Nothing to Disclose

PURPOSE

Cerebral amyloid angiopathy (CAA) is identified by deposition of amyloid in the cortical and meningeal vessel walls. In this work, the association of CAA with the transverse relaxation rate R2 values in a large community-based cohort of older adults was investigated.

METHODS AND MATERIALS

Cerebral hemispheres from 797 older adult participants of three cohort studies, the Rush Memory and Aging Project, the Minority Aging Research Study, and the Religious Orders Study were utilized in this work. All hemispheres were imaged ex-vivo at approximately 30 days postmortem using 3T clinical MRI scanners. Each scan included a multi-echo spin-echo sequence. The signals from different echoes were used to fit a mono-exponential T2 decay function (R2 is the reciprocal of T2) in each voxel. The obtained R2 maps were registered to an ex-vivo hemisphere template using ANTS. Following the MRI scan, each hemisphere underwent thorough neuropathologic evaluation. The assessed pathologies were: CAA, Alzheimer's pathology, LATE-NC, hippocampal sclerosis, Lewy bodies, arteriolosclerosis, atherosclerosis, gross and microscopic infarcts. Voxel-wise linear regression was carried out to determine the association of CAA with R2, controlling for all other pathologies listed above, demographics (age at death, sex, education), postmortem interval to fixation and imaging and scanner covariates. Statistical analysis was done using PALM with tail-accelerated 1000 permutations, threshold-free cluster enhancement, and family-wise error rate correction. Statistical significance was set at $p<0.05$.

RESULTS

The analysis showed a spatial pattern of higher R2 values for elevated CAA scores. The pattern comprised of structures such as the caudate, putamen, nucleus accumbens, hippocampus, insula, anterior cingulate cortex, orbitofrontal cortex, and superior frontal cortex. Negative association between R2 values and CAA scores were not found.

CONCLUSION

s Our work showed that CAA is associated with higher R2 among older adults, independent of demographic covariates and other neuropathologies. The spatial pattern included basal ganglia and frontal lobe structures.

CLINICAL RELEVANCE/APPLICATION

Our work demonstrates the association of CAA with relaxation rate R2 in older adults. The findings can be used to generate features for MRI-based classifier that can detect the CAA pathology.

T5A-SPNR-7

Migraine-Associated Vascular Changes on Structural 7T-MRI

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - NR DPS

Awards
Trainee Research Prize - Medical Student

Participants
Wilson Xu, Los Angeles, CA (*Presenter*) Nothing to Disclose

PURPOSE

Migraine is a complex medical disorder which might be associated with vascular-related changes in the brain, such as white matter hyperintensities (WMH), and in some cases cerebral microbleeds (CMB). The association between migraine and enlarged perivascular spaces (EPVS) has not been thoroughly investigated. Our study utilizes ultra-high field 7T MRI to compare structural microvascular changes in different types of migraine, comparing them for the first time to headache-free healthy controls (HC).

METHODS AND MATERIALS

Participants included 10 chronic migraine (CM), 10 episodic migraine without aura (EMWoA), and 5 age-matched HC. Inclusion criteria were ages 25-60 years and ongoing CM/EMWoA. Exclusion criteria were overt cognitive impairment, brain tumor, prior intracranial surgery, contraindications to MRI, and claustrophobia.Neuroimaging data were collected using 7T MRI scans utilizing T1, T2, FLAIR, and SWI/QSM sequences. We calculated EPVS in centrum semiovale (CSO) and basal ganglia (BG), WMH using the Fazekas scale, and CMB using the microbleed anatomical rating scale. We also collected clinical data such as disease duration and severity, symptoms at time of scan, presence of aura, and side of headache. Regression analysis compared neuroimaging data among CM, EMWoA, and HC.

RESULTS

Preliminary statistical analysis reveals that the number of EPVS in the CSO, but not in the BG, was significantly higher with migraine compared to HC (p=0.04). Frequency of WMH and CMB in migraine did not differ significantly from that of HC. However, migraine patients showed a significant correlation between EPVS quantity in CSO and deep WMH severity (p=0.04).

CONCLUSION

s Significant differences in the EPVS in migraine compared to HC might be suggestive of glymphatic disruption within the brain, but whether such changes affect migraine development or result from migraine is unknown. EPVS may influence other vascular-related changes in migraine, suggesting a pathophysiological mechanism or possible use as an early imaging biomarker. Continued study with larger case populations and longitudinal follow-up will better establish the relationship between structural changes and migraine development and type.

CLINICAL RELEVANCE/APPLICATION

7T MRI allows us to measure EPVS in migraine more accurately, advancing our knowledge on the effect of vascular/glymphatic changes on various types of migraine for future disease-specific therapy.

Migraine-Associated Perfusion Changes on 7T MRI

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Brendon Chou, Arcadia, CA (*Presenter*) Nothing to Disclose

PURPOSE

Perfusion studies using Arterial Spin Labeling (ASL) in migraines have had conflicting results. However, these studies were limited by image resolution of 1.5 and 3T MRI scanners. Our study utilizes ultra-high field 7T MRI to investigate perfusion changes in different types of migraine with comparison to healthy controls (HC) for the first time to improve our understanding of migraine pathophysiology and guide diagnosis and treatment.

METHODS AND MATERIALS

Participants were recruited as 10 chronic migraine (CM), 10 episodic migraine without aura (EMWoA), and 5 age-matched HC. Inclusion criteria were ages 25-60 years and ongoing CM/EMWoA. Exclusion criteria were overt cognitive impairment, brain tumor, prior intracranial surgery, contraindications to MRI, and claustrophobia.Neuroimaging data were acquired using the Human Connectome Project protocol implemented on a 7T MRI scanner. For the quantification of cerebral blood flow, we adopted a 3D gradient and spin-echo (GRASE) pseudo-continuous ASL (pCASL) sequence with background suppression. We also collected clinical data such as disease duration and severity, symptoms at time of scan, presence of aura, and side of headache. Cerebral blood flow (CBF) maps were generated by performing pairwise subtraction of motion-corrected label and control images from pCASL data, which were subsequently averaged across the time series.

RESULTS

We observed a trend for higher cerebral blood flow (CBF) in the cortex and white matter of CM patients compared with HC or EMWoA patients (p=0.07).

CONCLUSION

s This study is novel in its usage of 7T MRI pCASL to assess perfusion changes in migraine patients. CBF increase within the cortex and white matter may reflect the lasting effects of cerebral hyperperfusion in chronic migraine or can be secondary to repetitive and frequent cortical hyperactivity. In order to understand the underlying mechanism of these changes, further studies are required to investigate the relationship between CBF and functional connectivity changes in different migraine types and phases.

CLINICAL RELEVANCE/APPLICATION

Increase in CBF in CM migraine compared to EMWoA or HC can be suggestive of more extensive vascular dysregulation in this group, which may help us understand the underlying mechanism, differentiate specific types of migraine and guide further treatment.

T5A-SPOB-1 Role of Shear Wave Elastography of Placenta in Prediction of IUGR

Participants
Tulika Singh, MBBS, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To compare placental elasticity values between normal pregnancy and pregnancies with IUGR and evaluate utility of shear wave elastography of placenta as a predictor for IUGR in average risk pregnancies.

METHODS AND MATERIALS

A prospective study was performed with 105 singleton pregnant women. Shear wave elastography of placenta was performed in all patients at 18-22wks and at 28-32wks. 5 measurements were obtained separately each along the fetal edge and the maternal edge of the placenta. The mean of 5 measurements was accepted as the mean placental elasticity value . During follow-up between 28th to 32nd weeks, fetal biometry and placental SWE were also measured. Fetus with EFBW <10th percentile, taken as IUGR. The patients were divided into two groups - normal pregnancies (group A) and pregnancy who developed IUGR (group B). Group comparisons were done using the Chi-Square test or Fisher's exact test. Receiver Operating Characteristic (ROC) curves were calculated to find maximal cut-off values for Developed IUGR / Did not develop IUGR.

RESULTS

Shear wave elasticity values at 18th to 22nd weeks for IUGR pregnancies along fetal edge of placenta (11.75 kPa vs 9.7 kPa) and along maternal edge of placenta (11.5 kPa vs 9.6 kPa) were significantly as compared to the normal pregnancies ($p < 0.05$). Similarly, Mean elasticity values along fetal edge of placenta (14.54 kPa vs 10.7 kPa) and along maternal edge of placenta (14.07 kPa vs 10.82 kPa) were significantly higher in IUGR pregnancies compared to the control group ($p < 0.001$) during 28th to 32nd weeks Using cut-off of 12.5kpa, we attained sensitivity of 73.7%, specificity of 86% and diagnostic accuracy of 83.8% for predicting preeclampsia.

CONCLUSION

s Placental elasticity values are significantly higher in pregnancies with IUGR than the normal pregnancies. Also, pregnancies with a stiffer placenta in the second trimester were associated with an increased likelihood of developing IUGR. Elastography can be used as a supplementary tool for prediction of IUGR.

CLINICAL RELEVANCE/APPLICATION

Placental elastography can evaluate the stiffness of placenta which is shown higher in pregnancy with IUGR .With more such validation study it will a supplementary tool for prediction of IUGR in addition to grey scale ultrasound and doppler study.

Sub-Events

T5A-SPPD-1 Subpial Hemorrhage: An Unknown but Relevant Form of Neonatal Stroke

Participants
Maria Parra Hernandez, MD, Valencia, Spain (*Presenter*) Nothing to Disclose

PURPOSE

Subpial hemorrhage is a rare subtype of intracranial hemorrhage typically seen in neonates. Because of its infrequency, it has been often misdiagnosed and underreported. The distinctive neuroimaging characteristics of MRI, sometimes appreciated in US, enables an accurate diagnosis. Our goal with this case series is to analyze the demographic, clinical, and neuroimaging characteristics and contribute to the knowledge of this entity.

METHODS AND MATERIALS

Retrospective identified cases of subpial hemorrhage in neonates who were admitted to our hospital between 2014 and 2022. All the cases had available clinical and neuroimaging records. Cranial US was the first imaging test performed. MRI sequences included T2WI, T1WI, DWI, and GRET2*WI.

RESULTS

Ten patients were included, most of the neonates were male and full-term born (80% each). Pregnancy complications occurred in 60%. Most deliveries were vaginal (80%) and just two of them were instrumentalized. Signs of fetal distress during birth and coagulation abnormalities were present in 70% and 40% of cases, respectively. All patients eventually presented with apnea and/or clinical seizures within 48 hours of delivery. Subpial hemorrhages were mainly unifocal (80%) with heterogeneity in localization. On T2WI most cases presented a characteristic “yin-yang pattern”, with two differentiated components: the “yin side” was the hypointense acute focal subpial collection, and the “yang side” was the hyperintense underlying compressed brain parenchyma (also hyperintense on DWI). 30% of the cases didn't present this sign and showed chronic phase characteristics instead. Medullary vein congestion and underlying parenchyma bleeding were observed in 70%, the lack of this finding was due to small collections with little mass effect. Concomitant intraventricular hemorrhage was seen in 60%. Cranial US detected an extra-axial hemorrhage in 70% of cases and parenchymal injury in 90%. Before 2022 all cases were misdiagnosed as subdural hemorrhage, some of them with subarachnoid or intraparenchymal bleeding, or as isolated cortical bleeding. Within the cases with more than a year of follow-up data, two had developmental delay and three had epilepsy.

CONCLUSION

s Neonatal subpial hemorrhage is an entity with a distinctive neuroimaging pattern, whose knowledge allows a clear differentiation from other forms of intracranial hemorrhage. Despite MRI being fundamental in the diagnosis cranial US is an excellent screening tool.

CLINICAL RELEVANCE/APPLICATION

The importance of this pathology relies on its association with injury of adjacent cerebral parenchyma with potential long-term consequences. An accurate diagnosis allows an early intervention.

T5A-SPPH-1 Investigating Clinical and Technical Image Quality in Chest CT: Ultra-Fast Scans vs Standard Speed Scans

Participants
Vera Tormodsrud, MSc, (*Presenter*) Nothing to Disclose

PURPOSE

New techniques for CT imaging need to be qualified. It is also important to see how they affect other aspects of image quality. In this study, clinical image quality was compared between ultra-fast and standard speed chest CT. Subjective assessment of motion artefacts and quality criteria in chest CT was rated by radiologists. In addition, an advanced image quality phantom with 3D resolution measurements was used to measure the non-motion image quality between the ultra-fast and standard speed imaging.

METHODS AND MATERIALS

Clinical observer study: Over a 2-year period (2019-2021), 33 patients were, on separate occasions, scanned with low dose chest CT using both standard speed protocol (exposure time 500ms, pitch 1) and an ultra-fast protocol (exposure time 280ms, pitch 1.5) (HyperDrive, GE Healthcare). CTDIvol was kept close to constant between the scan techniques, varying from 3 mGy to 6 mGy between patients depending on patient size. Three readers scored general image quality and motion artefacts using a Likert scale from 1-4. In addition, ultra-fast and standard speed scans were compared on different image quality criteria. Phantom study: A Catphan® 700 (The Phantom Laboratory, Salem NY) phantom, equipped with a 3D resolution wave module was scanned on a GE Revolution CT with ultra-fast and standard scan. Images were analyzed using the SMARI software (The Phantom Laboratory).

RESULTS

Clinical observer study: Analysis of data from one reader showed significantly higher image quality score (p=0,007) and reduced motion artefacts (cardiac wall: p=0,001 and lung tissue: p<0,001) for the ultra-fast scan protocol. Visual score of structures in the lung were also improved with ultra-fast scans. Results pending from the remaining readers. Phantom study: Ultra-fast scans showed a slight reduction in volumetric resolution compared to the standard speed protocol. However, the counteracting blurring from motion in the standard speed scans cannot be detected by the phantom test.

CONCLUSION

s Although ultra-fast scans may show reduced resolution in a non-motion phantom, the benefit of reduced motion artefacts, mainly from heart beats, improve overall image quality.

CLINICAL RELEVANCE/APPLICATION

Fast scanning may affect image quality but reduces motion artefacts. When motion artefacts are sufficiently reduced the resulting diagnostic quality is superior to that of the standard speed scans.

T5A-SPPH-2 A Metal Artifact Reduction Algorithm for Computed Tomography Utilizing a Raw Data Level Noise Recovery Technique

Participants
Taisei Nakagawa, MSc, Kanazawa-Shi, Japan (*Presenter*) Nothing to Disclose

PURPOSE

The metal artifact reduction (MAR) algorithm has been clinically used for patients with metal implants; however, streak artifacts often remain and become obstacles for viewing soft tissues around the metal. The remained streaks tend to be due to the frequency split method (FS) that blends high-passed information in the uncorrected image to preserve anatomical details close to metal implants and improve unnatural image textures by high-frequency noise included in the high-passed information. The purpose of this study is to propose a MAR technique using a combination of the FS method and a low data level noise recovery that prevents the remaining of streak artifacts and improves unnatural image appearances that generally occur without the FS.

METHODS AND MATERIALS

The proposed method performs the sinogram inpainting with a noise recovery applied during the inpainting process. The noise levels were determined by the levels of projection data adjacent to portions for inpainting, using a simple calculation based on the Poisson distribution and the dose level (effective mAs) for acquiring each target raw data. In our method, the FS method was applied to restricted regions just around the metal; thereby, the streak artifacts generally occur over a wide area were suppressed. The noise

recovery was adopted to improve unnatural image textures caused by the restrictive FS. CT images of clinical cases of dental implant and hip prostheses (two cases each) were reconstructed by the FS method and our proposed method. The normalized artifact index (nAI) was measured with five consecutive images for each reconstruction.

RESULTS

The proposed method improved nAI values from the FS method by 52.9% and 55.9% for the dental implant cases; 54.2% and 25.6% for the hip prostheses ($p < 0.05$). The edge information around the metal was maintained by the FS method restrictively applied and unnatural image appearances were improved by the noise recovery.

CONCLUSION

s It was indicated that the proposed MAR method would improve the CT image quality for patients with metal implants, by suppressing the remaining of streak artifacts that frequently occurs in images reconstructed by the existing FS method.

CLINICAL RELEVANCE/APPLICATION

The FS method for the MAR is useful; however, the remaining of streak artifacts is a drawback. Our proposed method can improve the drawback and achieve natural image appearances.

T5A-SPPH-3 In Vivo Determination of Potential Iodine Contrast Agent Dose Reduction for Photon-Counting CT in Comparison to Conventional CTS for Venous Phase Abdominal Scans

Participants
Rashel De Stefanis, (*Presenter*) Nothing to Disclose

PURPOSE

To calculate the possible contrast agent dose reduction based on clinical image quality criteria on photon-counting CT (PCCT) for venous phase abdominal CT scans using conventional CT-systems as a reference.

METHODS AND MATERIALS

Scans were collected from 56 patients who had undergone a contrast-enhanced abdominal CT examination on both a photon-counting CT (NAEOTOM Alpha, Siemens), and a conventional CT within a time frame of 2 years. Conventional CT used tube current modulation and kVp modulation (80kVp - 120kVp); PCCT used tube current modulation and a standard kVp of 120. The PCCT images were reconstructed at 70 keV. Contrast injections used patient BMI and heart rate to achieve a global HU target. The iodine weight for examinations on the PCCT was lower than on conventional CT due to an immediate contrast dose reduction request by radiologists at commissioning. Contrast measurements were performed in all paired image sets, in 7 venous phase ROIs located in left iliac vein, vena cava, vena porta, liver segment 2 and 7, spleen and the right renal pyramid. We report averaged HU-values. Assuming that a given percentage reduction in the administered contrast weight (m) yields the same percentage reduction in average HU, the weight of contrast agent on the PCCT to achieve the reference HU on conventional CT is mnew=mPCCT measured*HUreference/HUPCCT.

RESULTS

No significant difference in HU values was found between the various conventional CT systems (single factor ANOVA, $p = 0.30$); the data were pooled for further analysis. The PCCT scans yielded a mean HU of 155 ± 34 at a mean administered iodine weight of 27 ± 4 g. Conventional CT scans yielded a significantly different value of 113 ± 24 HU at 32 ± 3 g iodine (two-tailed paired t-test, HU: $p << 0.01$, weight iodine: $p << 0.01$). From the measurements it follows that the reference enhancement of 113 HU in going from conventional CT to PCCT would be achieved with a 38% reduction in iodine (20 g). The proposed 38% reduction would change the average administered weight iodine from 27 g ± 4, to an average weight of 20 g ± 3. The HU enhancement would remain body weight independent and have reduced variance. In order to keep the timing identical, dilution rather than a shorter bolus should be applied.

CONCLUSION

s In venous phase abdominal photon-counting CT a contrast dose reduction of 38% on PCCT versus conventional scanners would lead to similar contrast intensities in the images. This target could be put in gradual optimization studies.

CLINICAL RELEVANCE/APPLICATION

Several parameters have an impact on the enhancement after contrast agent administration; not all factors are incorporated in phantom studies. Our in vivo study suggests a 38% contrast agent reduction.

T5A-SPPH-4 Impact on Image Quality and Liver Lesion Detection of an Artificial Intelligence Deep-Learning Reconstruction Algorithm

Participants
Quentin DURAND, Montpellier, France (*Presenter*) Nothing to Disclose

PURPOSE

To assess the impact of an artificial intelligence deep-learning reconstruction (Precise Image; AI-DLR) algorithm on image quality and liver lesion detection compared to a hybrid iterative reconstruction (iDose4, IR) algorithm.

METHODS AND MATERIALS

This retrospective study included 30 consecutive patients with at least one liver lesion diagnosed between December 2021 and February 2022.Images were reconstructed using the level 4 of IR algorithm (i4) and the levels Standard/Smooth/Smoother of AI-DLR algorithm. A radiologist measured the mean attenuation and standard deviation placing ROIs in the fat, muscle, healthy liver and liver tumor areas. Two radiologists assessed subjectively and in consensus, the image noise, the image smoothness, the diagnostic and overall image quality and the confidence level using Likert scales.

RESULTS

Of the 30 patients included, 17 were men and 13 women, of mean age 70.4 ± 9.8 years. The mean CTDIvol was 6.3 ± 2.1 mGy and

the mean dose-length product 446.7 ± 178.8 mGy.cm. Compared to i4, HU values were similar with AI-DLR at all levels for all tissues studied. For each tissue, the image noise decreased with AI-DLR compared to i4 and decreased from Standard to Smooth (-28% ± 3%) and from Smooth to Smoother (-34% ± 8%). The subjective image assessment confirmed that the image noise decreased between i4 and AI-DLR and from Standard to Smoother levels but the opposite for the image smoothing. The highest scores of diagnostic and overall image quality were found for the Smooth and Smoother levels. The confidence level was rated "certain" for all patients for the three AI-DLR levels.

CONCLUSION

s The use of AI-DLR compared to i4 reduces the image noise and improves diagnostic and overall image quality. However, from Standard to Smoother levels, image smoothing is increased. The use of the Smooth and Smoother levels therefore seems suitable for the detection of liver lesions, but the radiologist's choice of level will depend on his/her appreciation of the image smoothness.

CLINICAL RELEVANCE/APPLICATION

For the first time, we evaluated the impact on image quality and liver lesion detection of a new AI deep learning reconstruction algorithm developed by Philips Healthcare (Precise Image) compared to an iterative hybrid reconstruction.

T5A-SPPH-5 Photon-counting Computer Tomography of Small Vessel Stents: A Phantom Study

Participants
Thomas Stein, Freiburg, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Accurate assessment of intravascular stents is of crucial importance to proof patency or detect complications such as in-stent stenosis, thrombosis or fracture. Non-invasive imaging of small vessel stents using CT remains still a challenge. Photon-counting CT (PCD-CT) with a novel detector technology presents the potential to overcome current drawbacks by improving image quality and reducing image artifacts. Here, we use a small vessel stent phantom to investigate the value of PCD-CT with different reconstruction kernels in comparison to a conventional energy-integrating (EID) CT serving as reference standard.

METHODS AND MATERIALS

For phantom measurements, 12 different stents comprising various sizes (2.25mm - 8 mm), designs (covered vs. non-covered) and vendors were used. Prior to image acquisition, the stents were filled with a water-contrast agent mixed diluted to 300 HU. All scans were performed on a clinical PCD-CT and a 3rd generation dual-source EID-CT serving as reference standard. First, PCD-CT images were reconstructed using dedicated vascular kernels (Bv40, Bv44, Bv48, Bv56, Bv60). For EID-CT, the established clinical acquisition and reconstruction settings were used. Subsequently, images were assessed quantitatively by calculating multi-row intensity profiles (increasing edge rise slope [ERS]=lower blooming artifacts). In addition, subjective image quality (overall, sharpness, noise, blooming, diagnostic confidence) was evaluated by three radiologists independently (5-point Likert-scale; 5=excellent) in a random fashion and blinded to the type of reconstruction and CT system. P-values are Bonferroni-corrected for multiple testing.

RESULTS

Best objective image quality was observed in the Bv60 kernel reconstruction (ERS=1611.1±608.3; $p<0.05$). Highest reading scores for overall image quality were found for Bv56/Bv60 images (3.3 [2.9-3.4] and 3.8 [3.6-3.8]), which were significantly superior to the EID-CT images (2 [2.0-2.4]; $p<0.05$ for both comparisons). Similar results were found for sharpness, blooming and diagnostic confidence ($p<0.05$ for all comparisons). Most severe subjective image noise was found in Bv60 reconstructions ($p<0.05$ compared to Bv40).

CONCLUSION

s PCD-CT facilitates a significantly improved assessment of small vessel stents compared to a 3rd generation dual-source EID-CT. Confirmatory studies translating our findings into clinical routine are needed to investigate whether PCD-CT has the potential to reduce the number of invasive angiographies in the future.

CLINICAL RELEVANCE/APPLICATION

PCT-CT significantly improves non-invasive imaging of small vessel stents in a phantom study. Prospective patient studies are necessary to confirm the clinical value in daily care.

T5A-SPPH-6 Low Contrast Detectability Comparison between a Prototype Photon-Counting Computed Tomography System and a Conventional CT system across a range of attenuation levels

Participants
Kirsten Lee Boedeker, PHD, Los Angeles, CA (*Presenter*) Employee, Canon Medical Systems Corporation

PURPOSE

The goal of this work is to compare the Low Contrast Detectability (LCD) of a prototype photon-counting computed tomography (PCCT) system to a traditional Energy-Integrated Detector (EID) CT using comparable scan protocols across a range of attenuations, including low dose, large attenuation scenarios representative of bariatric patients.

METHODS AND MATERIALS

The 20cm Catphan as well as a set of water phantoms 24cm, 32cm, and 40cm in diameter were scanned on a prototype PCCT, as well as on an EID-CT, with 120kVp and tube current ranging from 50 to 400mA, i.e., 5.7mGy to 40mGy. Counting images were generated based on total counts registered over five energy bins. For both systems, images were reconstructed using Filtered Backprojection (FBP) with a body kernel and reconstructed to a 500mm FOV. The prototype PCCT was based on a Canon Aquilion ONE ViSION™ system. The smallest detector pixel size was 342µm, and each pixel can output measurements up to 6 energy bins starting from 20keV. The readout can be configured into various macro-pixel schemes to reconstruct images at different spatial resolutions. The 3x3 macro-pixel mode generates a similar detection pitch as the typical EID-CT, and the resulting images were evaluated here. Low Contrast Detectability was estimated by using a Fourier domain implementation of a Non-Prewhitening Model Observer (NPW MO) using the measured Modulation Transfer Function (MTF), Noise Power Spectrum (NPS) and a variety of task functions.

RESULTS

The PCCT images had both higher MTF and lower noise compared to EID CT for all conditions. LCD was improved for all conditions. Compared to EID-CT, for a 5mm, 1% contrast object the PCCT counting images demonstrated increased LCD ranging from 5 to 47% for the 40cm phantom, 10 to 20% for the 32cm and 4 to 9% for the 24cm phantom.

CONCLUSION

s The PCCT offers a considerable increase in low contrast performance, particularly in low dose/large size scenarios

CLINICAL RELEVANCE/APPLICATION

The PCCT counting images offer better general low contrast detectability than the EID system and demonstrates the potential to achieve better performance in low dose scenarios, such as lung cancer screening or with bariatric patients.

T5A-SPPH-7 Cardiac-Induced Motion of the Abdominal Organs and Its Effect on Ultra-High-Resolution CT

Participants
Amir Pourmorteza, PhD, Bethesda, MD (*Presenter*) Nothing to Disclose

PURPOSE

The recent significant leap in spatial resolution of diagnostic CT scanners have made voxel sizes as small as 150 microns also called ultra-high-resolution (UHR) possible. With such spatial acuity, effects of biological motions such as the pulsatile motion of heart, the aorta, and systolic pressure wave in the abdominal organs, can no longer be neglected. Here, we measured the cardiac-induced motion of the abdominal organs such as the pancreas and the kidneys, and used the results to simulate its impact on the spatial resolution of a UHR CT scanner.

METHODS AND MATERIALS

We acquired Displacement Encoding with Stimulated Echoes (DENSE) magnetic resonance images (MRI) in three volunteers. orthogonal 2D scans of the pancreas were acquired in the three main anatomical planes, all centered in one location in the body of the pancreas. Additional 2D axial images were acquired at the mid-level of the left kidney. The measured displacements were then used to guide a computer simulation of a UHR CT scanner. We simulated a disk of 200 HU the diameter of which pulsated with the biological displacements measured from DENSE-MRI. The resting diameter of the disk was set at 2 cm. CT images were reconstructed from the analytically calculated projections of the pulsating disk at standard resolution, and UHR, with CT detector pixel sizes of 0.5mm and 0.25 mm at the isocenter. Radial modulation transfer function (MTF) of the images were calculated and used for analysis.

RESULTS

The range of pancreatic motion in 3D was 0.8-1.8 mm during a cardiac cycle (Fig 1). The analytical CT simulations showed that motion with amplitude of up to 1-mm did not significantly affect the MTF of the standard resolution system. However, the 1-mm motion reduced the MTF of the UHR system by approximately 38d%. We simulated different CT acquisition windows and the MTF results showed significant correlation to the acquisition window. The best cardiac phase for pancreas imaging was different for the 3 participants.

CONCLUSION

s The spatial resolution of UHR CT can easily be impacted by cardiac-induced motion in the abdominal organs. Here we established that motion-correction or abdominal CT gating strategies may be necessary to fully take advantage of this new technology.

CLINICAL RELEVANCE/APPLICATION

With the new advances in the spatial resolution of CT, the old sub-pixel biological motions now amount to up 10 pixels with the new resolution. Therefore, if left uncorrected these motions will blur the UHR images. Here we present our measurements of the pancreatic displacement during a cardiac cycle, and recommend ways to correct it.

T5A-SPPH-8 Reduction of Blooming Artifact using a Clinical Photon Counting Detector CT System and Novel Bioresorbable Flow Diverters

Participants
Emily Koons, Rochester, MN (*Presenter*) Nothing to Disclose

PURPOSE

Metallic implants for aneurysm treatment require surveillance imaging to monitor both aneurysm closure and parent artery patency. Invasive catheter angiography remains the standard technique owing to substantial metallic blooming with CT. Our aim was to quantify blooming artifact reduction from novel bioresorbable flow diverters (BRFD) using a high-resolution photon-counting-detector (PCD) CT (NAEOTOM Alpha, Siemens) in comparison with a standard clinical device and an energy-integrating-detector (EID) CT (Force, Siemens).

METHODS AND MATERIALS

Two BRFD composed of proprietary bioresorbable materials (primarily Mg and Fe alloys) and one standard clinical device were deployed in anatomical aneurysm models and perfused with 21mg/cc iodine solution mimicking contrast-enhanced vessels in the brain. Models were placed in a 20cm water tank and scanned on both EID and PCD. EID scans were performed using routine CTA Circle of Willis (COW) protocol in our institute: 120kV, 280 quality reference mAs. PCD scans were performed using an ultra-high-resolution (UHR) mode with 120x0.2mm collimation and 120kV. Tube current was adjusted such that CTDIvol between was matched (CTDIvol 43 mGy) between scanners. EID images were reconstructed using the routine clinical protocol (Hr40 kernel, 0.75mm slice thickness), while PCD images were reconstructed using 0.6mm slice thickness and a dedicated UHR kernel Hr89 that is only available on PCD. The aneurysm models were scanned on micro-CT which served as the reference standard. Radial line profiles were drawn across the flow diverter images over 4 angles and averaged across 3 slices. Inner lumen diameter of each diverter was measured based on semi-automated full width half maximum thresholding. Results were compared with measurements from microCT (reference standard).

RESULTS

EID images showed substantial blooming artifacts, especially for the standard clinical device, which obstructed views of the neighboring aneurysms. Blooming artifacts were substantially reduced on PCD-UHR images, with sharper delineation of the flow diverters and better visualization of the aneurysms. Overall, EID underestimated inner lumen diameter (plt0.05) by 46 percent (1.95±0.29mm) compared to microCT (3.84mm), which was reduced to 13 percent for PCD (3.42±0.04mm).

CONCLUSION

s Decreased blooming artifacts using PCD UHR mode improved lumen visibility in all three devices compared to EID images. Novel BRFD materials decreased blooming artifacts, allowing better visualization of vessels and aneurysms.

CLINICAL RELEVANCE/APPLICATION

Use of PCD UHR mode accompanied by novel BRFD allows for improved visualization of neuroanatomy following device deployment, leading to potential prevention of unnecessary interventions.

T5A-SPPH-9 Renal Imaging at 5T Versus 3T: A Comparison Study

Participants
Liyun Zheng, Shanghai, China (*Presenter*) Nothing to Disclose

PURPOSE

This study aimed to investigate the performance of renal MRI at 5T, and compare it with 3T.

METHODS AND MATERIALS

Fifteen healthy volunteers were included in this study. All the participants were examined on a 3T MR scanner and a 5T MR scanner by using optimal coil setups for both field strengths, respectively. The MRI sequences included coronal T1-weightd 3D volume-interpolated breath-hold gradient-echo (GRE) sequence (QUICK 3D), axial T2-weighted fast spin-echo (FSE) with fat saturation and respiratory trigger, and diffusion weighted imaging (DWI). T2* mapping was performed based on multi-echo GRE sequence. Qualitative and quantitative analysis were performed in consensus by two experienced radiologists. The image quality for each sequence type was evaluated by using a three-point scale (score 1 = poor quality, score 2 = moderate [diagnostic] quality, score 3 = good quality). The evaluation criteria were based on: 1) the cortico-medullary differentiation and 2) the delineation of adrenal glands, proximal ureter, renal arteries, and renal veins. Considering the chemical shift, B1 inhomogeneity, susceptibility, motion artifacts and the overall image impairment, the presence of artifacts was assessed by using a three-point scale (score 1 = strong impairment, score 2 = moderate impairment, score 3 = no artifact present or insignificant). For the quantitative analysis, SNR (cortex) = Signal (cortex)/noise, SNR (medulla) = Signal (medulla)/noise, and CNR = [Signal(cortex)-Signal(medulla)]/noise were measured for images of all the sequences. For functional imaging, mean apparent diffusion coefficient (ADC) and T2* relaxation time were calculated from cortex and medulla for each subject, respectively. Wilcoxon signed rank-sum test was used to compare the visual evaluation scores and quantitative measurements between 3T and 5T images.

RESULTS

For all the sequences, the image quality, SNR and CNR of 5T images were significantly higher than 3T images while there is no significant difference between the present of artifacts. For the functional maps, ADC of the cortex is significantly higher than that of the medulla at both 3T and 5T. There were no significant differences for the ADCs between 3T and 5T. Further, T2* value of the cortex is also significantly higher than that of the medulla at both 3T and 5T. Compared to 3T, renal MRI at 5T resulted in significantly shorter T2* values in both cortex (66.14 ms in 3T and 44.62 ms in 5T) and medulla (30.39 ms in 3T and 16.67 ms in 5T).

CONCLUSION

s Both anatomical images and functional maps of renal MRI were feasible at 5T.

CLINICAL RELEVANCE/APPLICATION

In vivo 5T renal MRI may better elucidate the renal diseases with both anatomical and functional imaging, compared to conventional clinical MRI scanners.

T5A-SPPH-1

Investigating Clinical and Technical Image Quality in Chest CT: Ultra-Fast Scans vs Standard Speed Scans

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Vera Tormodsrud, MSc, (*Presenter*) Nothing to Disclose

PURPOSE

New techniques for CT imaging need to be qualified. It is also important to see how they affect other aspects of image quality. In this study, clinical image quality was compared between ultra-fast and standard speed chest CT. Subjective assessment of motion artefacts and quality criteria in chest CT was rated by radiologists. In addition, an advanced image quality phantom with 3D resolution measurements was used to measure the non-motion image quality between the ultra-fast and standard speed imaging.

METHODS AND MATERIALS

Clinical observer study: Over a 2-year period (2019-2021), 33 patients were, on separate occasions, scanned with low dose chest CT using both standard speed protocol (exposure time 500ms, pitch 1) and an ultra-fast protocol (exposure time 280ms, pitch 1.5) (HyperDrive, GE Healthcare). CTDIvol was kept close to constant between the scan techniques, varying from 3 mGy to 6 mGy between patients depending on patient size. Three readers scored general image quality and motion artefacts using a Likert scale from 1-4. In addition, ultra-fast and standard speed scans were compared on different image quality criteria. Phantom study: A Catphan® 700 (The Phantom Laboratory, Salem NY) phantom, equipped with a 3D resolution wave module was scanned on a GE Revolution CT with ultra-fast and standard scan. Images were analyzed using the SMARI software (The Phantom Laboratory).

RESULTS

Clinical observer study: Analysis of data from one reader showed significantly higher image quality score (p=0,007) and reduced motion artefacts (cardiac wall: p=0,001 and lung tissue: p<0,001) for the ultra-fast scan protocol. Visual score of structures in the lung were also improved with ultra-fast scans. Results pending from the remaining readers. Phantom study: Ultra-fast scans showed a slight reduction in volumetric resolution compared to the standard speed protocol. However, the counteracting blurring from motion in the standard speed scans cannot be detected by the phantom test.

CONCLUSION

s Although ultra-fast scans may show reduced resolution in a non-motion phantom, the benefit of reduced motion artefacts, mainly from heart beats, improve overall image quality.

CLINICAL RELEVANCE/APPLICATION

Fast scanning may affect image quality but reduces motion artefacts. When motion artefacts are sufficiently reduced the resulting diagnostic quality is superior to that of the standard speed scans.

A Metal Artifact Reduction Algorithm for Computed Tomography Utilizing a Raw Data Level Noise Recovery Technique

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Taisei Nakagawa, MSc, Kanazawa-Shi, Japan (*Presenter*) Nothing to Disclose

PURPOSE

The metal artifact reduction (MAR) algorithm has been clinically used for patients with metal implants; however, streak artifacts often remain and become obstacles for viewing soft tissues around the metal. The remained streaks tend to be due to the frequency split method (FS) that blends high-passed information in the uncorrected image to preserve anatomical details close to metal implants and improve unnatural image textures by high-frequency noise included in the high-passed information. The purpose of this study is to propose a MAR technique using a combination of the FS method and a low data level noise recovery that prevents the remaining of streak artifacts and improves unnatural image appearances that generally occur without the FS.

METHODS AND MATERIALS

The proposed method performs the sinogram inpainting with a noise recovery applied during the inpainting process. The noise levels were determined by the levels of projection data adjacent to portions for inpainting, using a simple calculation based on the Poisson distribution and the dose level (effective mAs) for acquiring each target raw data. In our method, the FS method was applied to restricted regions just around the metal; thereby, the streak artifacts generally occur over a wide area were suppressed. The noise recovery was adopted to improve unnatural image textures caused by the restrictive FS. CT images of clinical cases of dental implant and hip prostheses (two cases each) were reconstructed by the FS method and our proposed method. The normalized artifact index (nAI) was measured with five consecutive images for each reconstruction.

RESULTS

The proposed method improved nAI values from the FS method by 52.9% and 55.9% for the dental implant cases; 54.2% and 25.6% for the hip prostheses ($p < 0.05$). The edge information around the metal was maintained by the FS method restrictively applied and unnatural image appearances were improved by the noise recovery.

CONCLUSION

s It was indicated that the proposed MAR method would improve the CT image quality for patients with metal implants, by suppressing the remaining of streak artifacts that frequently occurs in images reconstructed by the existing FS method.

CLINICAL RELEVANCE/APPLICATION

The FS method for the MAR is useful; however, the remaining of streak artifacts is a drawback. Our proposed method can improve the drawback and achieve natural image appearances.

T5A-SPPH-3

In Vivo Determination of Potential Iodine Contrast Agent Dose Reduction for Photon-Counting CT in Comparison to Conventional CTS for Venous Phase Abdominal Scans

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Rashel De Stefanis, (*Presenter*) Nothing to Disclose

PURPOSE

To calculate the possible contrast agent dose reduction based on clinical image quality criteria on photon-counting CT (PCCT) for venous phase abdominal CT scans using conventional CT-systems as a reference.

METHODS AND MATERIALS

Scans were collected from 56 patients who had undergone a contrast-enhanced abdominal CT examination on both a photon-counting CT (NAEOTOM Alpha, Siemens), and a conventional CT within a time frame of 2 years. Conventional CT used tube current modulation and kVp modulation (80kVp - 120kVp); PCCT used tube current modulation and a standard kVp of 120. The PCCT images were reconstructed at 70 keV. Contrast injections used patient BMI and heart rate to achieve a global HU target. The iodine weight for examinations on the PCCT was lower than on conventional CT due to an immediate contrast dose reduction request by radiologists at commissioning. Contrast measurements were performed in all paired image sets, in 7 venous phase ROIs located in left iliac vein, vena cava, vena porta, liver segment 2 and 7, spleen and the right renal pyramid. We report averaged HU-values. Assuming that a given percentage reduction in the administered contrast weight (m) yields the same percentage reduction in average HU, the weight of contrast agent on the PCCT to achieve the reference HU on conventional CT is mnew=mPCCT measured*HUreference/HUPCCT.

RESULTS

No significant difference in HU values was found between the various conventional CT systems (single factor ANOVA, p = 0.30); the data were pooled for further analysis. The PCCT scans yielded a mean HU of 155 ± 34 at a mean administered iodine weight of 27 ± 4 g. Conventional CT scans yielded a significantly different value of 113 ± 24 HU at 32 ± 3 g iodine (two-tailed paired t-test, HU: p << 0.01, weight iodine: p << 0.01). From the measurements it follows that the reference enhancement of 113 HU in going from conventional CT to PCCT would be achieved with a 38% reduction in iodine (20 g). The proposed 38% reduction would change the average administered weight iodine from 27 g ± 4, to an average weight of 20 g ± 3. The HU enhancement would remain body weight independent and have reduced variance. In order to keep the timing identical, dilution rather than a shorter bolus should be applied.

CONCLUSION

s In venous phase abdominal photon-counting CT a contrast dose reduction of 38% on PCCT versus conventional scanners would lead to similar contrast intensities in the images. This target could be put in gradual optimization studies.

CLINICAL RELEVANCE/APPLICATION

Several parameters have an impact on the enhancement after contrast agent administration; not all factors are incorporated in phantom studies. Our in vivo study suggests a 38% contrast agent reduction.

Impact on Image Quality and Liver Lesion Detection of an Artificial Intelligence Deep-Learning Reconstruction Algorithm

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Quentin DURAND, Montpellier, France (*Presenter*) Nothing to Disclose

PURPOSE

To assess the impact of an artificial intelligence deep-learning reconstruction (Precise Image; AI-DLR) algorithm on image quality and liver lesion detection compared to a hybrid iterative reconstruction (iDose4, IR) algorithm.

METHODS AND MATERIALS

This retrospective study included 30 consecutive patients with at least one liver lesion diagnosed between December 2021 and February 2022.Images were reconstructed using the level 4 of IR algorithm (i4) and the levels Standard/Smooth/Smoother of AI-DLR algorithm. A radiologist measured the mean attenuation and standard deviation placing ROIs in the fat, muscle, healthy liver and liver tumor areas. Two radiologists assessed subjectively and in consensus, the image noise, the image smoothness, the diagnostic and overall image quality and the confidence level using Likert scales.

RESULTS

Of the 30 patients included, 17 were men and 13 women, of mean age 70.4 ± 9.8 years. The mean CTDIvol was 6.3 ± 2.1 mGy and the mean dose-length product 446.7 ± 178.8 mGy.cm. Compared to i4, HU values were similar with AI-DLR at all levels for all tissues studied. For each tissue, the image noise decreased with AI-DLR compared to i4 and decreased from Standard to Smooth (-28% ± 3%) and from Smooth to Smoother (-34% ± 8%). The subjective image assessment confirmed that the image noise decreased between i4 and AI-DLR and from Standard to Smoother levels but the opposite for the image smoothing. The highest scores of diagnostic and overall image quality were found for the Smooth and Smoother levels. The confidence level was rated “certain” for all patients for the three AI-DLR levels.

CONCLUSION

s The use of AI-DLR compared to i4 reduces the image noise and improves diagnostic and overall image quality. However, from Standard to Smoother levels, image smoothing is increased. The use of the Smooth and Smoother levels therefore seems suitable for the detection of liver lesions, but the radiologist's choice of level will depend on his/her appreciation of the image smoothness.

CLINICAL RELEVANCE/APPLICATION

For the first time, we evaluated the impact on image quality and liver lesion detection of a new AI deep learning reconstruction algorithm developed by Philips Healthcare (Precise Image) compared to an iterative hybrid reconstruction.

Photon-counting Computer Tomography of Small Vessel Stents: A Phantom Study

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Thomas Stein, Freiburg, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Accurate assessment of intravascular stents is of crucial importance to proof patency or detect complications such as in-stent stenosis, thrombosis or fracture. Non-invasive imaging of small vessel stents using CT remains still a challenge. Photon-counting CT (PCD-CT) with a novel detector technology presents the potential to overcome current drawbacks by improving image quality and reducing image artifacts. Here, we use a small vessel stent phantom to investigate the value of PCD-CT with different reconstruction kernels in comparison to a conventional energy-integrating (EID) CT serving as reference standard.

METHODS AND MATERIALS

For phantom measurements, 12 different stents comprising various sizes (2.25mm - 8 mm), designs (covered vs. non-covered) and vendors were used. Prior to image acquisition, the stents were filled with a water-contrast agent mixed diluted to 300 HU. All scans were performed on a clinical PCD-CT and a 3rd generation dual-source EID-CT serving as reference standard. First, PCD-CT images were reconstructed using dedicated vascular kernels (Bv40, Bv44, Bv48, Bv56, Bv60). For EID-CT, the established clinical acquisition and reconstruction settings were used. Subsequently, images were assessed quantitatively by calculating multi-row intensity profiles (increasing edge rise slope [ERS]=lower blooming artifacts). In addition, subjective image quality (overall, sharpness, noise, blooming, diagnostic confidence) was evaluated by three radiologists independently (5-point Likert-scale; 5=excellent) in a random fashion and blinded to the type of reconstruction and CT system. P-values are Bonferroni-corrected for multiple testing.

RESULTS

Best objective image quality was observed in the Bv60 kernel reconstruction (ERS=1611.1±608.3; $p<0.05$). Highest reading scores for overall image quality were found for Bv56/Bv60 images (3.3 [2.9-3.4] and 3.8 [3.6-3.8]), which were significantly superior to the EID-CT images (2 [2.0-2.4]; $p<0.05$ for both comparisons). Similar results were found for sharpness, blooming and diagnostic confidence ($p<0.05$ for all comparisons). Most severe subjective image noise was found in Bv60 reconstructions ($p<0.05$ compared to Bv40).

CONCLUSION

s PCD-CT facilitates a significantly improved assessment of small vessel stents compared to a 3rd generation dual-source EID-CT. Confirmatory studies translating our findings into clinical routine are needed to investigate whether PCD-CT has the potential to reduce the number of invasive angiographies in the future.

CLINICAL RELEVANCE/APPLICATION

PCT-CT significantly improves non-invasive imaging of small vessel stents in a phantom study. Prospective patient studies are necessary to confirm the clinical value in daily care.

Low Contrast Detectability Comparison between a Prototype Photon-Counting Computed Tomography System and a Conventional CT system across a range of attenuation levels

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Kirsten Lee Boedeker, PHD, Los Angeles, CA (*Presenter*) Employee, Canon Medical Systems Corporation

PURPOSE

The goal of this work is to compare the Low Contrast Detectability (LCD) of a prototype photon-counting computed tomography (PCCT) system to a traditional Energy-Integrated Detector (EID) CT using comparable scan protocols across a range of attenuations, including low dose, large attenuation scenarios representative of bariatric patients.

METHODS AND MATERIALS

The 20cm Catphan as well as a set of water phantoms 24cm, 32cm, and 40cm in diameter were scanned on a prototype PCCT, as well as on an EID-CT, with 120kVp and tube current ranging from 50 to 400mA, i.e., 5.7mGy to 40mGy. Counting images were generated based on total counts registered over five energy bins. For both systems, images were reconstructed using Filtered Backprojection (FBP) with a body kernel and reconstructed to a 500mm FOV. The prototype PCCT was based on a Canon Aquilion ONE ViSION™ system. The smallest detector pixel size was 342µm, and each pixel can output measurements up to 6 energy bins starting from 20keV. The readout can be configured into various macro-pixel schemes to reconstruct images at different spatial resolutions. The 3x3 macro-pixel mode generates a similar detection pitch as the typical EID-CT, and the resulting images were evaluated here. Low Contrast Detectability was estimated by using a Fourier domain implementation of a Non-Prewhitening Model Observer (NPW MO) using the measured Modulation Transfer Function (MTF), Noise Power Spectrum (NPS) and a variety of task functions.

RESULTS

The PCCT images had both higher MTF and lower noise compared to EID CT for all conditions. LCD was improved for all conditions. Compared to EID-CT, for a 5mm, 1% contrast object the PCCT counting images demonstrated increased LCD ranging from 5 to 47% for the 40cm phantom, 10 to 20% for the 32cm and 4 to 9% for the 24cm phantom.

CONCLUSION

s The PCCT offers a considerable increase in low contrast performance, particularly in low dose/large size scenarios

CLINICAL RELEVANCE/APPLICATION

The PCCT counting images offer better general low contrast detectability than the EID system and demonstrates the potential to achieve better performance in low dose scenarios, such as lung cancer screening or with bariatric patients.

Cardiac-Induced Motion of the Abdominal Organs and Its Effect on Ultra-High-Resolution CT

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Amir Pourmorteza, PhD, Bethesda, MD (*Presenter*) Nothing to Disclose

PURPOSE

The recent significant leap in spatial resolution of diagnostic CT scanners have made voxel sizes as small as 150 microns also called ultra-high-resolution (UHR) possible. With such spatial acuity, effects of biological motions such as the pulsatile motion of heart, the aorta, and systolic pressure wave in the abdominal organs, can no longer be neglected. Here, we measured the cardiac-induced motion of the abdominal organs such as the pancreas and the kidneys, and used the results to simulate its impact on the spatial resolution of a UHR CT scanner.

METHODS AND MATERIALS

We acquired Displacement Encoding with Stimulated Echoes (DENSE) magnetic resonance images (MRI) in three volunteers. orthogonal 2D scans of the pancreas were acquired in the three main anatomical planes, all centered in one location in the body of the pancreas. Additional 2D axial images were acquired at the mid-level of the left kidney. The measured displacements were then used to guide a computer simulation of a UHR CT scanner. We simulated a disk of 200 HU the diameter of which pulsated with the biological displacements measured from DENSE-MRI. The resting diameter of the disk was set at 2 cm. CT images were reconstructed from the analytically calculated projections of the pulsating disk at standard resolution, and UHR, with CT detector pixel sizes of 0.5mm and 0.25 mm at the isocenter. Radial modulation transfer function (MTF) of the images were calculated and used for analysis.

RESULTS

The range of pancreatic motion in 3D was 0.8-1.8 mm during a cardiac cycle (Fig 1). The analytical CT simulations showed that motion with amplitude of up to 1-mm did not significantly affect the MTF of the standard resolution system. However, the 1-mm motion reduced the MTF of the UHR system by approximately 38d%. We simulated different CT acquisition windows and the MTF results showed significant correlation to the acquisition window. The best cardiac phase for pancreas imaging was different for the 3 participants.

CONCLUSION

s The spatial resolution of UHR CT can easily be impacted by cardiac-induced motion in the abdominal organs. Here we established that motion-correction or abdominal CT gating strategies may be necessary to fully take advantage of this new technology.

CLINICAL RELEVANCE/APPLICATION

With the new advances in the spatial resolution of CT, the old sub-pixel biological motions now amount to up 10 pixels with the new resolution. Therefore, if left uncorrected these motions will blur the UHR images. Here we present our measurements of the pancreatic displacement during a cardiac cycle, and recommend ways to correct it.

Reduction of Blooming Artifact using a Clinical Photon Counting Detector CT System and Novel Bioresorbable Flow Diverters

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Emily Koons, Rochester, MN (*Presenter*) Nothing to Disclose

PURPOSE

Metallic implants for aneurysm treatment require surveillance imaging to monitor both aneurysm closure and parent artery patency. Invasive catheter angiography remains the standard technique owing to substantial metallic blooming with CT. Our aim was to quantify blooming artifact reduction from novel bioresorbable flow diverters (BRFD) using a high-resolution photon-counting-detector (PCD) CT (NAEOTOM Alpha, Siemens) in comparison with a standard clinical device and an energy-integrating-detector (EID) CT (Force, Siemens).

METHODS AND MATERIALS

Two BRFD composed of proprietary bioresorbable materials (primarily Mg and Fe alloys) and one standard clinical device were deployed in anatomical aneurysm models and perfused with 21mg/cc iodine solution mimicking contrast-enhanced vessels in the brain. Models were placed in a 20cm water tank and scanned on both EID and PCD. EID scans were performed using routine CTA Circle of Willis (COW) protocol in our institute: 120kV, 280 quality reference mAs. PCD scans were performed using an ultra-high-resolution (UHR) mode with 120x0.2mm collimation and 120kV. Tube current was adjusted such that CTDIvol between was matched (CTDIvol 43 mGy) between scanners. EID images were reconstructed using the routine clinical protocol (Hr40 kernel, 0.75mm slice thickness), while PCD images were reconstructed using 0.6mm slice thickness and a dedicated UHR kernel Hr89 that is only available on PCD. The aneurysm models were scanned on micro-CT which served as the reference standard. Radial line profiles were drawn across the flow diverter images over 4 angles and averaged across 3 slices. Inner lumen diameter of each diverter was measured based on semi-automated full width half maximum thresholding. Results were compared with measurements from microCT (reference standard).

RESULTS

EID images showed substantial blooming artifacts, especially for the standard clinical device, which obstructed views of the neighboring aneurysms. Blooming artifacts were substantially reduced on PCD-UHR images, with sharper delineation of the flow diverters and better visualization of the aneurysms. Overall, EID underestimated inner lumen diameter (plt0.05) by 46 percent (1.95±0.29mm) compared to microCT (3.84mm), which was reduced to 13 percent for PCD (3.42±0.04mm).

CONCLUSION

s Decreased blooming artifacts using PCD UHR mode improved lumen visibility in all three devices compared to EID images. Novel BRFD materials decreased blooming artifacts, allowing better visualization of vessels and aneurysms.

CLINICAL RELEVANCE/APPLICATION

Use of PCD UHR mode accompanied by novel BRFD allows for improved visualization of neuroanatomy following device deployment, leading to potential prevention of unnecessary interventions.

T5A-SPPH-9

Renal Imaging at 5T Versus 3T: A Comparison Study

Tuesday, Nov. 29 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Liyun Zheng, Shanghai, China (*Presenter*) Nothing to Disclose

PURPOSE

This study aimed to investigate the performance of renal MRI at 5T, and compare it with 3T.

METHODS AND MATERIALS

Fifteen healthy volunteers were included in this study. All the participants were examined on a 3T MR scanner and a 5T MR scanner by using optimal coil setups for both field strengths, respectively. The MRI sequences included coronal T1-weightd 3D volume-interpolated breath-hold gradient-echo (GRE) sequence (QUICK 3D), axial T2-weighted fast spin-echo (FSE) with fat saturation and respiratory trigger, and diffusion weighted imaging (DWI). T2* mapping was performed based on multi-echo GRE sequence. Qualitative and quantitative analysis were performed in consensus by two experienced radiologists. The image quality for each sequence type was evaluated by using a three-point scale (score 1 = poor quality, score 2 = moderate [diagnostic] quality, score 3 = good quality). The evaluation criteria were based on: 1) the cortico-medullary differentiation and 2) the delineation of adrenal glands, proximal ureter, renal arteries, and renal veins. Considering the chemical shift, B1 inhomogeneity, susceptibility, motion artifacts and the overall image impairment, the presence of artifacts was assessed by using a three-point scale (score 1 = strong impairment, score 2 = moderate impairment, score 3 = no artifact present or insignificant). For the quantitative analysis, SNR (cortex) = Signal (cortex)/noise, SNR (medulla) = Signal (medulla)/noise, and CNR = [Signal(cortex)-Signal(medulla)]/noise were measured for images of all the sequences. For functional imaging, mean apparent diffusion coefficient (ADC) and T2* relaxation time were calculated from cortex and medulla for each subject, respectively. Wilcoxon signed rank-sum test was used to compare the visual evaluation scores and quantitative measurements between 3T and 5T images.

RESULTS

For all the sequences, the image quality, SNR and CNR of 5T images were significantly higher than 3T images while there is no significant difference between the present of artifacts. For the functional maps, ADC of the cortex is significantly higher than that of the medulla at both 3T and 5T. There were no significant differences for the ADCs between 3T and 5T. Further, T2* value of the cortex is also significantly higher than that of the medulla at both 3T and 5T. Compared to 3T, renal MRI at 5T resulted in significantly shorter T2* values in both cortex (66.14 ms in 3T and 44.62 ms in 5T) and medulla (30.39 ms in 3T and 16.67 ms in 5T).

CONCLUSION

s Both anatomical images and functional maps of renal MRI were feasible at 5T.

CLINICAL RELEVANCE/APPLICATION

In vivo 5T renal MRI may better elucidate the renal diseases with both anatomical and functional imaging, compared to conventional clinical MRI scanners.

Sub-Events

T5A-SPRO-1 Comparison Between CT Texture Data, Resection Margin Status And Clinical Outcomes In Pancreatic Adenocarcinoma Resected After Induction Chemotherapy And Neoadjuvant Stereotactic Body Radiation Therapy

Participants
Luca Geraci, MD, Verona, Italy (*Presenter*) Nothing to Disclose

PURPOSE

The aim of this study is to compare computed tomography (CT) texture analysis parameters with the resection margin status, the recurrence-free survival (RFS) and the overall survival (OS) in patients with pancreatic ductal adenocarcinoma (PDAC) resected after induction chemotherapy and neoadjuvant stereotactic body radiotherapy (SBRT). Preoperative prediction of patients who are likely to have positive resection margins and worse clinical outcome is beneficial to avoid early disease recurrence after surgery.

METHODS AND MATERIALS

Between January 2017 and May 2019, 134 patients with histologically proven unresectable PDAC underwent induction chemotherapy (FOLFIRINOX or Gemcitabine + Nab-Paclitaxel), followed by radiotherapy. Patients who received surgery after neoadjuvant SBRT were included. 47 texture features were extracted from 3D regions of interest (ROIs) based on unenhanced, arterial- and portal-phase CT images performed for SBRT planning. Clinical features and texture-derived parameters were compared; receiver operating characteristic (ROC) curves were constructed for the features that showed a significant difference between groups. Cox regression analysis and Kaplan-Meier curves were used to determine the association of clinical-pathological variables and texture parameters with RFS and OS.

RESULTS

43 patients (27 males, 16 females; mean age, 65 years; age range, 48-81 years) were included in this retrospective study. 14 patients (32.6%) had vascular resection. Patients with higher arterial HU_Q1 had significantly shorter RFS than patients who didn’t meet this criteria (p=.032 and .005; mean RFS 9.6 vs 14.8 months and 8 vs 14.3 months, respectively); no significant predictors were found for OS.

CONCLUSION

s CT texture analysis could predict RFS in patients with PDAC resected after induction chemotherapy and neoadjuvant SBRT.

CLINICAL RELEVANCE/APPLICATION

Prediction of prognosis by adding texture analysis. Change in follow up and patients management.

T5A-SPVA-1 Incidence of IVC Filter Thrombosis During the COVID-19 Pandemic at a Single Tertiary Referral Center

Participants
Bennett Ahearn, San Antonio, TX (*Presenter*) Nothing to Disclose

PURPOSE

Thrombotic complications in patients with COVID-19 have been well documented, however, data regarding the rate of inferior vena cava (IVC) filter thrombosis among patients diagnosed with COVID-19 is limited. We aim to compare the rate of IVC filter thrombosis in patients with and without a diagnosis of COVID-19.

METHODS AND MATERIALS

An IRB approved single institution retrospective chart review was conducted on IVC filters placed between January 1, 2020 to September 22, 2021. Patients with existing IVC thrombus (n=4) or no COVID-19 test on file (n=7) were excluded. The review included 111 patients (66 males, 45 females; mean age, 54 years; range, 15-94 years). Indications for IVC filter placement were DVT (n=59), Pulmonary Embolism (n=28), and prophylactic placement (n=24) The most common filter placed was the Denali filter (n=110). The remaining filter was an Option Elite. Patients were grouped by COVID-19 status and the rates of IVC thrombosis were compared using a chi-squared test.

RESULTS

Seventeen patients tested positive for COVID-19 while the remaining 94 patients were COVID negative. The average length of time between IVC filter placement and a positive COVID-19 test before or after filter placement was 43 days (range, 0-181 days). Three COVID-19 negative patients developed IVC thrombus (3.2%) at 3, 35, and 37 days after placement. Two COVID-19 positive patients developed IVC thrombus (11.7%) at 7 and 71 days post filter placement. The rates of IVC thrombosis were not statistically significant between cohorts (p=0.11).

CONCLUSION

s Despite an increase in the risk of thrombotic complications in patients with COVID-19, there may not be a significant increase in the risk of IVC filter thrombosis. Larger datasets are needed to investigate the true risk of developing COVID-19 associated IVC filter thrombosis.

CLINICAL RELEVANCE/APPLICATION

Thrombotic complications in patients with COVID-19 have been well documented. This review compares the rate of IVC filter thrombosis in patients with and without a diagnosis of COVID-19.

T5B-SPBR-1 A Three-sequence Abbreviated MRI Protocol to Evaluate Response to Breast Cancer Neoadjuvant Chemotherapy

Participants
Eduardo Dornelas, MD, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

To develop an abbreviated MRI protocol (ABP-MRI) to evaluate response to neoadjuvant chemotherapy (NAC) for invasive breast cancer carcinoma with diagnostic performance equivalent to that of the full protocol (FP-MRI) and with reduction of the examination time.

METHODS AND MATERIALS

This was a retrospective, single-center, cross-sectional study. It comprised 210 consecutive women diagnosed with invasive breast carcinoma of no special type who underwent breast MRI after NAC between 2016 and 2020. Breast MRI scans were independently reevaluated by two radiologists, with a level of agreement of 96,2% (202/210), first with access only to axial 3D SPAIR without contrast and then to the first (two-sequences ABP-MRI), second (three-sequences ABP-MRI), and third (four-sequences ABP-MRI) post-contrast times and finally, to the FP-MRI. The diagnostic performance (sensitivity, specificity, positive predictive value, negative predictive value, and accuracy) of the three ABP-MRIs and the FP-MRI were analyzed comparing to the pathological results of the surgical specimen. The Wilcoxon non-parametric test (p-value <. 050) was used to compare the accuracy of ABP-MRIs and the FP-MRI in the measurement of the longest axis in the most extensive residual lesion.

RESULTS

The median age of the study population was 47 (24-80) years. The two-sequences ABP-MRI showed higher specificity (84.6%; 77/91), but a higher probability of false-negative (16.8%) and a lower sensitivity (83.2%; 99/119) than the three and four-sequences ABP-MRIs and the FP-MRI, which were identical in specificity (81.3%; 74/91), probability of false-negative (8.4%), and sensitivity (91.6%; 109/119). The three-sequences ABP-MRI showed an average underestimation of only 0.03 cm in the measurement of the longest axis of the residual lesion (p=0.008) and with an average reduction in the acquisition time of 75% (20 minutes to 5 minutes), compared with FP-MRI.

CONCLUSION

s The three-sequence ABP-MRI showed diagnostic performance equivalent to the FP-MRI, with a 75% reduction in the acquisition time.

CLINICAL RELEVANCE/APPLICATION

Using the three-sequence ABP-MRI to evaluate the response to NAC, patient discomfort and examination costs can be reduced without sacrificing diagnostic performance.

T5B-SPBR-2 Changes in Kinetic Heterogeneity of Breast Cancer via Computer-aided Diagnosis of Magnetic Resonance Imaging Predict the Pathological Response to Neoadjuvant Systemic Therapy

Participants
Jin Joo Kim, MD, Busan, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate whether the "computer-aided diagnosis (CAD)-extracted" kinetic heterogeneity of breast cancer on MRI, and changes therein during treatment, were associated with the pathological response to neoadjuvant systemic therapy (NST).

METHODS AND MATERIALS

Consecutive patients with invasive breast cancer, who underwent NST followed by surgery between 2014 and 2020, were retrospectively evaluated. Using a commercial CAD system, kinetic features (angiovolume, peak enhancement, delayed

enhancement profiles, and kinetic heterogeneity) of breast cancer were assessed with pre- and mid-treatment MRI. Multivariate logistic regression was used to identify the associations between CAD-extracted kinetic features and pathological complete response (pCR).

RESULTS

A total of 130 patients (mean age, 55 years) were included, 37 (28.5%) of whom achieved a pCR. When the pre- and mid-treatment MRI data were compared, the pCR group exhibited greater changes in kinetic heterogeneity (86.14 ± 32.05% vs. 8.50 ± 141.01%, P < 0.001) and angiovolume (95.20 ± 14.29% vs. 19.89 ± 320.16%; P < 0.001) than the non-pCR group. Multivariate regression analysis showed that a large change in kinetic heterogeneity [odds ratio (OR) = 1.030, P < 0.001)], age (OR = 0.931, P = 0.005), progesterone receptor negativity (OR = 7.831, P = 0.001), and HER2 positivity (OR = 3.455, P = 0.017) were associated with pCR.

CONCLUSION

s A greater change in the CAD-extracted kinetic heterogeneity of breast cancer between pre- and mid-treatment MRI was associated with a pCR in patients on NST.

CLINICAL RELEVANCE/APPLICATION

CAD-extracted kinetic heterogeneity can be used as a quantitative imaging biomarker of tumor response to therapy to identify patients who are unlikely to responds well. This represents personalized medicine at its best, where the chemotherapy is tailored according to biological changes in breast cancer heterogeneity.

T5B-SPBR-3 Diagnostic Value of the Ultrafast Technique When Added to The Standard Protocol in Breast MRI Screening for High-risk Patients: Multi-reader Study

Participants
Joya Hadchiti, MD, MD, Paris, France (*Presenter*) Nothing to Disclose

PURPOSE

This study aims to show the diagnostic value of Ultrafast sequence when added to a classic MRI protocol in the screening of patients with a high risk of breast cancer. We compared the diagnostic accuracy of the two approaches using the BIRADS classification in correspondence with 4 readers and 3 levels of expertise.

METHODS AND MATERIALS

We conducted a retrospective observational study on 181 women(mean age=48years, range 26-71 years) at high risk who underwent annual screening breast MRI between March 2018 and March 2019. Eligible women had at least a biopsy (n=35 including 3 malignant and 32 benign lesions) or 2 years of breast MRI follow-up. Four readers with different levels of experience (R1: 10 years, R2 and 3: 3 years, and R4: <6 months) classified lesions according to the BIRADS classification. They all made two reading sessions performed blindly with 2 month wash-out period. The first MRI reading session included the classic protocol consisting of T1, T2, DWI, and Vibrant sequences and the second reading included the full protocol consisting of T1, T2, DWI, Ultrafast DISCO, and vibrant sequences. The reference standard was defined as a combination of histological diagnosis for BIRADS IV and V classification and 2 years of imaging follow-up for BIRADS I, II, and III patients.

RESULTS

All lesions were detected using both protocols. There were 3 malignant lesions. The accuracy of the reader BIRADS classification with the reference standard was higher when adding the Ultrafast sequence to the classic protocol for all readers(R1=87%/99%; R2=82%/89% R3=81%/85% R4=61%/84% for the classic and full protocol respectively). With the Ultrafast sequence, the beginner radiologist(R4) can catch up with the diagnostic performance of a more experienced radiologist. Compared to the classic protocol, we observed lower rates of false BIRADS III classified in the full protocol including the Ultrafast sequence decreasing the close follow up with cost and time-saving in the daily practices. Lower rates of false BIRADS IV are also noted avoiding unnecessary biopsy.

CONCLUSION

s The Ultrafast sequence presented an additive diagnostic value to the classic protocol for all readers. Due to its high performance, the Ultrafast sequence could be part of the standard breast MRI protocol.

CLINICAL RELEVANCE/APPLICATION

By using the Ultrafast sequence, BIRADS classification performance is close to the real nature of the breast lesions. The shorter acquisition time of the Ultrafast sequence can make breast MRI screening more readily available beyond those at high risk for breast cancer however validation studies using data from a different population are warranted.

T5B-SPBR-4 Abbreviated Breast MR: Our 2-Year Initial Experience

Participants
Lauren Burkard-Mandel, MD, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

The aim of this study was to retrospectively evaluate and present our two-year experience with AB-MR at our academic institution.

METHODS AND MATERIALS

Employing eight specialty trained breast imagers, studies were interpreted via the ACR BI-RADS MR lexicon. The protocol utilized T1-weighted fat saturated pre- and post-contrast, Short T1 Inversion Recovery images, and was completed within 10 minutes. AB-MR was offered to asymptomatic women, whose ages ranged from 24 to 90 years.

RESULTS

Out of 1338 patients included in the cohort for this study, 1111 (83.0%) were BI-RADS 1 or 2, 121 (9.0%) were a BI-RADS 3, and 106 (8%) were categorized as either BI-RADS 4 or 5 with recommended biopsy. Biopsy of BI-RADS 4 and 5 categorized patients

yielded 15 cancers for a PPV2 of 14.2% and a PPV3 of 18.5% with 81 of 106 patients undergoing the recommended biopsy. Overall, 16 cancers were detected, yielding a cancer detection rate of 12.0/1000. Over the next 12-24 months, no interval cancers were detected in these patients.

CONCLUSION

s AB-MR demonstrates a notable cancer detection rate and may provide an alternative screening method to detecting breast cancers in high-risk patients.

CLINICAL RELEVANCE/APPLICATION

Abbreviated MR screening may offer an alternative option, especially to high risk patients, which is both more affordable and less time consuming than full protocol MR.

T5B-SPBR-5 Breast MRI Screening Results: Comparison Between Patients with Personal History of Breast Cancer and Other High-risk Patients

Participants
Karina Zoghbi, MD, Sao Paulo, Brazil (*Presenter*) Nothing to Disclose

PURPOSE

Breast magnetic resonance imaging (MRI) is recommended for breast cancer screening in high-risk patients, however personal history of breast cancer is not considered an unequivocal recommendation for MRI surveillance. The aim of this study was to compare the results of breast cancer screening with magnetic resonance imaging (MRI) in patients with personal history of breast cancer and other high-risk patients.

METHODS AND MATERIALS

Retrospective single-center IRB-approved study that included 597 patients (mean age: 48.8 years; range: 19-82 years) who performed screening breast MRI from January to December 2020.

RESULTS

Most included patients had a prior history of breast cancer (n=354; 59.8%). MRI results were benign (BIRADS 1/2) in 425 (71.2%), probably benign (BIRADS 3) in 143 (24.0%) and suspicious (BIRADS 4/5) in 29 (4.9%). Eleven breast carcinomas were identified on screening MRI (cancer detection rate of 18.4/1000 exams; minimal cancer percentage: 54.5%; node-negative percentage: 90.9%). Abnormal interpretation rate was lower in patients with prior breast cancer compared with other high-risk factors (20.9% vs. 40.3%; p<0.001), however, there was no statistically significant difference on the rates of recommendation for tissue diagnosis (3.7% vs. 6.6%; p=0.104). The cancer detection rate was 20.5/1000 exams in patients with personal history of breast cancer and 14.1/1000 in other high-risk patients. PPV1 (abnormal interpretation) and PPV2 (recommendation for tissue diagnosis) were respectively 8.1% and 46.2% for patients with personal history, and 5.1% and 31.3% for other high-risk patients. During the 1-year follow-up after MRI, five other patients were diagnosed with malignancy (one patient with personal history of breast cancer and 4 patients with other high-risk factors), including three with ductal carcinoma in situ (DCIS) identified through calcifications on mammography and two with invasive carcinomas diagnosed 10 months after MRI.

CONCLUSION

s Patients with personal history of breast cancer showed similar screening results to other high-risk patients, suggesting that MRI surveillance should be considered in this population.

CLINICAL RELEVANCE/APPLICATION

Patients with personal history of breast cancer have higher than average risk to develop new malignant breast tumors and MRI surveillance should be considered in this population.

T5B-SPBR-6 High Temporal/High Spatial Resolution Breast MRI Outperforms Standard Protocol in Patients with High Background Parenchymal Enhancement (BPE)

Participants
Sarah Eskreis-Winkler, MD, New York, NY (*Presenter*) Nothing to Disclose

PURPOSE

Breast MRI is the most sensitive test for breast cancer detection, but high background parenchymal enhancement (BPE) can impact lesion conspicuity, leading to decreased positive predictive value (PPV) and specificity. With a high temporal/high spatial (HTHS) resolution MRI protocol, the breast is imaged within 1 minute after contrast injection, before BPE washes in, potentially improving diagnostic accuracy. The purpose of this study was to compare diagnostic performance of a HTHS protocol to a standard breast MR protocol in women with high BPE.

METHODS AND MATERIALS

Breast MRI is the most sensitive test for breast cancer detection, but high background parenchymal enhancement (BPE) can impact lesion conspicuity, leading to decreased positive predictive value (PPV) and specificity. With a high temporal/high spatial (HTHS) resolution MRI protocol, the breast is imaged within 1 minute after contrast injection, before BPE washes in, potentially improving diagnostic accuracy. The purpose of this study was to compare diagnostic performance of a HTHS protocol to a standard breast MR protocol in women with high BPE.

RESULTS

Our study cohort included 6,880 breast MRIs from 5,231 patients (mean age 53yrs), of which 1,342 exams (19.5%) had high BPE. Among these, CDR (37 per 1000 (25/676) v. 12 per 1000 (8/666); p = 0.002) and PPV (24.3% (25/103) v. 9.3% (8/86); p = 0.004) were increased with the HTHS protocol compared to the standard protocol. There was no significant difference in ICR (5.9/1000 v. 6.0/1000, p = 0.51). For women with priors, CDR was increased with the HTHS protocol (2.6 per 1000 (12/463) v. 6.0 per 1000 (3/464); p = 0.001). For those without priors, CDR trended higher with HTHS but was not statistically significant after applying Bonferonni correction (6.1 per 1000 (13/213) v. 2.5 per 1000 (5/202); p = 0.035).

CONCLUSION

s The HTHS protocol significantly improves diagnostic breast MRI performance in women with high BPE, with an additional cancer yield of 25 cancers per 1000 compared to the standard protocol, and with a concomitant decrease in unnecessary biopsies.

CLINICAL RELEVANCE/APPLICATION

Our study shows that a high temporal/high spatial resolution breast MRI protocol detects more cancers and decreases unnecessary biopsies in patients with high background parenchymal enhancement compared to a standard breast MRI protocol. It should therefore be considered the protocol-of-choice for screening MRI in the future.

T5B-SPBR-7 Potential of Stimulated Echo Acquisition Mode Diffusion Weighted Imaging (STEAM-DWI) in Breast MRI: First Experiences

Participants
Sabine Ohlmeyer, PhD, MD, Erlangen, Germany (*Presenter*) Nothing to Disclose

PURPOSE

The spin echo diffusion weighted imaging (SE-DWI) technique is most commonly used for lesion characterisation in breast MRI, which does not allow the measurement of the diffusivity at diffusion times much longer than the T2 time. At these long diffusion times, the long-range structural tissue order could be assessed, which is potentially beneficial for the diagnostic performance. Furthermore, suppression of olefinic fat signal is sometimes insufficient. STEAM-DWI might overcome these limitations by using long mixing times, and therewith long diffusion times. The aim of this study was to assess image quality and diagnostic performance of STEAM-DWI in breast MRI compared to SE-DWI.

METHODS AND MATERIALS

Prototypical STEAM-DWI and SE-DWI were performed in addition to the standard MRI protocol on a 3T MAGNETOM Vida scanner (Siemens Healthcare, Erlangen, Germany). Image quality was compared in 91 datasets, with respect to the presence of artifacts, signal voids, quality of fat suppression, and lesion and lymph node conspicuity. These parameters were rated using a 5-point Likert scale (1 = worst to 5 = best). The apparent diffusion coefficient (ADC) was measured in 27 mass lesions (16 breast carcinomas, 11 benign lesions), and the diagnostic value of both DWIs was statistically evaluated and compared.

RESULTS

Artifacts and signal voids were almost negligible in both DWI datasets (STEAM 4.40 vs SE 4.02, and 4.88 vs 4.81, respectively). Fat suppression was significantly better in STEAM (4.32 vs 3.87, $P < 0.001$, $r = 0.27$). The conspicuity of mass lesions was quite similar with STEAM and SE (2.19 vs 1.91). No significant difference was observed for the AUC (STEAM, 0.50; SE, 0.52). The cut-off for differentiation of benign and malignant lesions was at ADC = 0.93 · 10-3 mm2/s for STEAM and at 1.05 · 10-3 mm2/s for SE (both sensitivity, 1; specificity, 0.45). The conspicuity of axillary lymph nodes was better with SE than with STEAM (3.38 vs 1.50, $P < 0.001$, $r = 0.44$).

CONCLUSION

s Our data indicate that STEAM-DWI might be a robust technique for diffusion-weighted breast imaging with better fat-suppression and equal diagnostic accuracy compared to SE-DWI. The conspicuity of axillary lymph nodes seems to be inferior in STEAM-DWI compared to SE-DWI, here T1 and T2 weighted sequences from the standard protocol may have to be taken also into account.

CLINICAL RELEVANCE/APPLICATION

STEAM-DWI could represent a robust technique in breast MRI with stable fat saturation and same diagnostic accuracy compared to standard SE-DWI with regard to detection and characterization of mass lesions in breast tissue.

T5B-SPBR-8 Breast Ultrasound Volume Sweep Imaging: A New Horizon in Breast Cancer Detection

Participants
Yu Zhao, MD, Rochester, NY (*Presenter*) Nothing to Disclose

PURPOSE

Most of the world lacks access to basic breast imaging which presumably results in delays to detection of breast cancer. In low- and middle-income countries this delay can be on the scale of months. While ultrasound is an ideal imaging modality to screen for breast abnormalities, its deployment is limited by a lack of trained sonographers. In this study, we tested a simple volume sweep imaging (VSI) ultrasound protocol for the evaluation of palpable breast masses. This protocol can be performed by individuals without prior ultrasound training removing a major barrier to ultrasound deployment.

METHODS AND MATERIALS

Medical students without prior ultrasound experience were trained to perform the VSI protocol with less than 2 hours of training. The VSI protocol involves placing an "X" over the patient's palpable lump and scanning in transverse, sagittal, and radial/antiradial orientations over the lump. The operator uses a preset obviating the need for technical adjustments. The scanner only performs the standardized sweeps of the probe which are saved as video clips for later interpretation by a specialist. The operator does not interpret the ultrasound images. Patients over 18 of either sex were enrolled in this study if they had a palpable breast mass. The trained medical student performed the VSI protocol with a handheld Butterfly iQ ultrasound probe. A standard of care (SOC) ultrasound was performed the same day by an experienced sonographer using a high-end ultrasound machine. Agreement was assessed for mass visualization, size, orientation, shape, margins, echogenicity, posterior acoustic features, and BI-RADS assessment. All interpretations were performed by an attending breast imager.

RESULTS

Students scanned 170 palpable lumps with the VSI protocol. VSI showed 97% sensitivity and 100% specificity for breast mass detection. There was 97.6% agreement with standard of care (Cohen's ?=0.95, p<0.0001). All cancer presenting as a sonographic mass (n=20) were detected. There was substantial agreement for mass characteristics between VSI and SOC, including 87% agreement on BI-RADS assessments (Cohen's ?=0.82, p<0.0001). The average largest mass diameter on SOC was 23.1±16.9 mm and 22.5±15.6 mm on VSI (ICC=0.98 (0.96-0.98, p<0.0001)). The Bland-Altman Bias for these measurements was -1.02 (-7.8-5.77,

p=0.002)

CONCLUSION

s There was substantial agreement between VSI ultrasound and standard of care breast imaging for palpable lumps with VSI acquiring images of diagnostic quality.

CLINICAL RELEVANCE/APPLICATION

VSI breast ultrasound is a potential way to increase access to breast imaging in areas without other access to breast imaging. Access to VSI exams could potentially help decrease delays to diagnosis of breast cancer improving outcomes.

T5B-SPBR-1

A Three-sequence Abbreviated MRI Protocol to Evaluate Response to Breast Cancer Neoadjuvant Chemotherapy

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - BR DPS

Participants
Eduardo Dornelas, MD, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

To develop an abbreviated MRI protocol (ABP-MRI) to evaluate response to neoadjuvant chemotherapy (NAC) for invasive breast cancer carcinoma with diagnostic performance equivalent to that of the full protocol (FP-MRI) and with reduction of the examination time.

METHODS AND MATERIALS

This was a retrospective, single-center, cross-sectional study. It comprised 210 consecutive women diagnosed with invasive breast carcinoma of no special type who underwent breast MRI after NAC between 2016 and 2020. Breast MRI scans were independently reevaluated by two radiologists, with a level of agreement of 96,2% (202/210), first with access only to axial 3D SPAIR without contrast and then to the first (two-sequences ABP-MRI), second (three-sequences ABP-MRI), and third (four-sequences ABP-MRI) post-contrast times and finally, to the FP-MRI. The diagnostic performance (sensitivity, specificity, positive predictive value, negative predictive value, and accuracy) of the three ABP-MRIs and the FP-MRI were analyzed comparing to the pathological results of the surgical specimen. The Wilcoxon non-parametric test (p-value <. 050) was used to compare the accuracy of ABP-MRIs and the FP-MRI in the measurement of the longest axis in the most extensive residual lesion.

RESULTS

The median age of the study population was 47 (24-80) years. The two-sequences ABP-MRI showed higher specificity (84.6%; 77/91), but a higher probability of false-negative (16.8%) and a lower sensitivity (83.2%; 99/119) than the three and four-sequences ABP-MRIs and the FP-MRI, which were identical in specificity (81.3%; 74/91), probability of false-negative (8.4%), and sensitivity (91.6%; 109/119). The three-sequences ABP-MRI showed an average underestimation of only 0.03 cm in the measurement of the longest axis of the residual lesion (p=0.008) and with an average reduction in the acquisition time of 75% (20 minutes to 5 minutes), compared with FP-MRI.

CONCLUSION

s The three-sequence ABP-MRI showed diagnostic performance equivalent to the FP-MRI, with a 75% reduction in the acquisition time.

CLINICAL RELEVANCE/APPLICATION

Using the three-sequence ABP-MRI to evaluate the response to NAC, patient discomfort and examination costs can be reduced without sacrificing diagnostic performance.

Changes in Kinetic Heterogeneity of Breast Cancer via Computer-aided Diagnosis of Magnetic Resonance Imaging Predict the Pathological Response to Neoadjuvant Systemic Therapy

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - BR DPS

Participants
Jin Joo Kim, MD, Busan, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate whether the "computer-aided diagnosis (CAD)-extracted" kinetic heterogeneity of breast cancer on MRI, and changes therein during treatment, were associated with the pathological response to neoadjuvant systemic therapy (NST).

METHODS AND MATERIALS

Consecutive patients with invasive breast cancer, who underwent NST followed by surgery between 2014 and 2020, were retrospectively evaluated. Using a commercial CAD system, kinetic features (angiovolume, peak enhancement, delayed enhancement profiles, and kinetic heterogeneity) of breast cancer were assessed with pre- and mid-treatment MRI. Multivariate logistic regression was used to identify the associations between CAD-extracted kinetic features and pathological complete response (pCR).

RESULTS

A total of 130 patients (mean age, 55 years) were included, 37 (28.5%) of whom achieved a pCR. When the pre- and mid-treatment MRI data were compared, the pCR group exhibited greater changes in kinetic heterogeneity (86.14 ± 32.05% vs. 8.50 ± 141.01%, $P < 0.001$) and angiovolume (95.20 ± 14.29% vs. 19.89 ± 320.16%; $P < 0.001$) than the non-pCR group. Multivariate regression analysis showed that a large change in kinetic heterogeneity [odds ratio (OR) = 1.030, $P < 0.001$)], age (OR = 0.931, $P = 0.005$), progesterone receptor negativity (OR = 7.831, $P = 0.001$), and HER2 positivity (OR = 3.455, $P = 0.017$) were associated with pCR.

CONCLUSION

s A greater change in the CAD-extracted kinetic heterogeneity of breast cancer between pre- and mid-treatment MRI was associated with a pCR in patients on NST.

CLINICAL RELEVANCE/APPLICATION

CAD-extracted kinetic heterogeneity can be used as a quantitative imaging biomarker of tumor response to therapy to identify patients who are unlikely to responds well. This represents personalized medicine at its best, where the chemotherapy is tailored according to biological changes in breast cancer heterogeneity.

T5B-SPBR-3

Diagnostic Value of the Ultrafast Technique When Added to The Standard Protocol in Breast MRI Screening for High-risk Patients: Multi-reader Study

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - BR DPS

Participants
Joya Hadchiti, MD, MD, Paris, France (*Presenter*) Nothing to Disclose

PURPOSE

This study aims to show the diagnostic value of Ultrafast sequence when added to a classic MRI protocol in the screening of patients with a high risk of breast cancer. We compared the diagnostic accuracy of the two approaches using the BIRADS classification in correspondence with 4 readers and 3 levels of expertise.

METHODS AND MATERIALS

We conducted a retrospective observational study on 181 women(mean age=48years, range 26-71 years) at high risk who underwent annual screening breast MRI between March 2018 and March 2019. Eligible women had at least a biopsy (n=35 including 3 malignant and 32 benign lesions) or 2 years of breast MRI follow-up. Four readers with different levels of experience (R1: 10 years, R2 and 3: 3 years, and R4: <6 months) classified lesions according to the BIRADS classification. They all made two reading sessions performed blindly with 2 month wash-out period. The first MRI reading session included the classic protocol consisting of T1, T2, DWI, and Vibrant sequences and the second reading included the full protocol consisting of T1, T2, DWI, Ultrafast DISCO, and vibrant sequences. The reference standard was defined as a combination of histological diagnosis for BIRADS IV and V classification and 2 years of imaging follow-up for BIRADS I, II, and III patients.

RESULTS

All lesions were detected using both protocols. There were 3 malignant lesions. The accuracy of the reader BIRADS classification with the reference standard was higher when adding the Ultrafast sequence to the classic protocol for all readers(R1=87%/99%; R2=82%/89% R3=81%/85% R4=61%/84% for the classic and full protocol respectively). With the Ultrafast sequence, the beginner radiologist(R4) can catch up with the diagnostic performance of a more experienced radiologist. Compared to the classic protocol, we observed lower rates of false BIRADS III classified in the full protocol including the Ultrafast sequence decreasing the close follow up with cost and time-saving in the daily practices. Lower rates of false BIRADS IV are also noted avoiding unnecessary biopsy.

CONCLUSION

s The Ultrafast sequence presented an additive diagnostic value to the classic protocol for all readers. Due to its high performance, the Ultrafast sequence could be part of the standard breast MRI protocol.

CLINICAL RELEVANCE/APPLICATION

By using the Ultrafast sequence, BIRADS classification performance is close to the real nature of the breast lesions. The shorter acquisition time of the Ultrafast sequence can make breast MRI screening more readily available beyond those at high risk for breast cancer however validation studies using data from a different population are warranted.

T5B-SPBR-4

Abbreviated Breast MR: Our 2-Year Initial Experience

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - BR DPS

Participants
Lauren Burkard-Mandel, MD, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

The aim of this study was to retrospectively evaluate and present our two-year experience with AB-MR at our academic institution.

METHODS AND MATERIALS

Employing eight specialty trained breast imagers, studies were interpreted via the ACR BI-RADS MR lexicon. The protocol utilized T1-weighted fat saturated pre- and post-contrast, Short T1 Inversion Recovery images, and was completed within 10 minutes. AB-MR was offered to asymptomatic women, whose ages ranged from 24 to 90 years.

RESULTS

Out of 1338 patients included in the cohort for this study, 1111 (83.0%) were BI-RADS 1 or 2, 121 (9.0%) were a BI-RADS 3, and 106 (8%) were categorized as either BI-RADS 4 or 5 with recommended biopsy. Biopsy of BI-RADS 4 and 5 categorized patients yielded 15 cancers for a PPV2 of 14.2% and a PPV3 of 18.5% with 81 of 106 patients undergoing the recommended biopsy. Overall, 16 cancers were detected, yielding a cancer detection rate of 12.0/1000. Over the next 12-24 months, no interval cancers were detected in these patients.

CONCLUSION

s AB-MR demonstrates a notable cancer detection rate and may provide an alternative screening method to detecting breast cancers in high-risk patients.

CLINICAL RELEVANCE/APPLICATION

Abbreviated MR screening may offer an alternative option, especially to high risk patients, which is both more affordable and less time consuming than full protocol MR.

Breast MRI Screening Results: Comparison Between Patients with Personal History of Breast Cancer and Other High-risk Patients

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - BR DPS

Participants
Karina Zoghbi, MD, Sao Paulo, Brazil (*Presenter*) Nothing to Disclose

PURPOSE

Breast magnetic resonance imaging (MRI) is recommended for breast cancer screening in high-risk patients, however personal history of breast cancer is not considered an unequivocal recommendation for MRI surveillance. The aim of this study was to compare the results of breast cancer screening with magnetic resonance imaging (MRI) in patients with personal history of breast cancer and other high-risk patients.

METHODS AND MATERIALS

Retrospective single-center IRB-approved study that included 597 patients (mean age: 48.8 years; range: 19-82 years) who performed screening breast MRI from January to December 2020.

RESULTS

Most included patients had a prior history of breast cancer (n=354; 59.8%). MRI results were benign (BIRADS 1/2) in 425 (71.2%), probably benign (BIRADS 3) in 143 (24.0%) and suspicious (BIRADS 4/5) in 29 (4.9%). Eleven breast carcinomas were identified on screening MRI (cancer detection rate of 18.4/1000 exams; minimal cancer percentage: 54.5%; node-negative percentage: 90.9%). Abnormal interpretation rate was lower in patients with prior breast cancer compared with other high-risk factors (20.9% vs. 40.3%; p<0.001), however, there was no statistically significant difference on the rates of recommendation for tissue diagnosis (3.7% vs. 6.6%; p=0.104). The cancer detection rate was 20.5/1000 exams in patients with personal history of breast cancer and 14.1/1000 in other high-risk patients. PPV1 (abnormal interpretation) and PPV2 (recommendation for tissue diagnosis) were respectively 8.1% and 46.2% for patients with personal history, and 5.1% and 31.3% for other high-risk patients. During the 1-year follow-up after MRI, five other patients were diagnosed with malignancy (one patient with personal history of breast cancer and 4 patients with other high-risk factors), including three with ductal carcinoma in situ (DCIS) identified through calcifications on mammography and two with invasive carcinomas diagnosed 10 months after MRI.

CONCLUSION

s Patients with personal history of breast cancer showed similar screening results to other high-risk patients, suggesting that MRI surveillance should be considered in this population.

CLINICAL RELEVANCE/APPLICATION

Patients with personal history of breast cancer have higher than average risk to develop new malignant breast tumors and MRI surveillance should be considered in this population.

High Temporal/High Spatial Resolution Breast MRI Outperforms Standard Protocol in Patients with High Background Parenchymal Enhancement (BPE)

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - BR DPS

Participants
Sarah Eskreis-Winkler, MD, New York, NY (*Presenter*) Nothing to Disclose

PURPOSE

Breast MRI is the most sensitive test for breast cancer detection, but high background parenchymal enhancement (BPE) can impact lesion conspicuity, leading to decreased positive predictive value (PPV) and specificity. With a high temporal/high spatial (HTHS) resolution MRI protocol, the breast is imaged within 1 minute after contrast injection, before BPE washes in, potentially improving diagnostic accuracy. The purpose of this study was to compare diagnostic performance of a HTHS protocol to a standard breast MR protocol in women with high BPE.

METHODS AND MATERIALS

Breast MRI is the most sensitive test for breast cancer detection, but high background parenchymal enhancement (BPE) can impact lesion conspicuity, leading to decreased positive predictive value (PPV) and specificity. With a high temporal/high spatial (HTHS) resolution MRI protocol, the breast is imaged within 1 minute after contrast injection, before BPE washes in, potentially improving diagnostic accuracy. The purpose of this study was to compare diagnostic performance of a HTHS protocol to a standard breast MR protocol in women with high BPE.

RESULTS

Our study cohort included 6,880 breast MRIs from 5,231 patients (mean age 53yrs), of which 1,342 exams (19.5%) had high BPE. Among these, CDR (37 per 1000 (25/676) v. 12 per 1000 (8/666); p = 0.002) and PPV (24.3% (25/103) v. 9.3% (8/86); p = 0.004) were increased with the HTHS protocol compared to the standard protocol. There was no significant difference in ICR (5.9/1000 v. 6.0/1000, p = 0.51). For women with priors, CDR was increased with the HTHS protocol (2.6 per 1000 (12/463) v. 6.0 per 1000 (3/464); p = 0.001). For those without priors, CDR trended higher with HTHS but was not statistically significant after applying Bonferonni correction (6.1 per 1000 (13/213) v. 2.5 per 1000 (5/202); p = 0.035).

CONCLUSION

s The HTHS protocol significantly improves diagnostic breast MRI performance in women with high BPE, with an additional cancer yield of 25 cancers per 1000 compared to the standard protocol, and with a concomitant decrease in unnecessary biopsies.

CLINICAL RELEVANCE/APPLICATION

Our study shows that a high temporal/high spatial resolution breast MRI protocol detects more cancers and decreases unnecessary biopsies in patients with high background parenchymal enhancement compared to a standard breast MRI protocol. It should therefore be considered the protocol-of-choice for screening MRI in the future.

Potential of Stimulated Echo Acquisition Mode Diffusion Weighted Imaging (STEAM-DWI) in Breast MRI: First Experiences

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - BR DPS

Participants
Sabine Ohlmeyer, PhD, MD, Erlangen, Germany (*Presenter*) Nothing to Disclose

PURPOSE

The spin echo diffusion weighted imaging (SE-DWI) technique is most commonly used for lesion characterisation in breast MRI, which does not allow the measurement of the diffusivity at diffusion times much longer than the T2 time. At these long diffusion times, the long-range structural tissue order could be assessed, which is potentially beneficial for the diagnostic performance. Furthermore, suppression of olefinic fat signal is sometimes insufficient. STEAM-DWI might overcome these limitations by using long mixing times, and therewith long diffusion times. The aim of this study was to assess image quality and diagnostic performance of STEAM-DWI in breast MRI compared to SE-DWI.

METHODS AND MATERIALS

Prototypical STEAM-DWI and SE-DWI were performed in addition to the standard MRI protocol on a 3T MAGNETOM Vida scanner (Siemens Healthcare, Erlangen, Germany). Image quality was compared in 91 datasets, with respect to the presence of artifacts, signal voids, quality of fat suppression, and lesion and lymph node conspicuity. These parameters were rated using a 5-point Likert scale (1 = worst to 5 = best). The apparent diffusion coefficient (ADC) was measured in 27 mass lesions (16 breast carcinomas, 11 benign lesions), and the diagnostic value of both DWIs was statistically evaluated and compared.

RESULTS

Artifacts and signal voids were almost negligible in both DWI datasets (STEAM 4.40 vs SE 4.02, and 4.88 vs 4.81, respectively). Fat suppression was significantly better in STEAM (4.32 vs 3.87, $P < 0.001$, $r = 0.27$). The conspicuity of mass lesions was quite similar with STEAM and SE (2.19 vs 1.91). No significant difference was observed for the AUC (STEAM, 0.50; SE, 0.52). The cut-off for differentiation of benign and malignant lesions was at ADC = 0.93 · 10-3 mm2/s for STEAM and at 1.05 · 10-3 mm2/s for SE (both sensitivity, 1; specificity, 0.45). The conspicuity of axillary lymph nodes was better with SE than with STEAM (3.38 vs 1.50, $P < 0.001$, $r = 0.44$).

CONCLUSION

s Our data indicate that STEAM-DWI might be a robust technique for diffusion-weighted breast imaging with better fat-suppression and equal diagnostic accuracy compared to SE-DWI. The conspicuity of axillary lymph nodes seems to be inferior in STEAM-DWI compared to SE-DWI, here T1 and T2 weighted sequences from the standard protocol may have to be taken also into account.

CLINICAL RELEVANCE/APPLICATION

STEAM-DWI could represent a robust technique in breast MRI with stable fat saturation and same diagnostic accuracy compared to standard SE-DWI with regard to detection and characterization of mass lesions in breast tissue.

Breast Ultrasound Volume Sweep Imaging: A New Horizon in Breast Cancer Detection

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - BR DPS

Participants
Yu Zhao, MD, Rochester, NY (*Presenter*) Nothing to Disclose

PURPOSE

Most of the world lacks access to basic breast imaging which presumably results in delays to detection of breast cancer. In low- and middle-income countries this delay can be on the scale of months. While ultrasound is an ideal imaging modality to screen for breast abnormalities, its deployment is limited by a lack of trained sonographers. In this study, we tested a simple volume sweep imaging (VSI) ultrasound protocol for the evaluation of palpable breast masses. This protocol can be performed by individuals without prior ultrasound training removing a major barrier to ultrasound deployment.

METHODS AND MATERIALS

Medical students without prior ultrasound experience were trained to perform the VSI protocol with less than 2 hours of training. The VSI protocol involves placing an "X" over the patient's palpable lump and scanning in transverse, sagittal, and radial/antiradial orientations over the lump. The operator uses a preset obviating the need for technical adjustments. The scanner only performs the standardized sweeps of the probe which are saved as video clips for later interpretation by a specialist. The operator does not interpret the ultrasound images. Patients over 18 of either sex were enrolled in this study if they had a palpable breast mass. The trained medical student performed the VSI protocol with a handheld Butterfly iQ ultrasound probe. A standard of care (SOC) ultrasound was performed the same day by an experienced sonographer using a high-end ultrasound machine. Agreement was assessed for mass visualization, size, orientation, shape, margins, echogenicity, posterior acoustic features, and BI-RADS assessment. All interpretations were performed by an attending breast imager.

RESULTS

Students scanned 170 palpable lumps with the VSI protocol. VSI showed 97% sensitivity and 100% specificity for breast mass detection. There was 97.6% agreement with standard of care (Cohen's ?=0.95, p<0.0001). All cancer presenting as a sonographic mass (n=20) were detected. There was substantial agreement for mass characteristics between VSI and SOC, including 87% agreement on BI-RADS assessments (Cohen's ?=0.82, p<0.0001). The average largest mass diameter on SOC was 23.1±16.9 mm and 22.5±15.6 mm on VSI (ICC=0.98 (0.96-0.98, p<0.0001)). The Bland-Altman Bias for these measurements was -1.02 (-7.8-5.77, p=0.002)

CONCLUSION

s There was substantial agreement between VSI ultrasound and standard of care breast imaging for palpable lumps with VSI acquiring images of diagnostic quality.

CLINICAL RELEVANCE/APPLICATION

VSI breast ultrasound is a potential way to increase access to breast imaging in areas without other access to breast imaging. Access to VSI exams could potentially help decrease delays to diagnosis of breast cancer improving outcomes.

Cardiac Tuesday Poster Discussions - B

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - CA DPS

Sub-Events

T5B-SPCA-1 Prediction of Pericardial Adhesion and Diagnostic Performance of Hemodynamically Significant Constrictive Pericarditis by using Feature Tracking Cine MR

Participants
Yasutoshi Ohta, MD, PhD, Suita, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the diagnostic performances of pericardial adhesion and hemodynamically significant constrictive pericarditis using cine MR feature tracking

METHODS AND MATERIALS

Eligible cases were extracted from patients who underwent cardiac MRI between 2011 and 2021. From patients with suspected CP who underwent CMR and catheter-based hemodynamic evaluation, 24 patients(70±8 years) with cine imaging and tagging were selected (cath group). As an age-matched control group (control group), CMR images were extracted from 24 patients with no history of cardiac surgery or ischemic heart disease.10 healthy-volunteer were also analyzed for comparison. Displacement and strain of fibrous pericardium and epicardium covering the entire ventricle were analyzed using the feature tracking (FT) method for cine short-axis images and evaluated on a global displacement graph of the pericardium surrounding the left and right ventricle, and the presence of dip or plateau was assessed from the graph. The presence of pericardial adhesions was evaluated on a 5-point scale by assessing the trajectory of myocardium points using cine images and the FT method. The ventricular septum was tracked using the FT method, and septal displacement was evaluated semiquantitatively utilizing a graph. In the cath group, the presence of adhesions was defined by tagging cine. In the combined control and cath CP group (n=48), the diagnosis of clinical CP was based on the presence of hemodynamic CP or pericardial adhesions proved by pericardiectomy. In catheterized patients (n=24), the diagnostic performance of each index for CP was evaluated based on the presence of hemodynamic CP by catheterization. The area under the receiver-operating characteristic curve (AUROC) was calculated for the diagnosis of pericardial adhesion based on pericardial adhesion in tagging cine.

RESULTS

For detecting hemodynamically significant CP, the sensitivity and specificity of each finding were: Septal bounce, 84.6% and 81.8%; Adhesion, 100% and 9.1%; Dip, 76.9% and 36.4%; Plateau, 69.2% and 45.5%, respectively.For clinical diagnosis of CP, sensitivity and specificity of each findings were: Septal bounce, 80.0% and 97.0%; Adhesion, 83.3% and 75.8%; Dip, 80.0% and 81.8%; Plateau, 73.3% and 78.8%, respectively.In healthy volunteers, septal bounce, adhesion, dip, and plateau were not observed. The AUROC of diagnosing pericardial adhesion by the FT method was 0.846.

CONCLUSION

s Feature-tracking cine MRI yields high diagnostic performance for hemodynamically significant CP.

CLINICAL RELEVANCE/APPLICATION

Although the tagging method has so far been considered beneficial for the diagnosis of pericardial adhesions, the FT method can also be used to evaluate the presence of adhesions.

T5B-SPCA-2 Cardiovascular Magnetic Resonance Pulmonary Transit Time for Assessment of Global Diastolic Dysfunction and Mitral Regurgitation

Participants
Martin Segeroth, Basel, Switzerland (*Presenter*) Nothing to Disclose

PURPOSE

Pulmonary transit time (PTT) is the time it takes blood to pass from the right ventricle to the left ventricle and as such is a surrogate marker of heart failure, pulmonary arterial hypertension and lung disease. We aim to associate PTT with global diastolic dysfunction and mitral regurgitation, which cannot be easily quantified in routine CMR scans.

METHODS AND MATERIALS

All patients referred for routine stress perfusion cardiac magnetic resonance (CMR) imaging to University Hospital Basel (Switzerland) with simultaneously available digital electrocardiograms and in-house echocardiographic assessment between January 2014 and August 2020 were included (n=83). Reporting of echocardiographies was done according to American Society of Echocardiography guidelines. Global diastolic dysfunction (GDD) was defined as more than a Grade I (impaired relaxation). Mitral regurgitation (MR) was defined as more than mild regurgitation. PTT was determined from CMR rest perfusion scans as the time in seconds between peak signal intensities of the time signal curves of the right and left ventricle. PTT normalized for heart rate

(nPTT) was calculated by multiplying PTT with the heart rate. The diagnostic accuracy was assessed by receiver operating characteristics curves.

RESULTS

Median time between CMR and echocardiography was 6 days (IQR: 2 to 30 d). Higher PTT and nPTT values were associated with increasing GDD and MR. Echocardiographic parameters of diastolic dysfunction such as E/A ratio, E/e' ratio and tricuspid regurgitation (TR) velocity also correlated with CMR PTT and nPTT values.The diagnostic accuracy of PTT and nPTT for prediction of GDD as quantified by the area under the ROC curve (AUC) was 0.73 (CI 0.61 to 0.85; p = 0.001) for PTT and 0.76 (CI 0.64 to 0.86; p < 0.001) for nPTT. A PTT < 5.9 s resulted in a specificity of 94%, a sensitivity of 46% and a negative predictive value of 77%. An nPTT < 567 resulted in a specificity of 66%, a sensitivity of 76% and a NPV of 73% for GDD. For MR the diagnostic performance of PTT and nPTT amounted to an AUC of 0.80 (CI 0.68 to 0.92; p < 0.001) for PTT and 0.79 (CI 0.65 to 0.90; p < 0.001) for nPTT.

CONCLUSION

s PTT as an easily obtainable hemodynamic parameter is elevated in patients with global diastolic dysfunction and moderate to severe mitral regurgitation.

CLINICAL RELEVANCE/APPLICATION

In the assessment of patients with dyspnea, otherwise unexplained elevated values of PTT in perfusion CMR scans might be signs of relevant GDD or MVI and may trigger afresh echocardiographic assessment.

T5B-SPCA-3 Noninvasive Prediction of Short-term Therapy Effect of Pulmonary Arterial Hypertension by Using Base-line Cardiac Magnetic Resonance Native T1 Mapping

Participants
Yue Wang, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the role of base-line Cardiac Magnetic Resonance (CMR) native T1 mapping for predicting the short-term therapy effect in pulmonary arterial hypertension (PAH) patients.

METHODS AND MATERIALS

Thirty-four PAH patients who referred to our institution and received target therapy were retrospectively included. All patients underwent CMR examination prior to the beginning of the therapy. Patients were subdivided into effective group and ineffective group. Twenty-five healthy individuals were included as controls. Anterior right ventricular insertion point (ARVIP) native T1 times of all patients and controls were manually measured. The diameters of main pulmonary arterial (dMPA) and ascending aorta (dAA) were measured and ratio of dMPA/dAA was calculated. Receiver operating characteristics (ROC) curves and area under curve (AUC) were calculated.

RESULTS

PAH patients showed higher mid ventricle ARVIP native T1 as compared with controls. Base-line ARVIP native T1 were significantly higher in ineffective group as compared with effective group. The AUC of base-line ARVIP native T1 for predicting the therapy effect was 0.788. The dMPA/dAA ratio was significantly lower in effective group. The combining model integrated dMPA/dAA and ARVIP native T1 for predicting therapy effect was 0.846.

CONCLUSION

s The combining model integrated base-line ARVIP native T1 and dMPA/dAA ratio shows promise for prediction of the therapy effect of PAH patients

CLINICAL RELEVANCE/APPLICATION

Base-line cardiac magnetic resonance native T1 mapping hold promise for predicting the therapy effect of PAH patients and may assist the selection of the tailored treatment strategy to improve prognosis.

T5B-SPCH-1 Value of Computer Aided Diagnosis on Radiologists' Workflow and Recommendation for Reporting Lung Cancer Screening LDCT

Participants
Ren Yuan, MD, PhD, Vancouver, BC (*Presenter*) Nothing to Disclose

PURPOSE

In lung cancer screening, the utility of a Computer Aided Diagnostic (CAD) has not been tested in a prospective randomized clinical study. We aim to evaluate whether CAD would change the next step recommendation and how the use of CAD would influence the radiologist's reporting time.

METHODS AND MATERIALS

In the Vancouver site of the International Lung Screening Trial, the baseline CT scans were randomized to Radiologist or CAD reading-first arm (i.e. RAD-1st vs. CAD-1st). In Rad-1st arm, a chest radiologist read the CT alone, manually measured and recorded nodules (i.e., manual reading), and then turned on CAD annotations to accept, reject or add nodule(s) for the final "combined reading". In the CAD-1st arm, the CAD annotations were displayed first for the radiologist to accept, reject or add nodule(s) and to generate the report. In the RAD-1st arm, the PanCan nodule malignancy risk score (NEJM 2013) was automatically generated by the CAD based on the "combined reading" result and this score was also calculated for nodules found during "manual reading". Differences in triaging participants into biennial/annual follow-up. FU CT (Group 1), early recall CT in 3 months (Group 2) or diagnostic work-up referral (Group 3) were compared between the manual reading versus the combined reading. The radiologist's reading time was also compared between CAD-1st and Rad-1st arms.

RESULTS

Between 2016 and 2019, a total of 2053 ever smokers (age: 55~ 80 yo) who met the USPSTF 2013 screening criteria or those with a PLCOm2012 6-years lung cancer risk >1.5% were enrolled in the study. Seventy (3.4%) cancers were diagnosed after a minimum of 2-years of FU; 48/70 cancers were in Rad-1st arm. All cancers were successfully detected by both radiologist and CAD. In 42/48 cancers, the management recommendation using the PanCan nodule malignancy risk score was consistent between manual and combined reading. In 6/48 cancer cases, using CAD after manual reading prompted a shorter FU interval in 5 cancers (FU changed from 12 to 3 months in 3, and from 3 months to diagnostic workup in 2). In one 11.5mm GGN that was later found to be an adenocarcinoma, adding CAD changed the management from diagnostic work-up to a 3-month FU CT, which retrospectively seemed more appropriate. Radiologist's reading time was significantly shortened by using CAD concurrently in all 3 Groups (for CAD-1st versus Rad-1st arm: in Group1: 4.3±2.4 vs. 5.5±2.9 min; in Group2: 7.6±4.6 vs. 9.3± 4.6 min; in Group3: 7.9±3.9 vs. 12.3± 7.7 min, all $p<0.05$).

CONCLUSION

s Using CAD improved accuracy of reporting and management recommendation. Reading concurrently with CAD saved the radiologist's reading time.

CLINICAL RELEVANCE/APPLICATION

These features are important regarding the clinical implementation of CAD in a screening program.

T5B-SPCH-10 Role of Quantitative CT in evaluation of Chronic Obstructive Pulmonary Disease

Participants
Shuchi Bhatt, MD, MBBS, Delhi, India (*Presenter*) Nothing to Disclose

PURPOSE

COPD is diagnosed when post bronchodilator FEV1/FVC<0.70. Quantitative CT [QCT] can determine airway remodeling, air trapping emphysema in COPD. Aim: To determine compare QCT in cases controls, calculate inter-observer agreement and correlate with spirometry.

METHODS AND MATERIALS

After due ethical approval cross-sectional study was done over 18 months on 70 COPD patients using spirometry non-contrast chest CT (inspiration expiration) with 64 slice MDCT. 35 normal inspiratory chest CTs were controls. 1 mm sharp reconstructions

were used to calculate QCT parameters Parenchymal: • Emphysema: Mean lung density [MLD], % low attenuation areas %LAA(-950 HU) • Air trapping: %LAA(-850 HU), %LAA(-850 HU to -950 HU), • Inspiratory/Expiratory [I/E]-I/Evol, I/Eatt Airway: Segmental sub-segmental bronchi (1 each for upper, middle lower lobe for R L lung) • Inner luminal area (Ai) • Wall thickness [WT], wall area [WA], (WA%), Watt • Functional small airway disease: E(-850 HU) /I (-950 HU) Compared mean + SD QCT of cases controls (Unpaired student t test); QCT PFT of cases with Pearson correlation coefficient, ROC determined cut off values for QCT. ICC for Inter-observer agreement

RESULTS

GOLD Stage III- 61.4%, stage II- 38.5% were present; 85.71% were males, mean age 59.74 yrs, 87% were smokers. Significant difference existed in cases controls for MLD, %LAA-950HU, Ai, WT, WA, WA % (p=0.00, and p= 0.003 for Ai seg) Cases: Excellent ICC >0.990 existed for all except I/Eatt[ICC= 0.815], poor for bronchial Watt ICC= 0.358. Controls: ICC of 0.908 except for Watt [ICC=0.5]. Positive correlation: MLD with FEV1 [p =0.017]; I/E lung density with FEV1 [p =0.019] FVC [p=0.034] existed. Negative correlation seen for %LAA(-950 HU) with FEV1 (p-value 0.000), FVC (p= 0.001) FEV1/FVC (p= 0.023); %LAA(-850 HU) with FEV1 [p=0.002] FVC [p= 0.009]. WA % (seg, sub-seg) correlated negatively with FEV1 (p =0.013) FVC [p=0.027 for segmental]. Aiseg with FEV1 [p=0.008] FVC [p=0.029] correlated positively. MLD[HU] WTsubseg; %LAA(950HU), WTseg WA%subseg WAseg with sensitivity =90%. WAsubseg, %LAA(-950HU) WTsubseg had good specificity (80-89%). Cut off values are - MLD (-853.00 HU,98.60%,74.30%), %LAA(-950 HU) (13.24%, 91.50 %, 80.00%), WTseg (0.095cm, 91.40%, 74.30%), WTsubseg (0.065cm,98.60% and 80%), WAseg(14.00mm2, 98.60%. 80%), WAsubseg(8.20mm2,77.10%, 88.60%],WA%[sub-seg] (56.03%, 91.40%, 65.70%), WA%seg (60.65%, 84.305, 68.60%). Mean effective dose is 2.87 mSv (cases) 1.52 mSv (controls)

CONCLUSION

s QCT detects cases of COPD correlated with spirometry.

CLINICAL RELEVANCE/APPLICATION

QCT can selectively differentiate air flow limitation due to airway luminal compromise, emphysema, functional airway obstruction and optimize treatment.

T5B-SPCH-2 Natural History of Persistent Pulmonary Subsolid Nodules at multidetector CT: Analysis of Predictors of Growth

Participants
Yifan He, Dalian, China (*Presenter*) Nothing to Disclose

PURPOSE

Long-term follow-up strategies for subsolid nodules (SSNs), risk factors influencing the appearance of subsequent growth of SSNs need to be clarified.

METHODS AND MATERIALS

A total of 149 SSNs from 132 patients between June 2007 and October 2021 were retrospectively included in this study. All 149 SSNs on initial and final LDCT scans were manually segmented in three-dimensions to obtain SSNs diameter, density, volume and mass, thus to calculate volume doubling time (VDT) and mass doubling time (MDT). Kaplan-Meier analysis was performed using log-rank test, and independent risk factors affecting GGNs growth were analyzed using multivariate Cox proportional risk regression.

RESULTS

The median follow-up time for 149 SSNs (135 non-solid nodules (NSNS) and 14 part-solid nodules (PSNs)) was 1313 (376-4703) days. The median VDT and MDT of 88 SSNs having grown were 1093.7 (range, 156.3-6799.0) days and 1003.9 (range, 142.3-7264.5) days respectively, the median MDT was significantly shorter than VDT ($p < 0.001$). The cumulative percentages of SSN growth were significantly differed among the initial mean CT attenuation (m-CTA), diameter, volume, mass, age and vacuole subgroups (all $p < 0.05$). The multivariate Cox risk regression analysis showed that vacuole (HR = 1.646, p = 0.048), initial volume (HR = 0.999, p = 0.041), and initial mass (HR = 1.002, p = 0.022) were independent risk factors for SSN growth.

CONCLUSION

s In patients with vacuole sign, larger initial volume and mass, a more rational follow-up period is necessary to observe the presence or absence of interval growth of the SSNs.

CLINICAL RELEVANCE/APPLICATION

Persistent SSNs, especially showing interval growth, often indicate precursor glandular lesions or invasive adenocarcinomas (IACs). The diagnosis of SSN is challenging because there exists an apparent paradox, displaying indolent biological behavior with slow growth but a high rate of being malignant. There existed a large heterogeneity in the growth pattern of SSN, and the natural growth course of nodules and follow-up strategies need to be elucidated. Volume and mass are three-dimensional quantitative parameters that can reflect the actual growth of SSNs more accurately and earlier. In our study, vacuole, initial volume and mass were independent risk factors for the appearance of progression of SSN. Therefore, the observation of changes in these characteristics during follow-up is of value to assisting clinical practice and rational management of pulmonary nodules.

T5B-SPCH-3 Volumetric Analysis: Effect on Pulmonary Nodule Diagnosis and Management in Clinical Practice

Participants
Robert Lim, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the effect of volumetric analysis on the diagnosis and management of indeterminant solid nodules on computed tomography (CT).

METHODS AND MATERIALS

One hundred and seven CT cases of solid pulmonary nodules (size range, 6-15 mm) were selected, including 57 proven malignancies (lung cancer, n=34; metastasis, n=23) and 50 benign nodules. CT scans were from multiple institutions and of variable technique. Nine radiologists (attendings, n=3; fellows, n=3; residents, n=3) were asked their level of suspicion for malignancy (low/moderate or

high) and management recommendation (no follow-up; CT follow up; or care escalation) for baseline and follow-up studies first without and then with volumetric analysis. The effect of volumetric analysis on diagnosis and management of cases was assessed by logistic regression; its effect on timepoint when malignant nodules were first identified was tested by a test of symmetry. Differences in inter-observer kappa coefficients between assessments performed without and with volume analysis were tested by Gwet's linearized t-test for kappa.

RESULTS

Improved sensitivity (p=0.011) and earlier recognition (p<0.001) of malignant nodules occurred with use of volumetric analysis. Attending radiologists showed higher sensitivity in recognition of malignant nodules (p=0.03) and then to recommend care escalation (p<0.001) as compared to trainees. Use of volumetric analysis altered management of nodules assessed to be of high suspicion for malignancy only in the fellow group (p=0.008). Kappa statistics for suspicion for malignancy and recommended management were in the fair to substantial (0.38-0.66) and fair to good (0.33-0.50) ranges, respectively. Use of volumetric analysis improved inter-observer variability (p=0.004) only for assessment of nodule malignancy on the second follow-up study from 0.52 to 0.66.

CONCLUSION

s Volumetric analysis of solid indeterminant pulmonary nodules in routine clinical practice can result in improved sensitivity and earlier identification of malignant nodules. Its effect on recommendations for management of suspected malignant nodules is variable and may be influenced by reader experience.

CLINICAL RELEVANCE/APPLICATION

Adoption of volumetric analysis of solid indeterminant pulmonary nodules in routine CT clinical practice may allow more sensitive and earlier detection of cancers.

T5B-SPCH-4 Will I Change Nodule Management Recommendations If I Change My CAD System: Volumetry of Artificial Pulmonary Nodules by Different CAD Systems

Participants
Alan Peters, MD, Bern, Switzerland (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate and compare the measurement accuracy of two different CAD systems regarding artificial pulmonary nodules and assess the clinical impact of volumetric inaccuracies in a phantom study.

METHODS AND MATERIALS

In this phantom study, 59 different phantom arrangements with 326 artificial nodules (178 solid, 148 ground-glass) were scanned at 80 kV, 100 kV and 120 kV. Four different nodule diameters were used: 5 mm, 8 mm, 10 mm and 12 mm. Scans were analyzed by a DL-based CAD and a standard CAD system. Relative volumetric errors (RVE) of each system vs. ground truth and the relative volume difference (RVD) DL-based vs. standard CAD were calculated. The Bland-Altman method was used to define the limits of agreement (LOA). The hypothetical impact on LungRADS classification was assessed for both systems.

RESULTS

There was no difference between the three voltage groups regarding nodule volumetry. Regarding the solid nodules, the RVE of the 5 mm, 8 mm, 10 mm and 12 mm size group for the DL-CAD/standard CAD were 12.2/2.8% 1.3/-2.8%, -3.6/1.5% and -12.2/-0.3%, respectively. The corresponding values for the GGN were 25.6%/81.0%, 9.0%/28.0%, 7.6/20.6% and 6.8/21.2%. The mean RVD for solid nodules/GGN was 1.3/-15.2%. Regarding the LungRADS classification, 88.5% and 79.8% of all solid nodules were correctly assigned by the DL-CAD and the standard CAD, respectively. 14.9% of the nodules were assigned differently between the systems.

CONCLUSION

s Patient management may be affected by volumetric inaccuracy of the CAD systems.

CLINICAL RELEVANCE/APPLICATION

The results of this study highlight that supervision and / or manual correction by a radiologist is pertinent when using a CAD system in daily clinical routine.

T5B-SPCH-5 A General Approach for Automatic Segmentation of Pneumonia Pulmonary Nodule and Tuberculosis on CT Images

Participants
Jiangdian Song, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

Accurate segmentation of lung lesions on CT images will inform clinical diagnosis of multiple lung diseases including COVID-19 pneumonia. As a common framework for image segmentation, generative adversarial network (GAN) is hampered by the limited annotated samples available and the catastrophic forgetting of the discriminator when used to segment diverse lung lesions on computed tomography (CT) images. Therefore, a general self-supervised adversarial learning architecture that does not require large amounts of labeled data and mitigates discriminator forgetting is proposed to segment lung lesions including pneumonia, lung nodules, and tuberculosis precisely and automatically on CT images.

METHODS AND MATERIALS

For the generator network of the proposed model, a cascaded dual attention network with a context-aware pyramid feature extraction module is designed to model multi-scale semantic interdependencies of lung lesions in both spatial and channel dimensions. Then, a self-supervised rotation loss is introduced into the model to avoid discriminator forgetting and to achieve more efficient lung lesion feature representation. Multi-center pneumonia, lung nodule, and tuberculosis CT images were used to test the proposed model. A state-of-the-art nnU-Net is employed to compare with the proposed model on lung lesion segmentation.

RESULTS

A total of 14,260, 14,266, and 3,361 images of pneumonia, lung nodule, and tuberculosis were used in this study, and the lesions was randomly divided into training, validation, and test datasets (8:1:1), respectively. Average dice coefficients (DCs) of 75.05%, 74.22%, and 71.58% for the three lesion types were obtained on the test dataset when using all the images. When the training dataset was reduced to 10%, DCs of 71.10%, 72.80%, and 69.43% were obtained on test datasets, respectively, and no significant decrease in DC was found ($P > 0.10$). In addition, no significant difference was found between the nnU-Net and the proposed model for segmentation ($P > 0.05$).

CONCLUSION

s Our study provided a self-supervised adversarial learning architecture to enable the use of limited training samples for accurately segmenting multiple types of lung lesions without the need for massive annotation sample. The proposed model achieved competitive segmentation result compared with the state-of-the-art segmentation network.

CLINICAL RELEVANCE/APPLICATION

A general automatic segmentation approach for COVID-19 pneumonia, lung nodule, and tuberculosis enables to reduce the redundant work of repeatedly model training. Our model enables the reduction of GAN's dependence on massive manually annotated training data and thus relieves radiologists from tedious manual delineation labor.

T5B-SPCH-6 CT Radiomics-based Clustering in Lung Cancer: A Comparison with Comprehensive Genomic Profiling

Participants
Motohiko Yamazaki, MD, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

Comprehensive genomic profiling (CGP) is a new technology that can analyze hundreds of cancer genes at one assay and enables to determine the total number of gene mutations called tumor mutation burden (TMB). In lung cancer, driver gene mutations can be candidates for molecular targeted therapies, while a high TMB suggests good response to immune checkpoint inhibitors. This study aimed to compare CT radiomics-based clustering with CGP data and patient prognosis in lung cancer.

METHODS AND MATERIALS

This retrospective study comprised 93 patients with non-small cell lung cancer (66 adenocarcinomas and 27 squamous cell carcinomas) who underwent surgery. TMB and 415 cancer gene expression patterns were investigated in each surgical specimen by CGP using next-generation sequencing. All patients were classified into two clusters according to their radiomic features extracted from preoperative CT images using unsupervised k-means clustering. Differences between these two clusters were investigated with respect to gene mutations, TMB (low or high), recurrence-free survival, and visual CT features.

RESULTS

Unsupervised clustering classified 55 patients into Cluster 1 and 38 patients into Cluster 2 according to their radiomic features. Cluster 1 exhibited a significantly higher proportion of TP53 and CDKN2B gene mutations but a lower proportion of EGFR gene mutations compared with Cluster 2 (TP53 mutations, 34/55 [61.8%] vs 12/38 [31.6%]; CDKN2B mutations, 26/55 [47.3%] vs 10/38 [26.3%]; EGFR mutations, 13/55 [23.6%] vs 17/38 [44.7%]; all $P < 0.05$). A high TMB (= 20 mutations/megabase) was more frequently observed in Cluster 1 than in Cluster 2 (23/55 [41.8%] vs. 2/38 [5.3%]; $P < 0.01$). Recurrence-free survival at 5 years was significantly lower in Cluster 1 than in Cluster 2 (40.4% vs. 51.0%; $P = 0.038$). For visual CT features, Cluster 1 was more likely to indicate a lobulated margin but was less frequently accompanied by ground-glass opacity, air-bronchogram, cavity, and vacuole sign compared to Cluster 2 (all $P < 0.05$).

CONCLUSION

s CT radiomics-based clustering has significant association with CGP data as well as patient prognosis and may help predict genomic information in non-small cell lung cancer.

CLINICAL RELEVANCE/APPLICATION

CGP provides valuable information to determine therapeutic agents for lung cancer, leading to precision medicine. However, CGP is very expensive and requires invasive tissue sampling. Therefore, CT examination, which is non-invasive and relatively low costs, plays an important role in predicting genomic information. CT radiomics-based clustering created in this study could help predict CGP data.

T5B-SPCH-7 Correlation Between Intra-nodular Vessel and Tumor Invasiveness of Lung Adenocarcinoma Presenting as Ground-glass Nodules: A Deep Learning 3D Reconstruction Algorithm-based Quantitative Analysis on Non-contrast CT Images

Participants
Baolian Zhao, (*Presenter*) Nothing to Disclose

PURPOSE

To quantitatively analyze the pulmonary vessels inside ground-glass nodules (GGNs) on non-contrast CT (NCCT) images using fully automated deep learning (DL) approach and investigate the relationship between intra-nodular vessel and tumor invasiveness.

METHODS AND MATERIALS

A total of 741 pathologically confirmed GGNs from 719 patients were retrospectively collected, comprising 121 atypical adenomatous hyperplasia (AAH), 150 adenocarcinoma in situ (AIS), 154 minimally invasive adenocarcinoma (MIA) and 316 invasive adenocarcinoma (IAC). The pulmonary blood vessels were reconstructed on NCCT images using DL-based region segmentation and region growth technology (InferVisual Surgery Planning Research version). The presence of pulmonary vessels inside GGNs was quantitatively evaluated with respect to intra-nodular vessel prevalence and the automatedly calculated vessel volume percentage, which were further compared across different invasiveness categories by the Chi-square test, analysis of variance (ANOVA) and Mann-Whitney U test.

RESULTS

The automated DL algorithm showed high accuracy in vessels detection and reconstruction. There were significant differences in

The automated DL algorithm showed high accuracy in vessels detection and reconstruction. There were significant differences in the occurrences of internal vessels across different tumor invasiveness GGNs ($p < 0.001$). The prevalence of intra-nodular vessels in IAC (66.5%) was significantly higher than that of AAH (35.5%, $p < 0.001$), AIS (33.3%, $p < 0.001$) and MIA (50.6%, $p = 0.001$), while the vascular categories were similar (all $p > 0.05$). Vascular changes were more common in invasive lesions (MIA and IAC) than pre-invasive lesions (AAH and AIS), which mainly manifested as increased vessel volume percentage (10.23% vs 3.85%, $p < 0.001$). The average vessel volume percentage of IAC (12.01%) was also higher compared with that of AAH (3.85%), AIS (3.86%) and MIA (6.57%) with statistically significance (all $p < 0.001$).

CONCLUSION

s The quantitative analysis of intra-nodular vessels on NCCT images demonstrated that the incidence of internal vessels in GGNs was related to their pathological invasiveness. GGNs with increased internal vessel percentages had higher possibility of tumor invasiveness.

CLINICAL RELEVANCE/APPLICATION

Our deep learning-based quantitative analysis on NCCT images reveals that the incidence and volume percentage of intra-tumoral vessels in GGNs are correlated with pathological invasiveness.

T5B-SPCH-8 Cascade-network to Reduce False Positives for Pulmonary Nodule Detection on Chest X-ray Radiographs

Participants
Taehee Kim, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Recently, many deep learning-based nodule detection algorithms for chest X-ray radiographs (CXRs) have reported promising results. In real clinical environment, however, those algorithms have been reported to produce many false positives (FPs) caused by the similarity between hard negatives (e.g., nipple shadow, bone island, superimposed pulmonary vessels, etc.) and real nodules. Here, we propose a cascade-network to reduce these FPs in nodule detection.

METHODS AND MATERIALS

NODE21 challenge dataset (node21.grand-challenge.org) was utilized (training: 934/2404; validation: 100/300; testing: 100/300 for nodule/non-nodule CXRs). For each CXR in the training dataset, a set of multi-resolution patches (resolution: 112x112, 280x280, and 448x448) were generated. Three multi-resolution patches were resized to 112x112 and concatenated along the channel for training. Patches were classified as positive (i.e., nodule patches) when a nodule locates on the center of the patch. For nodule detection, two neural networks were used sequentially where first network was to detect nodule candidates on an input CXR, and the second network was to further screen out hard negatives. Both networks had same architecture (EfficientNet-B0) and trained based on multi-resolution patches. The output of the two networks was the probability of nodule for the input patch. The difference between the networks was the composition of training dataset. For first network, all negative patches for training were the patches with no nodule (i.e., non-nodule patches). In second network, half of negative patches for training were carefully selected among the false positive outputs in the training data of first network to design second network more sensitive to the hard negatives. The detection performances were measured based on the area under the Free-Response Receiver Operating Characteristics (FAUC) and Refined Competition Performance Metric (R-CPM). Comparison was performed before and after ablating second network.

RESULTS

The nodule detection performances of the cascade-network (FAUC:0.6033(95% CI: 0.5848-0.6217), R-CPM:0.5995(0.5778-0.6211)) outperformed those of the first network only (FAUC:0.4987(0.4667-0.5308), $p<0.001$, R-CPM:0.4967(0.4649-0.5285), $p<0.001$). When visually investigated, the outputs from the cascade-network showed a much smaller number of FPs.

CONCLUSION

s In this study, we proposed a cascade-network for nodule detection to reduce FPs, dramatically improving nodule detection performance.

CLINICAL RELEVANCE/APPLICATION

The proposed cascade-network with sequential training scheme would enable development of a nodule detection algorithm with high positive predictive value efficiently by using network-driven hard negatives.

T5B-SPCH-9 Implications of Radiologist-interpreted Subjective Standards for Evaluating the Diagnostic Performance of a Deep Learning Model: A Malignant Lung Nodule Detection Task on Chest Radiographs

Participants
Jung Eun Huh, BA, Oxford, United Kingdom (*Presenter*) Nothing to Disclose

PURPOSE

Little is known regarding the impact of radiologist-interpreted subjective standards as ground truth when evaluating the performance of deep learning (DL) models and their added value to radiologists. We assessed the adherence of the subjective standards to the reference standard, and the difference in diagnostic performance measurements of radiologists with and without a DL-based automatic detection (DLAD) model according to the standard used to detect malignant pulmonary nodules on chest radiographs.

METHODS AND MATERIALS

This study included 50 patients with pathology- and CT-proven lung cancers (reference standards) with 50 chest radiographs between December 2015 and February 2021, and 50 control individuals with normal chest radiographs. Five subjective standards were constructed using 10 radiologists' interpretations and compared: individual judgment by the most experienced radiologist, majority vote, consensus judgments of 2 and 3 radiologists, and a latent class analysis (LCA) model. In separate reader tests, 10 other radiologists (who did not participate in constructing the subjective standards) interpreted the radiographs with and without the DLAD model, and their diagnostic performance was compared between the reference standard and the five subjective

standards. The t-test with the Bonferroni correction was used to compare adherence and diagnostic performance.

RESULTS

The LCA model, which showed a sensitivity of 72.6% and a specificity of 100%, adhered more closely to the reference standard than any of the other subjective standards. In the reader tests, both the radiologists and the DLAD model tended to show overestimated sensitivity but underestimated specificity when the subjective standards were applied as the ground truths. However, these radiologists' tendencies were diminished by DLAD assistance (all P-values <0.001). Although using the DLAD improved the sensitivity and specificity (in some cases) when the subjective standards were used, the corresponding effects were estimated to be significantly smaller than when the reference standard was used (all P-values <0.001), except for sensitivity with the LCA model (P=0.094).

CONCLUSION

s The LCA model showed the closest adherence to the reference standard for detecting malignant pulmonary nodules on chest radiographs. Radiologists' sensitivity and specificity values were overestimated and underestimated, respectively, and the DLAD added less value with the subjective standards than with the reference standard.

CLINICAL RELEVANCE/APPLICATION

Since using only subjective standards can lead to bias in the diagnostic performance of DL models, evaluating DL models with a reference standard is necessary even in underserved settings.

Value of Computer Aided Diagnosis on Radiologists' Workflow and Recommendation for Reporting Lung Cancer Screening LDCT

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - CH DPS

Participants
Ren Yuan, MD, PhD, Vancouver, BC (*Presenter*) Nothing to Disclose

PURPOSE

In lung cancer screening, the utility of a Computer Aided Diagnostic (CAD) has not been tested in a prospective randomized clinical study. We aim to evaluate whether CAD would change the next step recommendation and how the use of CAD would influence the radiologist's reporting time.

METHODS AND MATERIALS

In the Vancouver site of the International Lung Screening Trial, the baseline CT scans were randomized to Radiologist or CAD reading-first arm (i.e. RAD-1st vs. CAD-1st). In Rad-1st arm, a chest radiologist read the CT alone, manually measured and recorded nodules (i.e., manual reading), and then turned on CAD annotations to accept, reject or add nodule(s) for the final "combined reading". In the CAD-1st arm, the CAD annotations were displayed first for the radiologist to accept, reject or add nodule(s) and to generate the report. In the RAD-1st arm, the PanCan nodule malignancy risk score (NEJM 2013) was automatically generated by the CAD based on the "combined reading" result and this score was also calculated for nodules found during "manual reading". Differences in triaging participants into biennial/annual follow-up. FU CT (Group 1), early recall CT in 3 months (Group 2) or diagnostic work-up referral (Group 3) were compared between the manual reading versus the combined reading. The radiologist's reading time was also compared between CAD-1st and Rad-1st arms.

RESULTS

Between 2016 and 2019, a total of 2053 ever smokers (age: 55~ 80 yo) who met the USPSTF 2013 screening criteria or those with a PLCOm2012 6-years lung cancer risk >1.5% were enrolled in the study. Seventy (3.4%) cancers were diagnosed after a minimum of 2-years of FU; 48/70 cancers were in Rad-1st arm. All cancers were successfully detected by both radiologist and CAD. In 42/48 cancers, the management recommendation using the PanCan nodule malignancy risk score was consistent between manual and combined reading. In 6/48 cancer cases, using CAD after manual reading prompted a shorter FU interval in 5 cancers (FU changed from 12 to 3 months in 3, and from 3 months to diagnostic workup in 2). In one 11.5mm GGN that was later found to be an adenocarcinoma, adding CAD changed the management from diagnostic work-up to a 3-month FU CT, which retrospectively seemed more appropriate. Radiologist's reading time was significantly shortened by using CAD concurrently in all 3 Groups (for CAD-1st versus Rad-1st arm: in Group1: 4.3±2.4 vs. 5.5±2.9 min; in Group2: 7.6±4.6 vs. 9.3± 4.6 min; in Group3: 7.9±3.9 vs. 12.3± 7.7 min, all $p<0.05$).

CONCLUSION

s Using CAD improved accuracy of reporting and management recommendation. Reading concurrently with CAD saved the radiologist's reading time.

CLINICAL RELEVANCE/APPLICATION

These features are important regarding the clinical implementation of CAD in a screening program.

Role of Quantitative CT in evaluation of Chronic Obstructive Pulmonary Disease

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - CH DPS

Participants
Shuchi Bhatt, MD, MBBS, Delhi, India (*Presenter*) Nothing to Disclose

PURPOSE

COPD is diagnosed when post bronchodilator FEV1/FVC<0.70. Quantitative CT [QCT] can determine airway remodeling, air trapping emphysema in COPD. Aim: To determine compare QCT in cases controls, calculate inter-observer agreement and correlate with spirometry.

METHODS AND MATERIALS

After due ethical approval cross-sectional study was done over 18 months on 70 COPD patients using spirometry non-contrast chest CT (inspiration expiration) with 64 slice MDCT. 35 normal inspiratory chest CTs were controls. 1 mm sharp reconstructions were used to calculate QCT parameters Parenchymal: • Emphysema: Mean lung density [MLD], % low attenuation areas %LAA(-950 HU) • Air trapping: %LAA(-850 HU), %LAA(-850 HU to -950 HU), • Inspiratory/Expiratory [I/E]-I/Evol, I/Eatt Airway: Segmental sub-segmental bronchi (1 each for upper, middle lower lobe for R L lung) • Inner luminal area (Ai) • Wall thickness [WT], wall area [WA], (WA%), Watt • Functional small airway disease: E(-850 HU) /I (-950 HU) Compared mean + SD QCT of cases controls (Unpaired student t test); QCT PFT of cases with Pearson correlation coefficient, ROC determined cut off values for QCT. ICC for Inter-observer agreement

RESULTS

GOLD Stage III- 61.4%, stage II- 38.5% were present; 85.71% were males, mean age 59.74 yrs, 87% were smokers. Significant difference existed in cases controls for MLD, %LAA-950HU, Ai, WT, WA, WA % (p=0.00, and p= 0.003 for Ai seg) Cases: Excellent ICC >0.990 existed for all except I/Eatt[ICC= 0.815], poor for bronchial Watt ICC= 0.358. Controls: ICC of 0.908 except for Watt [ICC=0.5]. Positive correlation: MLD with FEV1 [p =0.017]; I/E lung density with FEV1 [p =0.019] FVC [p=0.034] existed. Negative correlation seen for %LAA(-950 HU) with FEV1 (p-value 0.000), FVC (p= 0.001) FEV1/FVC (p= 0.023); %LAA(-850 HU) with FEV1 [p=0.002] FVC [p= 0.009]. WA % (seg, sub-seg) correlated negatively with FEV1 (p =0.013) FVC [p=0.027 for segmental]. Aiseg with FEV1 [p=0.008] FVC [p=0.029] correlated positively. MLD[HU] WTsubseg; %LAA(950HU), WTseg WA%subseg WAseg with sensitivity =90%. WAsubseg, %LAA(-950HU) WTsubseg had good specificity (80-89%). Cut off values are - MLD (-853.00 HU,98.60%,74.30%), %LAA(-950 HU) (13.24%, 91.50 %, 80.00%), WTseg (0.095cm, 91.40%, 74.30%), WTsubseg (0.065cm,98.60% and 80%), WAseg(14.00mm2, 98.60%. 80%), WAsubseg(8.20mm2,77.10%, 88.60%],WA%[sub-seg] (56.03%, 91.40%, 65.70%), WA%seg (60.65%, 84.305, 68.60%). Mean effective dose is 2.87 mSv (cases) 1.52 mSv (controls)

CONCLUSION

s QCT detects cases of COPD correlated with spirometry.

CLINICAL RELEVANCE/APPLICATION

QCT can selectively differentiate air flow limitation due to airway luminal compromise, emphysema, functional airway obstruction and optimize treatment.

T5B-SPCH-2

Natural History of Persistent Pulmonary Subsolid Nodules at multidetector CT: Analysis of Predictors of Growth

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - CH DPS

Participants
Yifan He, Dalian, China (*Presenter*) Nothing to Disclose

PURPOSE

Long-term follow-up strategies for subsolid nodules (SSNs), risk factors influencing the appearance of subsequent growth of SSNs need to be clarified.

METHODS AND MATERIALS

A total of 149 SSNs from 132 patients between June 2007 and October 2021 were retrospectively included in this study. All 149 SSNs on initial and final LDCT scans were manually segmented in three-dimensions to obtain SSNs diameter, density, volume and mass, thus to calculate volume doubling time (VDT) and mass doubling time (MDT). Kaplan-Meier analysis was performed using log-rank test, and independent risk factors affecting GGNs growth were analyzed using multivariate Cox proportional risk regression.

RESULTS

The median follow-up time for 149 SSNs (135 non-solid nodules (NSNS) and 14 part-solid nodules (PSNs)) was 1313 (376-4703) days. The median VDT and MDT of 88 SSNs having grown were 1093.7 (range, 156.3-6799.0) days and 1003.9 (range, 142.3-7264.5) days respectively, the median MDT was significantly shorter than VDT ($p < 0.001$). The cumulative percentages of SSN growth were significantly differed among the initial mean CT attenuation (m-CTA), diameter, volume, mass, age and vacuole subgroups (all $p < 0.05$). The multivariate Cox risk regression analysis showed that vacuole (HR = 1.646, $p = 0.048$), initial volume (HR = 0.999, $p = 0.041$), and initial mass (HR = 1.002, $p = 0.022$) were independent risk factors for SSN growth.

CONCLUSION

s In patients with vacuole sign, larger initial volume and mass, a more rational follow-up period is necessary to observe the presence or absence of interval growth of the SSNs.

CLINICAL RELEVANCE/APPLICATION

Persistent SSNs, especially showing interval growth, often indicate precursor glandular lesions or invasive adenocarcinomas (IACs). The diagnosis of SSN is challenging because there exists an apparent paradox, displaying indolent biological behavior with slow growth but a high rate of being malignant. There existed a large heterogeneity in the growth pattern of SSN, and the natural growth course of nodules and follow-up strategies need to be elucidated. Volume and mass are three-dimensional quantitative parameters that can reflect the actual growth of SSNs more accurately and earlier. In our study, vacuole, initial volume and mass were independent risk factors for the appearance of progression of SSN. Therefore, the observation of changes in these characteristics during follow-up is of value to assisting clinical practice and rational management of pulmonary nodules.

Volumetric Analysis: Effect on Pulmonary Nodule Diagnosis and Management in Clinical Practice

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - CH DPS

Participants
Robert Lim, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the effect of volumetric analysis on the diagnosis and management of indeterminant solid nodules on computed tomography (CT).

METHODS AND MATERIALS

One hundred and seven CT cases of solid pulmonary nodules (size range, 6-15 mm) were selected, including 57 proven malignancies (lung cancer, n=34; metastasis, n=23) and 50 benign nodules. CT scans were from multiple institutions and of variable technique. Nine radiologists (attendings, n=3; fellows, n=3; residents, n=3) were asked their level of suspicion for malignancy (low/moderate or high) and management recommendation (no follow-up; CT follow up; or care escalation) for baseline and follow-up studies first without and then with volumetric analysis. The effect of volumetric analysis on diagnosis and management of cases was assessed by logistic regression; its effect on timepoint when malignant nodules were first identified was tested by a test of symmetry. Differences in inter-observer kappa coefficients between assessments performed without and with volume analysis were tested by Gwet's linearized t-test for kappa.

RESULTS

Improved sensitivity ($p=0.011$) and earlier recognition ($p<0.001$) of malignant nodules occurred with use of volumetric analysis. Attending radiologists showed higher sensitivity in recognition of malignant nodules ($p=0.03$) and then to recommend care escalation ($p<0.001$) as compared to trainees. Use of volumetric analysis altered management of nodules assessed to be of high suspicion for malignancy only in the fellow group ($p=0.008$). Kappa statistics for suspicion for malignancy and recommended management were in the fair to substantial (0.38-0.66) and fair to good (0.33-0.50) ranges, respectively. Use of volumetric analysis improved inter-observer variability ($p=0.004$) only for assessment of nodule malignancy on the second follow-up study from 0.52 to 0.66.

CONCLUSION

s Volumetric analysis of solid indeterminant pulmonary nodules in routine clinical practice can result in improved sensitivity and earlier identification of malignant nodules. Its effect on recommendations for management of suspected malignant nodules is variable and may be influenced by reader experience.

CLINICAL RELEVANCE/APPLICATION

Adoption of volumetric analysis of solid indeterminant pulmonary nodules in routine CT clinical practice may allow more sensitive and earlier detection of cancers.

Will I Change Nodule Management Recommendations If I Change My CAD System: Volumetry of Artificial Pulmonary Nodules by Different CAD Systems

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - CH DPS

Participants
Alan Peters, MD, Bern, Switzerland (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate and compare the measurement accuracy of two different CAD systems regarding artificial pulmonary nodules and assess the clinical impact of volumetric inaccuracies in a phantom study.

METHODS AND MATERIALS

In this phantom study, 59 different phantom arrangements with 326 artificial nodules (178 solid, 148 ground-glass) were scanned at 80 kV, 100 kV and 120 kV. Four different nodule diameters were used: 5 mm, 8 mm, 10 mm and 12 mm. Scans were analyzed by a DL-based CAD and a standard CAD system. Relative volumetric errors (RVE) of each system vs. ground truth and the relative volume difference (RVD) DL-based vs. standard CAD were calculated. The Bland-Altman method was used to define the limits of agreement (LOA). The hypothetical impact on LungRADS classification was assessed for both systems.

RESULTS

There was no difference between the three voltage groups regarding nodule volumetry. Regarding the solid nodules, the RVE of the 5 mm, 8 mm, 10 mm and 12 mm size group for the DL-CAD/standard CAD were 12.2/2.8% 1.3/-2.8%, -3.6/1.5% and -12.2/-0.3%, respectively. The corresponding values for the GGN were 25.6%/81.0%, 9.0%/28.0%, 7.6/20.6% and 6.8/21.2%. The mean RVD for solid nodules/GGN was 1.3/-15.2%. Regarding the LungRADS classification, 88.5% and 79.8% of all solid nodules were correctly assigned by the DL-CAD and the standard CAD, respectively. 14.9% of the nodules were assigned differently between the systems.

CONCLUSION

s Patient management may be affected by volumetric inaccuracy of the CAD systems.

CLINICAL RELEVANCE/APPLICATION

The results of this study highlight that supervision and / or manual correction by a radiologist is pertinent when using a CAD system in daily clinical routine.

T5B-SPCH-5

A General Approach for Automatic Segmentation of Pneumonia Pulmonary Nodule and Tuberculosis on CT Images

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - CH DPS

Participants
Jiangdian Song, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

Accurate segmentation of lung lesions on CT images will inform clinical diagnosis of multiple lung diseases including COVID-19 pneumonia. As a common framework for image segmentation, generative adversarial network (GAN) is hampered by the limited annotated samples available and the catastrophic forgetting of the discriminator when used to segment diverse lung lesions on computed tomography (CT) images. Therefore, a general self-supervised adversarial learning architecture that does not require large amounts of labeled data and mitigates discriminator forgetting is proposed to segment lung lesions including pneumonia, lung nodules, and tuberculosis precisely and automatically on CT images.

METHODS AND MATERIALS

For the generator network of the proposed model, a cascaded dual attention network with a context-aware pyramid feature extraction module is designed to model multi-scale semantic interdependencies of lung lesions in both spatial and channel dimensions. Then, a self-supervised rotation loss is introduced into the model to avoid discriminator forgetting and to achieve more efficient lung lesion feature representation. Multi-center pneumonia, lung nodule, and tuberculosis CT images were used to test the proposed model. A state-of-the-art nnU-Net is employed to compare with the proposed model on lung lesion segmentation.

RESULTS

A total of 14,260, 14,266, and 3,361 images of pneumonia, lung nodule, and tuberculosis were used in this study, and the lesions was randomly divided into training, validation, and test datasets (8:1:1), respectively. Average dice coefficients (DCs) of 75.05%, 74.22%, and 71.58% for the three lesion types were obtained on the test dataset when using all the images. When the training dataset was reduced to 10%, DCs of 71.10%, 72.80%, and 69.43% were obtained on test datasets, respectively, and no significant decrease in DC was found ($P > 0.10$). In addition, no significant difference was found between the nnU-Net and the proposed model for segmentation ($P > 0.05$).

CONCLUSION

s Our study provided a self-supervised adversarial learning architecture to enable the use of limited training samples for accurately segmenting multiple types of lung lesions without the need for massive annotation sample. The proposed model achieved competitive segmentation result compared with the state-of-the-art segmentation network.

CLINICAL RELEVANCE/APPLICATION

A general automatic segmentation approach for COVID-19 pneumonia, lung nodule, and tuberculosis enables to reduce the redundant work of repeatedly model training. Our model enables the reduction of GAN's dependence on massive manually annotated training data and thus relieves radiologists from tedious manual delineation labor.

CT Radiomics-based Clustering in Lung Cancer: A Comparison with Comprehensive Genomic Profiling

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - CH DPS

Participants
Motohiko Yamazaki, MD, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

Comprehensive genomic profiling (CGP) is a new technology that can analyze hundreds of cancer genes at one assay and enables to determine the total number of gene mutations called tumor mutation burden (TMB). In lung cancer, driver gene mutations can be candidates for molecular targeted therapies, while a high TMB suggests good response to immune checkpoint inhibitors. This study aimed to compare CT radiomics-based clustering with CGP data and patient prognosis in lung cancer.

METHODS AND MATERIALS

This retrospective study comprised 93 patients with non-small cell lung cancer (66 adenocarcinomas and 27 squamous cell carcinomas) who underwent surgery. TMB and 415 cancer gene expression patterns were investigated in each surgical specimen by CGP using next-generation sequencing. All patients were classified into two clusters according to their radiomic features extracted from preoperative CT images using unsupervised k-means clustering. Differences between these two clusters were investigated with respect to gene mutations, TMB (low or high), recurrence-free survival, and visual CT features.

RESULTS

Unsupervised clustering classified 55 patients into Cluster 1 and 38 patients into Cluster 2 according to their radiomic features. Cluster 1 exhibited a significantly higher proportion of TP53 and CDKN2B gene mutations but a lower proportion of EGFR gene mutations compared with Cluster 2 (TP53 mutations, 34/55 [61.8%] vs 12/38 [31.6%]; CDKN2B mutations, 26/55 [47.3%] vs 10/38 [26.3%]; EGFR mutations, 13/55 [23.6%] vs 17/38 [44.7%]; all $P < 0.05$). A high TMB (= 20 mutations/megabase) was more frequently observed in Cluster 1 than in Cluster 2 (23/55 [41.8%] vs. 2/38 [5.3%]; $P < 0.01$). Recurrence-free survival at 5 years was significantly lower in Cluster 1 than in Cluster 2 (40.4% vs. 51.0%; $P = 0.038$). For visual CT features, Cluster 1 was more likely to indicate a lobulated margin but was less frequently accompanied by ground-glass opacity, air-bronchogram, cavity, and vacuole sign compared to Cluster 2 (all $P < 0.05$).

CONCLUSION

s CT radiomics-based clustering has significant association with CGP data as well as patient prognosis and may help predict genomic information in non-small cell lung cancer.

CLINICAL RELEVANCE/APPLICATION

CGP provides valuable information to determine therapeutic agents for lung cancer, leading to precision medicine. However, CGP is very expensive and requires invasive tissue sampling. Therefore, CT examination, which is non-invasive and relatively low costs, plays an important role in predicting genomic information. CT radiomics-based clustering created in this study could help predict CGP data.

Correlation Between Intra-nodular Vessel and Tumor Invasiveness of Lung Adenocarcinoma Presenting as Ground-glass Nodules: A Deep Learning 3D Reconstruction Algorithm-based Quantitative Analysis on Non-contrast CT Images

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - CH DPS

Participants
Baolian Zhao, (*Presenter*) Nothing to Disclose

PURPOSE

To quantitatively analyze the pulmonary vessels inside ground-glass nodules (GGNs) on non-contrast CT (NCCT) images using fully automated deep learning (DL) approach and investigate the relationship between intra-nodular vessel and tumor invasiveness.

METHODS AND MATERIALS

A total of 741 pathologically confirmed GGNs from 719 patients were retrospectively collected, comprising 121 atypical adenomatous hyperplasia (AAH), 150 adenocarcinoma in situ (AIS), 154 minimally invasive adenocarcinoma (MIA) and 316 invasive adenocarcinoma (IAC). The pulmonary blood vessels were reconstructed on NCCT images using DL-based region segmentation and region growth technology (InferVisual Surgery Planning Research version). The presence of pulmonary vessels inside GGNs was quantitatively evaluated with respect to intra-nodular vessel prevalence and the automatedly calculated vessel volume percentage, which were further compared across different invasiveness categories by the Chi-square test, analysis of variance (ANOVA) and Mann-Whitney U test.

RESULTS

The automated DL algorithm showed high accuracy in vessels detection and reconstruction. There were significant differences in the occurrences of internal vessels across different tumor invasiveness GGNs ($p < 0.001$). The prevalence of intra-nodular vessels in IAC (66.5%) was significantly higher than that of AAH (35.5%, $p < 0.001$), AIS (33.3%, $p < 0.001$) and MIA (50.6%, $p = 0.001$), while the vascular categories were similar (all $p > 0.05$). Vascular changes were more common in invasive lesions (MIA and IAC) than pre-invasive lesions (AAH and AIS), which mainly manifested as increased vessel volume percentage (10.23% vs 3.85%, $p < 0.001$). The average vessel volume percentage of IAC (12.01%) was also higher compared with that of AAH (3.85%), AIS (3.86%) and MIA (6.57%) with statistically significance (all $p < 0.001$).

CONCLUSION

s The quantitative analysis of intra-nodular vessels on NCCT images demonstrated that the incidence of internal vessels in GGNs was related to their pathological invasiveness. GGNs with increased internal vessel percentages had higher possibility of tumor invasiveness.

CLINICAL RELEVANCE/APPLICATION

Our deep learning-based quantitative analysis on NCCT images reveals that the incidence and volume percentage of intra-tumoral vessels in GGNs are correlated with pathological invasiveness.

T5B-SPCH-8

Cascade-network to Reduce False Positives for Pulmonary Nodule Detection on Chest X-ray Radiographs

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - CH DPS

Participants
Taehee Kim, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Recently, many deep learning-based nodule detection algorithms for chest X-ray radiographs (CXRs) have reported promising results. In real clinical environment, however, those algorithms have been reported to produce many false positives (FPs) caused by the similarity between hard negatives (e.g., nipple shadow, bone island, superimposed pulmonary vessels, etc.) and real nodules. Here, we propose a cascade-network to reduce these FPs in nodule detection.

METHODS AND MATERIALS

NODE21 challenge dataset (node21.grand-challenge.org) was utilized (training: 934/2404; validation: 100/300; testing: 100/300 for nodule/non-nodule CXRs). For each CXR in the training dataset, a set of multi-resolution patches (resolution: 112x112, 280x280, and 448x448) were generated. Three multi-resolution patches were resized to 112x112 and concatenated along the channel for training. Patches were classified as positive (i.e., nodule patches) when a nodule locates on the center of the patch. For nodule detection, two neural networks were used sequentially where first network was to detect nodule candidates on an input CXR, and the second network was to further screen out hard negatives. Both networks had same architecture (EfficientNet-B0) and trained based on multi-resolution patches. The output of the two networks was the probability of nodule for the input patch. The difference between the networks was the composition of training dataset. For first network, all negative patches for training were the patches with no nodule (i.e., non-nodule patches). In second network, half of negative patches for training were carefully selected among the false positive outputs in the training data of first network to design second network more sensitive to the hard negatives. The detection performances were measured based on the area under the Free-Response Receiver Operating Characteristics (FAUC) and Refined Competition Performance Metric (R-CPM). Comparison was performed before and after ablating second network.

RESULTS

The nodule detection performances of the cascade-network (FAUC:0.6033(95% CI: 0.5848-0.6217), R-CPM:0.5995(0.5778-0.6211)) outperformed those of the first network only (FAUC:0.4987(0.4667-0.5308), $p<0.001$, R-CPM:0.4967(0.4649-0.5285), $p<0.001$). When visually investigated, the outputs from the cascade-network showed a much smaller number of FPs.

CONCLUSION

s In this study, we proposed a cascade-network for nodule detection to reduce FPs, dramatically improving nodule detection performance.

CLINICAL RELEVANCE/APPLICATION

The proposed cascade-network with sequential training scheme would enable development of a nodule detection algorithm with high positive predictive value efficiently by using network-driven hard negatives.

T5B-SPCH-9

Implications of Radiologist-interpreted Subjective Standards for Evaluating the Diagnostic Performance of a Deep Learning Model: A Malignant Lung Nodule Detection Task on Chest Radiographs

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - CH DPS

Participants
Jung Eun Huh, BA, Oxford, United Kingdom (*Presenter*) Nothing to Disclose

PURPOSE

Little is known regarding the impact of radiologist-interpreted subjective standards as ground truth when evaluating the performance of deep learning (DL) models and their added value to radiologists. We assessed the adherence of the subjective standards to the reference standard, and the difference in diagnostic performance measurements of radiologists with and without a DL-based automatic detection (DLAD) model according to the standard used to detect malignant pulmonary nodules on chest radiographs.

METHODS AND MATERIALS

This study included 50 patients with pathology- and CT-proven lung cancers (reference standards) with 50 chest radiographs between December 2015 and February 2021, and 50 control individuals with normal chest radiographs. Five subjective standards were constructed using 10 radiologists' interpretations and compared: individual judgment by the most experienced radiologist, majority vote, consensus judgments of 2 and 3 radiologists, and a latent class analysis (LCA) model. In separate reader tests, 10 other radiologists (who did not participate in constructing the subjective standards) interpreted the radiographs with and without the DLAD model, and their diagnostic performance was compared between the reference standard and the five subjective standards. The t-test with the Bonferroni correction was used to compare adherence and diagnostic performance.

RESULTS

The LCA model, which showed a sensitivity of 72.6% and a specificity of 100%, adhered more closely to the reference standard than any of the other subjective standards. In the reader tests, both the radiologists and the DLAD model tended to show overestimated sensitivity but underestimated specificity when the subjective standards were applied as the ground truths. However, these radiologists' tendencies were diminished by DLAD assistance (all P-values <0.001). Although using the DLAD improved the sensitivity and specificity (in some cases) when the subjective standards were used, the corresponding effects were estimated to be significantly smaller than when the reference standard was used (all P-values <0.001), except for sensitivity with the LCA model (P=0.094).

CONCLUSION

s The LCA model showed the closest adherence to the reference standard for detecting malignant pulmonary nodules on chest radiographs. Radiologists' sensitivity and specificity values were overestimated and underestimated, respectively, and the DLAD added less value with the subjective standards than with the reference standard.

CLINICAL RELEVANCE/APPLICATION

Since using only subjective standards can lead to bias in the diagnostic performance of DL models, evaluating DL models with a reference standard is necessary even in underserved settings.

T5B-SPER-1 Brain Hemorrhage and ECMO therapy in Patients with Severe COVID-19-Disease: A Systematic Multicenter Review (First Insights into the COVID-ECMO trial)

Participants
Philipp Josef Kuhl, MD, Wuerzburg, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To systematically evaluate the incidence of intracranial hemorrhage (ICH) associated with ECMO therapy in patients with COVID-19.

METHODS AND MATERIALS

Every COVID-19 patient admitted to intensive care unit (ICU) at 4 major German university hospitals throughout the course of the pandemic (03/2020 to 03/2022) who received a CT scan of the brain during hospitalization was retrospectively analyzed. Each scan was assessed for the presence of ICH. The most significant scan per patient was included for further analysis, usually at first occurrence of ICH. Patients with recent head trauma or preexisting ICH were excluded. On site, cerebral bleeding was rated for severity and predominant distribution type using a standardized set of specifications. Outcome, demographics, clinical data and time points of different events (e.g. admission to ICU, start of ECMO therapy) were obtained from patient records. The anonymized data sets were sent to the study center for statistical analysis.

RESULTS

In the university hospitals surveyed, 831 patients on ICU with COVID-19 underwent at least one CT scan of the brain (f=292, m=539, mean age 57.4±10.1 years). Nearly half of these patients (46,7%) received ECMO therapy (f=106, m=282; age 53.3±6,3 y). During or after ECMO, 89 patients (22,9%) sustained ICH, the vast majority of which was fatal (84,3%, n=75). Intraparenchymal hemorrhage was the most frequent predominant distribution type (41,6%), followed by subarachnoidal bleeding (38,2%).In patients who did not receive ECMO therapy, the occurrence of ICH was significantly lower (12.9% vs. 22.9%; $p<0.01$). Additionally, bleeding events showed a significantly lower mortality rate (45,6% vs. 84,3%; $p<0.001$).

CONCLUSION

s In non-COVID patients, brain hemorrhage is the most severe complication of ECMO therapy, associated with high mortality rates of up to 73%.COVID-19 associated coagulopathy combined with therapeutic anticoagulation required for ECMO therapy predispose patients to an increased risk of bleeding, yet recent studies reported a wide range of ECMO-associated ICH rates varying from 3.5% to 35.4%, leaving the true risk rates further unknown. This study provides strong evidence for the incidence of intracranial hemorrhage associated to ECMO therapy being near 22% due to its systematic and multicentric approach. In addition, the assessed mortality rates demonstrate the severity of ICH as a side effect of ECMO therapy.With proceeding data collection by additional participating centers in Germany, we expect these results to further consolidate, allowing the calculation of various risk models that will support clinical decision making.

CLINICAL RELEVANCE/APPLICATION

These first study results can already support clinical decision making regarding ECMO therapy.

T5B-SPGI-1 LI-RADS Treatment Response versus Modified RECIST for Diagnosing Viable Hepatocellular Carcinoma after Locoregional Therapy: A Systematic Review and Meta-Analysis of Comparative Studies

Participants
Sungmok Kim, Suwon-Si, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

We aimed to systematically compare the performance of Liver Imaging Reporting and Data Systems Treatment Response (LR-TR) with the modified Response Evaluation Criteria in Solid Tumors (mRECIST) for diagnosing viable hepatocellular carcinoma (HCC) treated with locoregional therapy (LRT).

METHODS AND MATERIALS

Original studies of intra-individual comparisons between the diagnostic performance of LR-TR and mRECIST using dynamic contrast-enhanced CT or MRI were searched in MEDLINE and EMBASE up to August 25, 2021. The reference standard for tumor viability was surgical pathology. The meta-analytic pooled sensitivity and specificity of the viable category using each criterion were calculated using a bivariate random-effects model and compared using bivariate meta-regression. Heterogeneity was evaluated using Higgins inconsistency index (I2) test or Cochran Q test. Subgroup meta-regression analysis was performed to investigate the causes of heterogeneity between studies. Publication bias was evaluated by visual assessment of funnel plot and Deeks' asymmetry test.

RESULTS

For five eligible studies (430 patients with 631 treated observations), the pooled per-lesion sensitivities and specificities were 58% (95% confidence interval [CI], 45-70%; I2, 77%; Cochran Q test, P<0.1) and 93% (95% CI, 88-96%; I2, 0%; Cochran Q test, P=0.51) for the LR-TR viable category and 56% (95% CI, 42-69%; I2, 74%; Cochran Q test, P<0.1) and 86% (95% CI, 72-94%; I2, 82%; Cochran Q test, P<0.1) for the mRECIST viable category. The LR-TR viable category provided significantly higher pooled specificity (P<0.01) than mRECIST but comparable pooled sensitivity (P=0.53). Meta-regression analysis revealed that type of LRT and the most common etiology of liver disease were significantly associated with the study heterogeneity for the mRECIST viable category (P=0.01). There was no significant publication bias across the studies for both criteria (P=0.35).

CONCLUSION

s LR-TR algorithm demonstrated better specificity than mRECIST without significant difference in sensitivity for the diagnosis of pathologically viable HCC after LRT.

CLINICAL RELEVANCE/APPLICATION

The specificity of the viable category for the diagnosis of pathologically viable HCC was significantly higher when applying LR-TR than mRECIST, but the sensitivity was comparable.

T5B-SPGI-10 MRI Correlation with Liver Explant Pathology: Routine Clinical Care vs. Expert Reader Using the LIRADS Treatment Response Algorithm in Assessing Residual HCC After Y-90 Therapy

Participants
Matthew Harwood, MD, Phoenix, AZ (*Presenter*) Nothing to Disclose

PURPOSE

The Liver Imaging Reporting and Data System treatment response algorithm (LIRADS-TRA) criteria can be used to predict HCC response to locoregional therapy, however, radiation-based methods such as transarterial radioembolization (TARE) with yttrium-90 have unique post-treatment features that can confound assessment. Prior studies used survival and/or time to progression as the primary endpoints after Y90. Few studies use pathology as the reference standard. This study compares an expert reader's blinded MRI or CT interpretation applying the LIRADS-TRA against interpretations obtained during routine clinical care.

METHODS AND MATERIALS

An IRB exemption was obtained. We identified adult patients (age range 37-72 years) who underwent liver explant after Y90 treatment for HCC (pre-treatment LR-5, OPTN5a/b, or biopsy proven HCC) then subsequently underwent liver transplant (dates of transplant between 10/2015 and 10/2021). Of the 96 patients identified, 27 were excluded because at least 90 days had not elapsed between treatment and MRI/CT, or because multiple treatments were employed. Ultimately, 25 patients with at least 1

treated HCC comprised the cohort. Most patients had MRIs before transplant (23/25), the rest multiphasic CTs (2/25). Mean MELD scores at transplant for this cohort was 13 ±5 (mean ±SD). The most common etiologies of cirrhosis were hepatitis C (40%), alcohol (24%), and NASH (20%). Mean time between treatment and MRI or CT was 164 ±89 days (mean ±SD).A fellowship-trained, board-certified abdominal radiologist with >20 years of experience blinded to the presence or absence of residual viable tumor in liver explant specimens independently reviewed the pre- and post-treatment exams. When two or more tumors were present or treated, the dominant treated lesion was evaluated. The LIRADS-TRA was strictly adhered to, wherein only 6 of 25 (24%) clinical reports explicitly used the LIRADS-TRA. LR-TR viable and LR-TR equivocal were considered positive. LR-TR nonviable was considered negative.

RESULTS

The clinical assessment and expert reader had fair agreement (?=0.29). Both "readers" had an accuracy of 60%. +LR for TRA: 2.3 (95%CI 0.55-9.7). -LR: 0.74 (0.45-1.2) . In a separate analysis, successful tumor debulking (90% or greater tumor necrosis) was also considered as a binary outcome.

CONCLUSION

s Adherence to the LIRADS-TRA did not improve accuracy or test performance as expected. Previous authors evaluating liver resection pathology after Y90 showed higher accuracy. However, their post-treatment imaging time frame was not defined, whereas this study focused on the 6-month post-treatment exam.

CLINICAL RELEVANCE/APPLICATION

To know the accuracy of our major CT and MRI criteria for assessing HCC treatment response, the LIRADS-TRA.

T5B-SPGI-3 Diagnostic Performance of LI-RADS v2018 Versus KLCA-NCC 2018 Criteria for Hepatocellular Carcinoma Using Magmetic Resonance Imaging: A Systematic Review and Meta-Analysis of Comparative Studies

Participants
Jaeseung Shin, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

We performed a meta-analysis to compare the performance of the Liver Imaging Reporting and Data System (LI-RADS) v2018 and Korean Liver Cancer Association-National Cancer Center (KLCA-NCC) 2018 criteria for diagnosing hepatocellular carcinoma (HCC) using magnetic resonance imaging (MRI).

METHODS AND MATERIALS

We searched the MEDLINE and EMBASE databases for studies published from January 1, 2018, to October 20, 2021, that compared the diagnostic performance of LR-5 of LI-RADS v2018 and definite HCC category of KLCA-NCC 2018 on MRI. Bivariate random-effects model was fitted to calculate the pooled per-observation sensitivity and specificity of both imaging criteria and compared the pooled estimates of paired data. Subgroup analysis was performed based on the observation size. Meta-regression analysis was performed to identify factors for study heterogeneity.

RESULTS

Of the six studies included (2,109 observations and 1,471 HCCs), the pooled sensitivity of the definite HCC category of KLCA-NCC criteria (81%; 95% confidence interval [CI], 73-90%; I2=86%) was higher than that of LR-5 of LI-RADS v2018 (65%; 95% CI, 53-78%; I2=96%) for diagnosing HCC (P<0.001), while the specificity was lower for KLCA-NCC 2018 (88%; 95% CI, 84-91%; I2=13%) than for LI-RADS v2018 (93%; 95% CI, 91-96%; I2=0%) (P=0.018). For observations sized =20 mm, sensitivity was higher for KLCA-NCC 2018 than for LI-RADS v2018 (83% versus 75%; P=0.017), with no significant difference in specificity (82% versus 86%; P=0.463). Meta-regression analyses revealed reference standard as a significant factor contributing to the heterogeneity of sensitivities.

CONCLUSION

s The definite HCC category of KLCA-NCC 2018 provided a higher pooled sensitivity and lower pooled specificity than the LR-5 of LI-RADS v2018 for diagnosing HCC using MRI.

CLINICAL RELEVANCE/APPLICATION

Compared with LI-RADS v2018, KLCA-NCC 2018 criteria might be preferred where sensitive diagnosis is demanded for earlier locoregional treatment (i.e. East Asia).

T5B-SPGI-4 Preoperative prediction of microvascular invasion in hepatocellular carcinoma based on three-phase contrast-enhanced CT images of the tumor and peritumoral regions

Participants
Xiaofei Yue, (*Presenter*) Nothing to Disclose

PURPOSE

To establish a clinical-radiomics nomogram for preoperative prediction of microvascular invasion (MVI) of hepatocellular carcinoma (HCC) and compare the diagnostic value of different tumor regions and phases for the MVI status in a non-invasive way.

METHODS AND MATERIALS

335 HCC patients (161 MVI-negative and 174 MVI-positive) who underwent three-phase contrast-enhanced CT before surgery were enrolled from May 2017 to July 2020. Regions of interest (ROI) of the tumor, peritumor(10mm), and tumor-peritumor(10mm) were manually segmented in the arterial phase (AP) and portal venous phase (PVP), and delayed phase (DP) images. A total of nine groups of ROIs were obtained, and 1218 radiomics features were extracted, respectively. Patients were randomly assigned to the training and inter-validation cohorts in a ratio of 7:3. The Analysis of Variance and least absolute shrinkage and selection operator (LASSO) algorithms with ten-fold cross validation were used to select radiomics features. Nine radiomics scores (Rad-Score) were established using multivariate logistic regression analysis. In addition, we combined the nine Rad-Scores with 18 clinical factors and

23 radiographic scores to construct a clinical-radiomics nomogram with multivariate logistic regression. Furthermore, all radiomics models and the combined clinical-radiomics model were independently validated with the data of the hospital's sub-campus (40 patients). ROC curves were used to compare the predictive power of the multiple models. Decision curve analysis (DCA) was used to compare the clinical benefit of the models.

RESULTS

Among the nine Rad-Scores, the tumor-peritumor in the AP cohort had the best predictive ability (AUCs of 0.912, 0.848, and 0.880 for the training cohort, inter-validation cohort, and independent validation cohort, respectively). The predicted values of the clinical model of AUCs were 0.775, 0.742, and 0.696 in the training cohort, inter-validation cohort, and independent validation cohort, respectively. The combined clinical-radiomics model performs well (AUCs for the training, inter-validation and independent validation cohorts are 0.938, 0.883, and 0.829). DCA demonstrated the highest clinical benefit in the combined clinical-radiomics model.

CONCLUSION

s The clinical-radiomics model has satisfactory results in preoperative prediction of MVI in patients with HCC and has potential value in guiding clinicians to individualize treatment.

CLINICAL RELEVANCE/APPLICATION

MVI of HCC usually indicates an increased risk of recurrence and a poor prognosis. The clinical-radiomics model can predict MVI preoperatively and has potential value in guiding clinicians to individualize treatment.

T5B-SPGI-5 Abbreviated MRI for secondary surveillance of recurrent hepatocellular carcinoma after curative treatment

Participants
Dong Ho Lee, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

There is no consensus regarding the ideal imaging modality of secondary surveillance of hepatocellular carcinoma (HCC). This study aimed to evaluate the detection performance of abbreviated MRI (AMRI) for secondary surveillance for HCC after curative treatment including surgical resection or radiofrequency ablation (RFA).

METHODS AND MATERIALS

This retrospective study analyzed 243 patients who received secondary surveillance for HCC using gadoxetic acid-enhanced MRI after more than two-year of disease-free period from curative treatment including surgical resection or RFA. Non-contrast AMRI (NC-AMRI) (T2-weighted and diffusion-weighted images), hepatobiliary phase AMRI (HBP-AMRI) (T2-weigted, diffusion-weighted and HBP images), and full-sequence MRI sets were independently reviewed by two abdominal radiologists. The confirmation of HCC was based either on histopathological confirmation or imaging-based diagnosis. HCC detection rate of each set was compared.

RESULTS

A total of 42 recurred HCCs were confirmed in 39 patients. Per-lesion and per-patient sensitivities didn’t show significant difference among three image sets in both reviewers (P=0.681): Per-lesion sensitivity: 81.1?83.3%, 76.2?85.7%, and 81.0?83.3% for NC-AMRI, HBP-AMRI, and full-sequence MRI, respectively; and per-patient sensitivity: 79.5?83.3%, 79.5?85.7%, and 79.5?83.3% for NC-AMRI, HBP-AMRI, and full-sequence MRI. Per-patient specificity didn’t show significant difference among three image set in both reviewers (95.6?97.1%, 96.1?97.1%, and 97.6?98.5% for NC-AMRI, HBP-AMRI, respectively; P=0.307).

CONCLUSION

s NC-AMRI and HBP-AMRI had comparable detection performance to that of full-sequence gadoxetic acid-enhanced MRI during secondary surveillance for HCC after more than 2-year disease free interval following curative treatment. Based on its good detection performance, short scan times, and the lack of contrast agent-associated risks, NC-AMRI would be a promising option for secondary surveillance of HCC.

CLINICAL RELEVANCE/APPLICATION

NC-AMRI would be a promising option for secondary surveillance for HCC after 2-year disease free interval following curative treatment including surgical resection and RFA.

T5B-SPGI-6 Preoperative prediction of microvascular invasion in hepatocellular carcinoma using computation modeling of interstitial fluid pressure and velocity

Participants
Liyun Zheng, Shanghai, China (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of present study was to develop and validate a new method for the interstitial fluid pressure (IFP) measurement in hepatocellular carcinoma (HCC) patients. We also aimed to depict the microenvironment of the tumor of HCC and predict the microvascular invasion (MVI) status preoperatively and noninvasively by this IFP model.

METHODS AND MATERIALS

A cohort of 27 patients were finally included in this study (mean age 57.6 ± 10.9 years, 77.8% males). There were 15 patients in the MVI-positive group and 12 patients in the MVI-negative group. MRI examinations were performed using a 3T scanner (uMR790, United Imaging Healthcare). DCE-MRI scan sequence utilized a transverse T1-weighted spoiled GRE sequence to obtain acquisition, and 60 time points were acquired with mean temporal resolution of 3.1 s and a total acquisition time of ~3 min. Patients were allowed to breathe freely. The extended tofts model (ETM) was used to estimate the permeability parameters. Volume of Interest (VOI) for Ktrans estimation were manually delineated on the tumor lesion present in all slices in the late phases of T1-weighted DCE-MRI images. The tumor volume was calculated from the T1w dynamic images. The continuity partial differential equation (PDE) was implemented and the estimation of of IFP and interstitial fluid velocity (IFV) were acquired. Mann-Whitney U test was performed to compare the mean IFP and mean IFV between MVI-positive group and MVI-negative group. The receiver operating characteristic (ROC) analysis was performed for differentiation between MVI-positive group and MVI-negative group. The Youden

index were exploited to determine the cutoff value, along with the area under the curve (AUC), sensitivity and specificity. P < 0.05 was considered statistically significant.

RESULTS

Significant difference was found in mean IFP between the MVI-positive group and MVI-negative group (P = 0.001), while there was no statistically differences in mean IFV between the two groups (P = 0.626). For the ROC analysis, mean IFP value proved to be the significant predictor with the best cut-off value 1854.22 Pa (AUC = 0.883, 95% confidence interval 0.701 to 0.974; sensitivity = 80.0%, specificity = 91.7%).

CONCLUSION

s The non-invasive interstitial fluid pressure (IFP) measurement model in liver tumors was developed. Significant difference was found in mean IFP between the MVI-positive group and MVI-negative group. IFP could be the significant predictor in the prediction of MVI status.

CLINICAL RELEVANCE/APPLICATION

This study developed a new method for the noninvasive IFP measurement in HCC patients. Our results revealed that MVI status can be predicted by this IFP model preoperatively.

T5B-SPGI-8 LI-RADS Category 4 Observations on Gadoxetic Acid-Enhanced MRI: Can Imaging Features Indicate High Risk of Early Progression (<6 Months) To LI-RADS Category 5?

Participants
Ijin Joo, MD, Seoul, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the value of gadoxetic acid-enhanced MRI (Gd-EOB-MRI) features of LI-RADS category 4 (LR-4: probably hepatocellular carcinoma [HCC]) observations for predicting early progression to LR-5 (definitely HCC)

METHODS AND MATERIALS

This retrospective study included liver observations in patients at high risk for HCC, assigned as LR-4 on index Gd-EOB-MRI and had available short-term (<6 months) follow-up Gd-EOB-MRI. For each observation, LI-RADS major and ancillary features on index MRI and final LI-RADS category on follow-up MRI were assessed by a consensus of three radiologists. Multivariate logistic regression analysis was performed to identify imaging predictors for early (<6 months) progression to LR-5. Diagnostic performances of each significant imaging feature and their combinations for identifying LR-4 observations with higher risk of early category progression were evaluated.

RESULTS

Among 101 index LR-4 observations in 101 patients, 57 progressed to LR-5, while the other 44 remained stable as LR-4 within 6 months. Multivariate logistic regression analysis revealed that nonrim arterial phase hyperenhancement (APHE), nonperipheral "washout", restricted diffusion, and fat in mass at index MRI were independent predictors for early category progression (odds ratio = 3.75, 3.17, 5.36, 12.2; P = 0.037, 0.036, 0.003, 0.030, respectively). For predicting the early category progression, nonrim APHE showed the highest sensitivity (47/57, 82.5%) followed by restricted diffusion (39/57, 68.4%), nonperipheral "washout" (27/57, 47.4%), and fat in mass (8/57, 14.0%); while the highest specificity was found in fat in mass (43/44, 97.7%) followed by restricted diffusion (33/44, 75.0%), nonperipheral "washout" (31/44, 70.5%), and nonrim APHE (17/44, 38.6%). When two or more of four imaging features listed above were present, the sensitivity was 82.5% (47/57) and the specificity was 61.4% (27/44).

CONCLUSION

s LI-RADS major and ancillary features on Gd-EOB-MRI can help identify LR-4 observations with higher risk of early category progression to LR-5.

CLINICAL RELEVANCE/APPLICATION

In LI-RADS category 4 observations, MRI-based risk stratification according to the probability of early category progression could potentially facilitate appropriate and timely management.

T5B-SPGI-9 Diagnostic Performance of CT versus MRI Liver Imaging Reporting and Data System Category 5 for Hepatocellular Carcinoma: A Systematic Review and Meta-Analysis of Comparative Studies

Participants
Sunyoung Lee, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To compare the performance of Liver Imaging Reporting and Data System category 5 (LR-5) for diagnosing HCC between CT and MRI using comparative studies.

METHODS AND MATERIALS

The MEDLINE and EMBASE databases were searched from inception to April 21, 2021, to identify studies that directly compare the diagnostic performance of LR-5 for HCC between CT and MRI. Bivariate random-effects model was fitted to calculate the pooled per-observation sensitivity and specificity of LR-5 of each modality, and compare the pooled estimates of paired data. Subgroup analysis was performed according to MRI contrast agent.

RESULTS

Seven studies with 1,145 observations (725 HCCs) were included in the final analysis. The pooled per-observation sensitivity of LR-5 for diagnosing HCC was higher using MRI (61%; 95% confidence interval [CI], 43-76%; I2 = 95%) than CT (48%; 95% CI, 31-65%; I2 = 97%) (P < 0.001). The pooled per-observation specificities of LR-5 did not show statistically significant difference between CT (96%; 95% CI, 92-98%; I2 = 0%) and MRI (93%; 95% CI, 88-96%; I2 = 16%) (P = 0.054). In the subgroup analysis, extracellular contrast agent-enhanced MRI showed significantly higher pooled per-observation sensitivity than gadoxetic acid-

enhanced MRI for diagnosing HCC (73% [95% CI, 55%-85%] vs. 55% [95% CI, 39%-70%]; P = 0.007), without a significant difference in specificity (93% [95% CI, 80%-98%] vs. 94% [95% CI, 87%-97%]; P = 0.884).

CONCLUSION

s The LR-5 of MRI showed significantly higher pooled per-observation sensitivity than CT for diagnosing HCC. The pooled per-observation specificities of LR-5 were comparable between the two modalities.

CLINICAL RELEVANCE/APPLICATION

Although LI-RADS provides a common diagnostic algorithm for CT or MRI, the per-observation performance of LR-5 can be affected by the imaging modality as well as the MRI contrast agent.

LI-RADS Treatment Response versus Modified RECIST for Diagnosing Viable Hepatocellular Carcinoma after Locoregional Therapy: A Systematic Review and Meta-Analysis of Comparative Studies

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - GI DPS

Participants
Sungmok Kim, Suwon-Si, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

We aimed to systematically compare the performance of Liver Imaging Reporting and Data Systems Treatment Response (LR-TR) with the modified Response Evaluation Criteria in Solid Tumors (mRECIST) for diagnosing viable hepatocellular carcinoma (HCC) treated with locoregional therapy (LRT).

METHODS AND MATERIALS

Original studies of intra-individual comparisons between the diagnostic performance of LR-TR and mRECIST using dynamic contrast-enhanced CT or MRI were searched in MEDLINE and EMBASE up to August 25, 2021. The reference standard for tumor viability was surgical pathology. The meta-analytic pooled sensitivity and specificity of the viable category using each criterion were calculated using a bivariate random-effects model and compared using bivariate meta-regression. Heterogeneity was evaluated using Higgins inconsistency index (I2) test or Cochran Q test. Subgroup meta-regression analysis was performed to investigate the causes of heterogeneity between studies. Publication bias was evaluated by visual assessment of funnel plot and Deeks' asymmetry test.

RESULTS

For five eligible studies (430 patients with 631 treated observations), the pooled per-lesion sensitivities and specificities were 58% (95% confidence interval [CI], 45-70%; I2, 77%; Cochran Q test, P<0.1) and 93% (95% CI, 88-96%; I2, 0%; Cochran Q test, P=0.51) for the LR-TR viable category and 56% (95% CI, 42-69%; I2, 74%; Cochran Q test, P<0.1) and 86% (95% CI, 72-94%; I2, 82%; Cochran Q test, P<0.1) for the mRECIST viable category. The LR-TR viable category provided significantly higher pooled specificity (P<0.01) than mRECIST but comparable pooled sensitivity (P=0.53). Meta-regression analysis revealed that type of LRT and the most common etiology of liver disease were significantly associated with the study heterogeneity for the mRECIST viable category (P=0.01). There was no significant publication bias across the studies for both criteria (P=0.35).

CONCLUSION

s LR-TR algorithm demonstrated better specificity than mRECIST without significant difference in sensitivity for the diagnosis of pathologically viable HCC after LRT.

CLINICAL RELEVANCE/APPLICATION

The specificity of the viable category for the diagnosis of pathologically viable HCC was significantly higher when applying LR-TR than mRECIST, but the sensitivity was comparable.

MRI Correlation with Liver Explant Pathology: Routine Clinical Care vs. Expert Reader Using the LIRADS Treatment Response Algorithm in Assessing Residual HCC After Y-90 Therapy

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - GI DPS

Participants
Matthew Harwood, MD, Phoenix, AZ (*Presenter*) Nothing to Disclose

PURPOSE

The Liver Imaging Reporting and Data System treatment response algorithm (LIRADS-TRA) criteria can be used to predict HCC response to locoregional therapy, however, radiation-based methods such as transarterial radioembolization (TARE) with yttrium-90 have unique post-treatment features that can confound assessment. Prior studies used survival and/or time to progression as the primary endpoints after Y90. Few studies use pathology as the reference standard. This study compares an expert reader's blinded MRI or CT interpretation applying the LIRADS-TRA against interpretations obtained during routine clinical care.

METHODS AND MATERIALS

An IRB exemption was obtained. We identified adult patients (age range 37-72 years) who underwent liver explant after Y90 treatment for HCC (pre-treatment LR-5, OPTN5a/b, or biopsy proven HCC) then subsequently underwent liver transplant (dates of transplant between 10/2015 and 10/2021). Of the 96 patients identified, 27 were excluded because at least 90 days had not elapsed between treatment and MRI/CT, or because multiple treatments were employed. Ultimately, 25 patients with at least 1 treated HCC comprised the cohort. Most patients had MRIs before transplant (23/25), the rest multiphasic CTs (2/25). Mean MELD scores at transplant for this cohort was 13 ±5 (mean ±SD). The most common etiologies of cirrhosis were hepatitis C (40%), alcohol (24%), and NASH (20%). Mean time between treatment and MRI or CT was 164 ±89 days (mean ±SD).A fellowship-trained, board-certified abdominal radiologist with >20 years of experience blinded to the presence or absence of residual viable tumor in liver explant specimens independently reviewed the pre- and post-treatment exams. When two or more tumors were present or treated, the dominant treated lesion was evaluated. The LIRADS-TRA was strictly adhered to, wherein only 6 of 25 (24%) clinical reports explicitly used the LIRADS-TRA. LR-TR viable and LR-TR equivocal were considered positive. LR-TR nonviable was considered negative.

RESULTS

The clinical assessment and expert reader had fair agreement (?=0.29). Both "readers" had an accuracy of 60%. +LR for TRA: 2.3 (95%CI 0.55-9.7). -LR: 0.74 (0.45-1.2) . In a separate analysis, successful tumor debulking (90% or greater tumor necrosis) was also considered as a binary outcome.

CONCLUSION

s Adherence to the LIRADS-TRA did not improve accuracy or test performance as expected. Previous authors evaluating liver resection pathology after Y90 showed higher accuracy. However, their post-treatment imaging time frame was not defined, whereas this study focused on the 6-month post-treatment exam.

CLINICAL RELEVANCE/APPLICATION

To know the accuracy of our major CT and MRI criteria for assessing HCC treatment response, the LIRADS-TRA.

Diagnostic Performance of LI-RADS v2018 Versus KLCA-NCC 2018 Criteria for Hepatocellular Carcinoma Using Magmetic Resonance Imaging: A Systematic Review and Meta-Analysis of Comparative Studies

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - GI DPS

Participants
Jaeseung Shin, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

We performed a meta-analysis to compare the performance of the Liver Imaging Reporting and Data System (LI-RADS) v2018 and Korean Liver Cancer Association-National Cancer Center (KLCA-NCC) 2018 criteria for diagnosing hepatocellular carcinoma (HCC) using magnetic resonance imaging (MRI).

METHODS AND MATERIALS

We searched the MEDLINE and EMBASE databases for studies published from January 1, 2018, to October 20, 2021, that compared the diagnostic performance of LR-5 of LI-RADS v2018 and definite HCC category of KLCA-NCC 2018 on MRI. Bivariate random-effects model was fitted to calculate the pooled per-observation sensitivity and specificity of both imaging criteria and compared the pooled estimates of paired data. Subgroup analysis was performed based on the observation size. Meta-regression analysis was performed to identify factors for study heterogeneity.

RESULTS

Of the six studies included (2,109 observations and 1,471 HCCs), the pooled sensitivity of the definite HCC category of KLCA-NCC criteria (81%; 95% confidence interval [CI], 73-90%; I2=86%) was higher than that of LR-5 of LI-RADS v2018 (65%; 95% CI, 53-78%; I2=96%) for diagnosing HCC (P<0.001), while the specificity was lower for KLCA-NCC 2018 (88%; 95% CI, 84-91%; I2=13%) than for LI-RADS v2018 (93%; 95% CI, 91-96%; I2=0%) (P=0.018). For observations sized =20 mm, sensitivity was higher for KLCA-NCC 2018 than for LI-RADS v2018 (83% versus 75%; P=0.017), with no significant difference in specificity (82% versus 86%; P=0.463). Meta-regression analyses revealed reference standard as a significant factor contributing to the heterogeneity of sensitivities.

CONCLUSION

s The definite HCC category of KLCA-NCC 2018 provided a higher pooled sensitivity and lower pooled specificity than the LR-5 of LI-RADS v2018 for diagnosing HCC using MRI.

CLINICAL RELEVANCE/APPLICATION

Compared with LI-RADS v2018, KLCA-NCC 2018 criteria might be preferred where sensitive diagnosis is demanded for earlier locoregional treatment (i.e. East Asia).

T5B-SPGI-4

Preoperative prediction of microvascular invasion in hepatocellular carcinoma based on three-phase contrast-enhanced CT images of the tumor and peritumoral regions

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - GI DPS

Participants
Xiaofei Yue, (*Presenter*) Nothing to Disclose

PURPOSE

To establish a clinical-radiomics nomogram for preoperative prediction of microvascular invasion (MVI) of hepatocellular carcinoma (HCC) and compare the diagnostic value of different tumor regions and phases for the MVI status in a non-invasive way.

METHODS AND MATERIALS

335 HCC patients (161 MVI-negative and 174 MVI-positive) who underwent three-phase contrast-enhanced CT before surgery were enrolled from May 2017 to July 2020. Regions of interest (ROI) of the tumor, peritumor(10mm), and tumor-peritumor(10mm) were manually segmented in the arterial phase (AP) and portal venous phase (PVP), and delayed phase (DP) images. A total of nine groups of ROIs were obtained, and 1218 radiomics features were extracted, respectively. Patients were randomly assigned to the training and inter-validation cohorts in a ratio of 7:3. The Analysis of Variance and least absolute shrinkage and selection operator (LASSO) algorithms with ten-fold cross validation were used to select radiomics features. Nine radiomics scores (Rad-Score) were established using multivariate logistic regression analysis. In addition, we combined the nine Rad-Scores with 18 clinical factors and 23 radiographic scores to construct a clinical-radiomics nomogram with multivariate logistic regression. Furthermore, all radiomics models and the combined clinical-radiomics model were independently validated with the data of the hospital's sub-campus (40 patients). ROC curves were used to compare the predictive power of the multiple models. Decision curve analysis (DCA) was used to compare the clinical benefit of the models.

RESULTS

Among the nine Rad-Scores, the tumor-peritumor in the AP cohort had the best predictive ability (AUCs of 0.912, 0.848, and 0.880 for the training cohort, inter-validation cohort, and independent validation cohort, respectively). The predicted values of the clinical model of AUCs were 0.775, 0.742, and 0.696 in the training cohort, inter-validation cohort, and independent validation cohort, respectively. The combined clinical-radiomics model performs well (AUCs for the training, inter-validation and independent validation cohorts are 0.938, 0.883, and 0.829). DCA demonstrated the highest clinical benefit in the combined clinical-radiomics model.

CONCLUSION

s The clinical-radiomics model has satisfactory results in preoperative prediction of MVI in patients with HCC and has potential value in guiding clinicians to individualize treatment.

CLINICAL RELEVANCE/APPLICATION

MVI of HCC usually indicates an increased risk of recurrence and a poor prognosis. The clinical-radiomics model can predict MVI preoperatively and has potential value in guiding clinicians to individualize treatment.

T5B-SPGI-5

Abbreviated MRI for secondary surveillance of recurrent hepatocellular carcinoma after curative treatment

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - GI DPS

Participants
Dong Ho Lee, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

There is no consensus regarding the ideal imaging modality of secondary surveillance of hepatocellular carcinoma (HCC). This study aimed to evaluate the detection performance of abbreviated MRI (AMRI) for secondary surveillance for HCC after curative treatment including surgical resection or radiofrequency ablation (RFA).

METHODS AND MATERIALS

This retrospective study analyzed 243 patients who received secondary surveillance for HCC using gadoxetic acid-enhanced MRI after more than two-year of disease-free period from curative treatment including surgical resection or RFA. Non-contrast AMRI (NC-AMRI) (T2-weighted and diffusion-weighted images), hepatobiliary phase AMRI (HBP-AMRI) (T2-weigted, diffusion-weighted and HBP images), and full-sequence MRI sets were independently reviewed by two abdominal radiologists. The confirmation of HCC was based either on histopathological confirmation or imaging-based diagnosis. HCC detection rate of each set was compared.

RESULTS

A total of 42 recurred HCCs were confirmed in 39 patients. Per-lesion and per-patient sensitivities didn’t show significant difference among three image sets in both reviewers (P=0.681): Per-lesion sensitivity: 81.1?83.3%, 76.2?85.7%, and 81.0?83.3% for NC-AMRI, HBP-AMRI, and full-sequence MRI, respectively; and per-patient sensitivity: 79.5?83.3%, 79.5?85.7%, and 79.5?83.3% for NC-AMRI, HBP-AMRI, and full-sequence MRI. Per-patient specificity didn’t show significant difference among three image set in both reviewers (95.6?97.1%, 96.1?97.1%, and 97.6?98.5% for NC-AMRI, HBP-AMRI, respectively; P=0.307).

CONCLUSION

s NC-AMRI and HBP-AMRI had comparable detection performance to that of full-sequence gadoxetic acid-enhanced MRI during secondary surveillance for HCC after more than 2-year disease free interval following curative treatment. Based on its good detection performance, short scan times, and the lack of contrast agent-associated risks, NC-AMRI would be a promising option for secondary surveillance of HCC.

CLINICAL RELEVANCE/APPLICATION

NC-AMRI would be a promising option for secondary surveillance for HCC after 2-year disease free interval following curative treatment including surgical resection and RFA.

Preoperative prediction of microvascular invasion in hepatocellular carcinoma using computation modeling of interstitial fluid pressure and velocity

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - GI DPS

Participants
Liyun Zheng, Shanghai, China (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of present study was to develop and validate a new method for the interstitial fluid pressure (IFP) measurement in hepatocellular carcinoma (HCC) patients. We also aimed to depict the microenvironment of the tumor of HCC and predict the microvascular invasion (MVI) status preoperatively and noninvasively by this IFP model.

METHODS AND MATERIALS

A cohort of 27 patients were finally included in this study (mean age 57.6 ± 10.9 years, 77.8% males). There were 15 patients in the MVI-positive group and 12 patients in the MVI-negative group. MRI examinations were performed using a 3T scanner (uMR790, United Imaging Healthcare). DCE-MRI scan sequence utilized a transverse T1-weighted spoiled GRE sequence to obtain acquisition, and 60 time points were acquired with mean temporal resolution of 3.1 s and a total acquisition time of ~3 min. Patients were allowed to breathe freely. The extended tofts model (ETM) was used to estimate the permeability parameters. Volume of Interest (VOI) for Ktrans estimation were manually delineated on the tumor lesion present in all slices in the late phases of T1-weighted DCE-MRI images. The tumor volume was calculated from the T1w dynamic images. The continuity partial differential equation (PDE) was implemented and the estimation of of IFP and interstitial fluid velocity (IFV) were acquired. Mann-Whitney U test was performed to compare the mean IFP and mean IFV between MVI-positive group and MVI-negative group. The receiver operating characteristic (ROC) analysis was performed for differentiation between MVI-positive group and MVI-negative group. The Youden index were exploited to determine the cutoff value, along with the area under the curve (AUC), sensitivity and specificity. $P < 0.05$ was considered statistically significant.

RESULTS

Significant difference was found in mean IFP between the MVI-positive group and MVI-negative group ($P = 0.001$), while there was no statistically differences in mean IFV between the two groups ($P = 0.626$). For the ROC analysis, mean IFP value proved to be the significant predictor with the best cut-off value 1854.22 Pa (AUC = 0.883, 95% confidence interval 0.701 to 0.974; sensitivity = 80.0%, specificity = 91.7%).

CONCLUSION

s The non-invasive interstitial fluid pressure (IFP) measurement model in liver tumors was developed. Significant difference was found in mean IFP between the MVI-positive group and MVI-negative group. IFP could be the significant predictor in the prediction of MVI status.

CLINICAL RELEVANCE/APPLICATION

This study developed a new method for the noninvasive IFP measurement in HCC patients. Our results revealed that MVI status can be predicted by this IFP model preoperatively.

LI-RADS Category 4 Observations on Gadoxetic Acid-Enhanced MRI: Can Imaging Features Indicate High Risk of Early Progression (<6 Months) To LI-RADS Category 5?

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - GI DPS

Participants
Ijin Joo, MD, Seoul, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the value of gadoxetic acid-enhanced MRI (Gd-EOB-MRI) features of LI-RADS category 4 (LR-4: probably hepatocellular carcinoma [HCC]) observations for predicting early progression to LR-5 (definitely HCC)

METHODS AND MATERIALS

This retrospective study included liver observations in patients at high risk for HCC, assigned as LR-4 on index Gd-EOB-MRI and had available short-term (<6 months) follow-up Gd-EOB-MRI. For each observation, LI-RADS major and ancillary features on index MRI and final LI-RADS category on follow-up MRI were assessed by a consensus of three radiologists. Multivariate logistic regression analysis was performed to identify imaging predictors for early (<6 months) progression to LR-5. Diagnostic performances of each significant imaging feature and their combinations for identifying LR-4 observations with higher risk of early category progression were evaluated.

RESULTS

Among 101 index LR-4 observations in 101 patients, 57 progressed to LR-5, while the other 44 remained stable as LR-4 within 6 months. Multivariate logistic regression analysis revealed that nonrim arterial phase hyperenhancement (APHE), nonperipheral "washout", restricted diffusion, and fat in mass at index MRI were independent predictors for early category progression (odds ratio = 3.75, 3.17, 5.36, 12.2; P = 0.037, 0.036, 0.003, 0.030, respectively). For predicting the early category progression, nonrim APHE showed the highest sensitivity (47/57, 82.5%) followed by restricted diffusion (39/57, 68.4%), nonperipheral "washout" (27/57, 47.4%), and fat in mass (8/57, 14.0%); while the highest specificity was found in fat in mass (43/44, 97.7%) followed by restricted diffusion (33/44, 75.0%), nonperipheral "washout" (31/44, 70.5%), and nonrim APHE (17/44, 38.6%). When two or more of four imaging features listed above were present, the sensitivity was 82.5% (47/57) and the specificity was 61.4% (27/44).

CONCLUSION

s LI-RADS major and ancillary features on Gd-EOB-MRI can help identify LR-4 observations with higher risk of early category progression to LR-5.

CLINICAL RELEVANCE/APPLICATION

In LI-RADS category 4 observations, MRI-based risk stratification according to the probability of early category progression could potentially facilitate appropriate and timely management.

Diagnostic Performance of CT versus MRI Liver Imaging Reporting and Data System Category 5 for Hepatocellular Carcinoma: A Systematic Review and Meta-Analysis of Comparative Studies

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - GI DPS

Participants
Sunyoung Lee, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To compare the performance of Liver Imaging Reporting and Data System category 5 (LR-5) for diagnosing HCC between CT and MRI using comparative studies.

METHODS AND MATERIALS

The MEDLINE and EMBASE databases were searched from inception to April 21, 2021, to identify studies that directly compare the diagnostic performance of LR-5 for HCC between CT and MRI. Bivariate random-effects model was fitted to calculate the pooled per-observation sensitivity and specificity of LR-5 of each modality, and compare the pooled estimates of paired data. Subgroup analysis was performed according to MRI contrast agent.

RESULTS

Seven studies with 1,145 observations (725 HCCs) were included in the final analysis. The pooled per-observation sensitivity of LR-5 for diagnosing HCC was higher using MRI (61%; 95% confidence interval [CI], 43-76%; I2 = 95%) than CT (48%; 95% CI, 31-65%; I2 = 97%) (P < 0.001). The pooled per-observation specificities of LR-5 did not show statistically significant difference between CT (96%; 95% CI, 92-98%; I2 = 0%) and MRI (93%; 95% CI, 88-96%; I2 = 16%) (P = 0.054). In the subgroup analysis, extracellular contrast agent-enhanced MRI showed significantly higher pooled per-observation sensitivity than gadoxetic acid-enhanced MRI for diagnosing HCC (73% [95% CI, 55%-85%] vs. 55% [95% CI, 39%-70%]; P = 0.007), without a significant difference in specificity (93% [95% CI, 80%-98%] vs. 94% [95% CI, 87%-97%]; P = 0.884).

CONCLUSION

s The LR-5 of MRI showed significantly higher pooled per-observation sensitivity than CT for diagnosing HCC. The pooled per-observation specificities of LR-5 were comparable between the two modalities.

CLINICAL RELEVANCE/APPLICATION

Although LI-RADS provides a common diagnostic algorithm for CT or MRI, the per-observation performance of LR-5 can be affected by the imaging modality as well as the MRI contrast agent.

T5B-SPGU-1 Does The Mid-urethral Sling Surgery Changes The Pelvic Floor MRI Parameters In Females With Stress Urinary Incontinence?: An initial experience

Participants
Mona Eldeeb, MBBCh, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

This study aimed to use pre and post-operative static and dynamic pelvic floor MRI to find out the parameters changed after the mid -urethral sling surgery. Also, we tried to compare post-operative quantitative and morphologic MRI pelvic floor parameters between the success and failure groups.

METHODS AND MATERIALS

This prospective study was conducted upon 42 female patients with stress urinary incontinence, the mean age was 47.33 ±?7.32 years. 3T pelvic MRI examination was carried on at rest and during straining. Paired t-test was performed to compare preoperative and post-operative data, and to compare the post-operative MRI findings between success and failure groups.

RESULTS

Of the 42 case included in our study, 33 patient (78.57%) had successful surgery versus 9 patients (21.43%) had failed surgery. H line at rest decreased to 5.46+ 0.89 cm postoperatively from 5.98+0.58 cm preoperatively (p = 0.015), Posterior vesicourethral angle (PUVA) decreased to 121.94 + 9.13 degree postoperatively from 128.26+9.57 degree preoperatively (p= 0.000) at rest, and from 152.34+9.2 degree preoperatively to 138.78+10.6 degree postoperatively (p= 0.011) during straining, difference in the vesical neck movement between rest and straining decreased from 2.02+ 0.16 cm preoperatively to 1.162+ 0.817 cm postoperatively (p= 0.000). As regard comparison between pre and post-operative static parameters, the length of the suprapubic part of the urethra, the retropubic space and the pubovaginal space showed significant difference. Postoperatively, PUVA during straining and difference in vesicourethral angle between rest and straining showed significant difference between success and failure groups (p = 0.000). The mean distance of the pubovaginal space in successful cases was 2.354+ 0.425 cm versus 2.688+ 0.513 cm in failed cases with a statistical significance noted in between (p value =0.05).

CONCLUSION

s Quantitative dynamic and static pelvic floor MRI is a promising tool in the evaluation of urethral and bladder neck parameters successfully corrected after mid-urethral sling surgery.

CLINICAL RELEVANCE/APPLICATION

As limited data are available about the role of dynamic pelvic floor MRI in stress urinary incontinence before and after mid-urethral sling surgery, this might help in better selection of the patients who will benefit from the surgery depending on the assessed preoperative parameters

T5B-SPGU-2 An AI and human reader study on recognition of ureter stone in non-contrast CT images

Participants
Sang Wouk Cho, MS, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Diagnoses of ureter stones are required for interpretation of medical images in patients with severe pain and renal obstruction. Non-contrast computed tomography (NCCT) is the gold standard for diagnosis of ureter stones. We developed the diagnostic programed using Artificial Intelligence (AI) and compared the diagnostic performance between AI and physicians.

METHODS AND MATERIALS

Of 450 NCCT data set with and without ureter stone (50%, stone positive), each of 200 cases regarding of presence of ureter stone was randomly selected to question for 7 physicians (3 professors, 2 senior residents and 2 junior residents) and AI for identifying stones. TASK1 is drawing the location for stones by identifying at a single NCCT image, and TASK2 at whole series images. A Modified U-net-based segmentation model was trained using a cohort of 1,440 patients with urinary stones, and performance of AI was evaluated as a result of generating masks. Both the answer sheet and stone masks for training were annotated by a urologist and double-checked by two uro-radiologists.

RESULTS

In Task 1, the professors showed the highest diagnostic performances (accuracy/sensitivity/specificity: 0.815/0.692/0.938),

following junior residents and senior residents (0.811/0.748/0.875 and 0.749/0.607/0.890). The tendency of diagnostic performances in Task2 was similar to the results in Task1 (0.848/0.765/0.930, 0.659/0.452/0.865 and 0.660/0.388/0.933). In the Task1 of recognizing stones by a single slide, diagnostic performances of AI (0.850/0.720/0.980) revealed significantly higher than those of all physicians ($p<0.005$). In Task2, AI (0.725/0.775/0.675) showed less diagnostic performance than professors, but it revealed the superior to each of senior and junior residents ($p <0.001$). There were significant differences of positive predictive values (PPV: AI 0.973, senior 0.840, junior 0.858, $p<0.0001$) in Task1 and negative predictive values (NPV: AI 0.750, senior 0.617, junior 0.612, $p<0.0001$) in Task2. In comparison of diagnostic performance for Task 1 and Task 2 according to the AI and human reader, professors showed the higher accuracy, sensitivity and NPV in Task 2, but AI showed the higher sensitivity.

CONCLUSION

s Although individual differences of diagnostic performances among physicians were associated with medical experiences, the diagnostic performances in AI were higher than those of senior and junior residents. Identifying ureter stone in whole series images was higher accuracy than that of Task 1 with recognizing stones by a single slide.

CLINICAL RELEVANCE/APPLICATION

It is important to encounter many cases of ureter stone for physicians to recognize stones in NCCT. By providing guidance, AI could help residents reach better decisions to indentify stones.

T5B-SPGU-3 Improving Prostate Cancer Detection on MRI Using Prostate-Specific Antigen Density: Additional Benefit from Zone-Specific Analyses?

Participants
Charlie Hamm, MD, Berlin, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the diagnostic value of ultrasound- and MRI-based prostate-specific antigen density (PSAD) to detect prostate cancer (PCa) and to compare PSAD based on whole organ volumetry against a transition zone-specific approach.

METHODS AND MATERIALS

This study included 1716 consecutive patients, who underwent transrectal ultrasound (TRUS), prostate MRI, and consecutive transrectal ultrasound-guided biopsy. After exclusion of 27 cases due to bad image quality, PCa was confirmed in 1185/1689 patients (348 Gleason Score (GS)=6; 837 GS=7) and the mean PSA was 11±23. Prostates of 1300 patients were manually segmented to train and test a deep learning (DL) nnUnet using cross-validation for automated prostate and prostate zone volumetry. Conventional whole organ-PSAD and transition zone-specific (TZ-s)PSAD were calculated. The results were compared to TRUS-based whole organ-PSAD and receiver operating characteristic area under the curve (AUC) of the models were determined using a hold-out test set comprising 389 patients, 55 of which were rated as PI-RADS 3.

RESULTS

The DL system reliably segmented the peripheral and transition zone on axial T2W-MRI with a dice coefficient of 0.87 and 0.81, respectively. In the test group, the mean TZ-sPSAD was 0.5±0.65 and the cut-off value of 0.27 showed the highest diagnostic accuracy in detecting PCa with an accuracy, sensitivity, and specificity of 0.71, 0.72, and 0.69, respectively. When compared to the established PSAD cut-off value of 0.15, the TZ-sPSAD (AUC: 0.74) detected significantly more PCa than the conventional MRI- (AUC: 0.72, $p=0.04$) and TRUS-based PSAD (0.65, $p<0.001$), respectively. Furthermore, the number of correctly identified clinically significant (cs)PCa (GS=7) was increased by 9% (18 vs. 23/55) in the PI-RADS 3 group, while the number of cases detected in the PI-RADS 1/2 and 4/5 groups was comparable.

CONCLUSION

s This study demonstrates a significantly improved PCa detection rate using MRI- compared to TRUS-based PSAD. Moreover, zone segmentation using a DL system to calculate TZ-sPSAD further improved PCa detection and can reduce the number of missed cases of csPCa in the PI-RADS 3 group.

CLINICAL RELEVANCE/APPLICATION

DL systems enabling automated zone-specific prostate volumetry may improve prostate MRI analysis suggesting the TZ-sPSAD as a potential biomarker for the detection of PCa.

T5B-SPGU-4 Performance of Clear Cell Likelihood Scores (ccLS) in Evaluating Solid Renal Masses at Multi-parametric MRI: Single Center Cohort Study

Awards
Trainee Research Prize - Resident

Participants
Aisin Ibrahim, MD, (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this study is to evaluate the accuracy and interobserver agreement of clear cell Likelihood scores (ccLS) in diagnosing clear cell renal cell carcinoma (ccRCC).

METHODS AND MATERIALS

This retrospective single-center study evaluated consecutive patients with solid renal masses who underwent mpMRI followed by percutaneous biopsy and/or surgical excision between January 2010 and December 2020. Predominantly (>75%) cystic masses, masses with macroscopic fat and infiltrative masses were excluded. Two abdominal radiologists independently scored each renal mass according to the proposed ccLS algorithm. The diagnostic performance of ccLS categories for ccRCC was calculated using logistic regression modeling. Diagnostic accuracy for predicting ccRCC was calculated using 2x2 contingency tables. Interobserver agreement for ccLS was evaluated with Cohen's k statistic.

RESULTS

A total of 79 patients (mean age, 63 years ± 12 [SD], 50 men) with 81 renal masses were evaluated. The mean size was 36 mm ± 28 (range, 10-160). Of the renal masses included, 44% (36/81) were ccRCC. The area under the receiver operating characteristic curve for the pooled results was 0.87 (95% CI: 0.79-0.95). Using ccLS = 4 to diagnose ccRCC, thesensitivity, specificity, and positive predictive value were 93% (95% CI: 79, 99), 63% (95% CI: 48, 77), and 67% (95% CI: 58, 75), respectively. The negative predictive value of ccLS = 2 was 93% (95% CI: 64, 99). The pooled proportion of ccRCC by ccLS category 1 to 5 were 10%, 0%, 10%, 57%, and 84% respectively. Interobserver agreement was moderate (k=0.47).

CONCLUSION

s In this study, ccLS had moderate interobserver agreement and resulted in 67% positive predictive value in diagnosing ccRCC and 93% negative predictive value in excluding ccRCC.

CLINICAL RELEVANCE/APPLICATION

The ccLS system could be a clinically efficient non-invasive tool in the assessment of solid renal masses in clinical practice. This could aid active surveillance and potentially limit the use of renal biopsy mainly for indeterminate renal lesions.

T5B-SPHN-1 Magnetic Resonance Imaging of Giant Cell Arteritis with Ocular Involvement: A Systematic Review

Participants
Jae Song, MD, MS, Philadelphia, PA (*Presenter*) Nothing to Disclose

PURPOSE

A systematic review of the literature was performed to examine orbital MRI findings in patients diagnosed with giant cell arteritis (GCA) and presenting with ophthalmic symptoms.

METHODS AND MATERIALS

PubMed was searched from inception to August 14, 2020 with an updated search on January 16, 2022. The review was registered with PROSPERO (CRD42021254494). Publications were included if a patient diagnosed with biopsy-proven GCA with ocular symptoms underwent an orbital MRI. Data on demographics, clinical symptoms, ophthalmologic exam, MRI, and follow-up data were extracted. Counts are presented as percentages. Correlation between imaging findings and symptoms/outcomes are examined by Spearman's rank-order correlation.

RESULTS

From 1302 publications, 42 met inclusion criteria. Data were extracted from 44 patients (females=20; males=24; mean age 74.7 [60-86] years) presenting with ocular symptoms, imaged with an orbital MRI and diagnosed with GCA. A diagnosis of GCA was confirmed by temporal artery (81%) or extraocular muscle biopsy (2%). Vision loss (45%) and pain (23%) were the most common ophthalmologic symptoms reported. Treatment was delayed in 14 cases due to misdiagnosis. At presentation, visual symptoms were reported to be unilateral (44%), bilateral (35%), or sequential (8%). On orbital MRI, abnormal enhancement suggestive of ischemia or inflammation of the optic nerve sheath (51%), intraconal fat (35%), optic nerve/chiasm (9%), extraocular muscle (5%), and lacrimal gland (1%) were reported. Three cohort/cross-sectional studies used vessel wall MRI and reported ophthalmic artery vessel wall enhancement (44%). Among patients presenting with monocular visual symptoms (n=18), abnormal orbital MR findings ipsilateral to the symptomatic eye were concordant in 94% of cases and most frequently showed optic nerve sheath (59%) and/or intraconal fat (41%) enhancement. The asymptomatic contralateral eye also showed optic nerve sheath enhancement in 28% of the cases. Vision loss at initial presentation significantly correlated with optic nerve sheath (?=0.25, p=0.03) and optic nerve/chiasm (?=0.37, p=0.001) enhancement. Among 26 cases reporting outcomes, poor visual recovery at follow-up correlated with optic nerve/chiasm enhancement (?=0.44, p=0.002).

CONCLUSION

s Nearly half of the patients diagnosed with GCA and ocular symptoms presented with vision loss, a symptom that significantly correlated with abnormal enhancement of the optic nerve and optic nerve sheath on MRI. Abnormal enhancement of orbital structures in both the symptomatic eye as well as the asymptomatic eye was reported in 28% of cases.

CLINICAL RELEVANCE/APPLICATION

Orbital MRI may have diagnostic and prognostic roles in patients with GCA and ocular symptoms.

T5B-SPHN-2 Skull-base Pseudotumor vs Nasopharyngeal Carcinoma: A Diagnostic Dilemma

Participants
Keivan Shifteh, MD, Brooklyn, NY (*Presenter*) Nothing to Disclose

PURPOSE

Nasopharyngeal Carcinoma (NPCa) is a primary mucosal malignancy arising in the nasopharynx, and is the most common nasopharyngeal malignancy in adults worldwide. However, multiple different pathologies can present in this region, and can be difficult to diagnose clinically. Many of them have similar appearances and can mimic NPCa on imaging, creating a diagnostic dilemma for radiologists. The purpose of this study is to describe common radiologic manifestations of NPCa, and to help establish a focused and clinically meaningful method of differentiating it from other pathologies in the Head Neck.

METHODS AND MATERIALS

Retrospective review of several cases of suspected nasopharyngeal carcinoma referred to radiology by ENT department.

RESULTS

A total of 18 cases of suspected nasopharyngeal carcinoma were referred to our department by ENT providers. These cases were comprised of 15 men and 3 women, with a male:female ratio of 5:1. Ages ranged from 19 to 87 years old. A total of 8/18 cases

(44%) were positive for NPCa, while 10/18 cases (56%) were negative. While all 18 of these cases demonstrated abnormal enhancement, only the biopsy-proven cases of NPCa involved the nasopharyngeal mucosa (8/8, 100%). Biopsy-negative cases were more likely to involve the prevertebral, carotid, parapharyngeal, and masticator spaces. Additionally, all 8 NPCa-positive cases demonstrated cervical adenopathy (100%), while only 2/10 negative cases did (20%). Biopsy-negative cases were more likely to result in osseous erosion/bone marrow signal abnormalities (90% vs 38% in positive-NPCa cases), more likely to demonstrate soft tissue necrosis (90% vs 0% in positive-NPCa cases), and more likely to demonstrate intracranial extension (50% vs 25% in positive-NPCa cases). Mastoid effusions were seen in 63% of positive-NPCa cases vs 90% in negative cases.

CONCLUSION

s In our practice, ENT referrals for imaging of suspected Nasopharyngeal carcinoma are relatively common. Although tissue biopsy is the gold standard for diagnosis, radiologic assessment prior to biopsy can narrow down differential considerations and help guide referring physician's next steps. Our research demonstrates several key imaging features of biopsy-proven cases of NPCa that can help differentiate it from alternate diagnoses, such as NHL or IgG4-RD. Among them, involvement of the nasopharyngeal mucosa (ie. abnormal enhancement), positive cervical adenopathy, and a lack of soft tissue necrosis were the most relevant findings.

CLINICAL RELEVANCE/APPLICATION

Tissue biopsy is the gold standard for the diagnosis of Nasopharyngeal Carcinoma. However, by focusing on specific imaging characteristics, a radiologist can help narrow differential considerations and guide the referring physician's next steps.

T5B-SPHN-3 Prognostic Value of PET/CT and MR-base Baseline Radiomics Among Patients with Nasopharyngeal Carcinoma

Participants
Roshini Kulanthaivelu, MBBS, FRCR, Toronto, ON (*Presenter*) Nothing to Disclose

PURPOSE

Radiomics is an emerging imaging assessment technique, which has shown promise predicting survival among nasopharyngeal carcinoma (NPC) patients. Studies so far have focused on MR-based radiomic analysis. The aim of our study was to evaluate the prognostic value of clinical and radiomic parameters derived from both PET/CT and MR.

METHODS AND MATERIALS

Retrospective evaluation of 124 NPC patients with PET/CT and radiotherapy planning MR (RP-MR). Primary tumors were segmented using dedicated software (LIFEx version 6.1) from PET, CT, contrast enhanced T1-weighted (T1-w), and T2-weighted (T2-w) MR sequences with 376 radiomic features extracted. Summary statistics described patient, disease and treatment characteristics. Kaplan Meier (KM) method estimated overall survival (OS) and progression free survival (PFS). Clinical factors selected based on univariate analysis and multivariate Cox model were subsequently constructed with radiomic features added.

RESULTS

The final models comparing clinical, clinical + RP-MR, clinical + PET/CT and clinical + RP-MR + PET/CT for OS and PFS demonstrated that combined radiomics signatures were significantly associated with improved survival prognostication (AUC 0.62 vs 0.81 vs 0.75 vs 0.86 at 21 months for PFS and 0.56 vs 0.85 vs 0.79 vs 0.96 at 24 months for OS). Clinical + RP-MR features initially outperform clinical + PET/CT for both OS and PFS (<18 months), and later in the clinical course for PFS (>42 months).

CONCLUSION

s Our study demonstrated that PET/CT-based radiomic features may improve survival prognostication among NPC patients when combined with baseline clinical and MR-based radiomic features.

CLINICAL RELEVANCE/APPLICATION

Our study demonstrated the improved prognostic value of combined clinical + PET/CT + MR features compared with clinical, PET/CT or MR features individually for both OS and PFS (AUC 0.96 at 24 months in OS and 0.86 at 21 months in PFS). This could potentially have implications on future imaging. Since PET and MR radiomic features appear to have prognostic value, combined PET/MR may have a clinical role in staging, prognostication and potentially future surveillance of patients with NPC.

Magnetic Resonance Imaging of Giant Cell Arteritis with Ocular Involvement: A Systematic Review

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - HN DPS

Participants
Jae Song, MD, MS, Philadelphia, PA (*Presenter*) Nothing to Disclose

PURPOSE

A systematic review of the literature was performed to examine orbital MRI findings in patients diagnosed with giant cell arteritis (GCA) and presenting with ophthalmic symptoms.

METHODS AND MATERIALS

PubMed was searched from inception to August 14, 2020 with an updated search on January 16, 2022. The review was registered with PROSPERO (CRD42021254494). Publications were included if a patient diagnosed with biopsy-proven GCA with ocular symptoms underwent an orbital MRI. Data on demographics, clinical symptoms, ophthalmologic exam, MRI, and follow-up data were extracted. Counts are presented as percentages. Correlation between imaging findings and symptoms/outcomes are examined by Spearman's rank-order correlation.

RESULTS

From 1302 publications, 42 met inclusion criteria. Data were extracted from 44 patients (females=20; males=24; mean age 74.7 [60-86] years) presenting with ocular symptoms, imaged with an orbital MRI and diagnosed with GCA. A diagnosis of GCA was confirmed by temporal artery (81%) or extraocular muscle biopsy (2%). Vision loss (45%) and pain (23%) were the most common ophthalmologic symptoms reported. Treatment was delayed in 14 cases due to misdiagnosis. At presentation, visual symptoms were reported to be unilateral (44%), bilateral (35%), or sequential (8%). On orbital MRI, abnormal enhancement suggestive of ischemia or inflammation of the optic nerve sheath (51%), intraconal fat (35%), optic nerve/chiasm (9%), extraocular muscle (5%), and lacrimal gland (1%) were reported. Three cohort/cross-sectional studies used vessel wall MRI and reported ophthalmic artery vessel wall enhancement (44%). Among patients presenting with monocular visual symptoms (n=18), abnormal orbital MR findings ipsilateral to the symptomatic eye were concordant in 94% of cases and most frequently showed optic nerve sheath (59%) and/or intraconal fat (41%) enhancement. The asymptomatic contralateral eye also showed optic nerve sheath enhancement in 28% of the cases. Vision loss at initial presentation significantly correlated with optic nerve sheath (?=0.25, p=0.03) and optic nerve/chiasm (?=0.37, p=0.001) enhancement. Among 26 cases reporting outcomes, poor visual recovery at follow-up correlated with optic nerve/chiasm enhancement (?=0.44, p=0.002).

CONCLUSION

s Nearly half of the patients diagnosed with GCA and ocular symptoms presented with vision loss, a symptom that significantly correlated with abnormal enhancement of the optic nerve and optic nerve sheath on MRI. Abnormal enhancement of orbital structures in both the symptomatic eye as well as the asymptomatic eye was reported in 28% of cases.

CLINICAL RELEVANCE/APPLICATION

Orbital MRI may have diagnostic and prognostic roles in patients with GCA and ocular symptoms.

T5B-SPHN-2

Skull-base Pseudotumor vs Nasopharyngeal Carcinoma: A Diagnostic Dilemma

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - HN DPS

Participants
Keivan Shifteh, MD, Brooklyn, NY (*Presenter*) Nothing to Disclose

PURPOSE

Nasopharyngeal Carcinoma (NPCa) is a primary mucosal malignancy arising in the nasopharynx, and is the most common nasopharyngeal malignancy in adults worldwide. However, multiple different pathologies can present in this region, and can be difficult to diagnose clinically. Many of them have similar appearances and can mimic NPCa on imaging, creating a diagnostic dilemma for radiologists. The purpose of this study is to describe common radiologic manifestations of NPCa, and to help establish a focused and clinically meaningful method of differentiating it from other pathologies in the Head Neck.

METHODS AND MATERIALS

Retrospective review of several cases of suspected nasopharyngeal carcinoma referred to radiology by ENT department.

RESULTS

A total of 18 cases of suspected nasopharyngeal carcinoma were referred to our department by ENT providers. These cases were comprised of 15 men and 3 women, with a male:female ratio of 5:1. Ages ranged from 19 to 87 years old. A total of 8/18 cases (44%) were positive for NPCa, while 10/18 cases (56%) were negative. While all 18 of these cases demonstrated abnormal enhancement, only the biopsy-proven cases of NPCa involved the nasopharyngeal mucosa (8/8, 100%). Biopsy-negative cases were more likely to involve the prevertebral, carotid, parapharyngeal, and masticator spaces. Additionally, all 8 NPCa-positive cases demonstrated cervical adenopathy (100%), while only 2/10 negative cases did (20%). Biopsy-negative cases were more likely to result in osseous erosion/bone marrow signal abnormalities (90% vs 38% in positive-NPCa cases), more likely to demonstrate soft tissue necrosis (90% vs 0% in positive-NPCa cases), and more likely to demonstrate intracranial extension (50% vs 25% in positive-NPCa cases). Mastoid effusions were seen in 63% of positive-NPCa cases vs 90% in negative cases.

CONCLUSION

s In our practice, ENT referrals for imaging of suspected Nasopharyngeal carcinoma are relatively common. Although tissue biopsy is the gold standard for diagnosis, radiologic assessment prior to biopsy can narrow down differential considerations and help guide referring physician’s next steps. Our research demonstrates several key imaging features of biopsy-proven cases of NPCa that can help differentiate it from alternate diagnoses, such as NHL or IgG4-RD. Among them, involvement of the nasopharyngeal mucosa (ie. abnormal enhancement), positive cervical adenopathy, and a lack of soft tissue necrosis were the most relevant findings.

CLINICAL RELEVANCE/APPLICATION

Tissue biopsy is the gold standard for the diagnosis of Nasopharyngeal Carcinoma. However, by focusing on specific imaging characteristics, a radiologist can help narrow differential considerations and guide the referring physician's next steps.

T5B-SPHN-3

Prognostic Value of PET/CT and MR-base Baseline Radiomics Among Patients with Nasopharyngeal Carcinoma

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - HN DPS

Participants
Roshini Kulanthaivelu, MBBS, FRCR, Toronto, ON (*Presenter*) Nothing to Disclose

PURPOSE

Radiomics is an emerging imaging assessment technique, which has shown promise predicting survival among nasopharyngeal carcinoma (NPC) patients. Studies so far have focused on MR-based radiomic analysis. The aim of our study was to evaluate the prognostic value of clinical and radiomic parameters derived from both PET/CT and MR.

METHODS AND MATERIALS

Retrospective evaluation of 124 NPC patients with PET/CT and radiotherapy planning MR (RP-MR). Primary tumors were segmented using dedicated software (LIFEx version 6.1) from PET, CT, contrast enhanced T1-weighted (T1-w), and T2-weighted (T2-w) MR sequences with 376 radiomic features extracted. Summary statistics described patient, disease and treatment characteristics. Kaplan Meier (KM) method estimated overall survival (OS) and progression free survival (PFS). Clinical factors selected based on univariate analysis and multivariate Cox model were subsequently constructed with radiomic features added.

RESULTS

The final models comparing clinical, clinical + RP-MR, clinical + PET/CT and clinical + RP-MR + PET/CT for OS and PFS demonstrated that combined radiomics signatures were significantly associated with improved survival prognostication (AUC 0.62 vs 0.81 vs 0.75 vs 0.86 at 21 months for PFS and 0.56 vs 0.85 vs 0.79 vs 0.96 at 24 months for OS). Clinical + RP-MR features initially outperform clinical + PET/CT for both OS and PFS (<18 months), and later in the clinical course for PFS (>42 months).

CONCLUSION

s Our study demonstrated that PET/CT-based radiomic features may improve survival prognostication among NPC patients when combined with baseline clinical and MR-based radiomic features.

CLINICAL RELEVANCE/APPLICATION

Our study demonstrated the improved prognostic value of combined clinical + PET/CT + MR features compared with clinical, PET/CT or MR features individually for both OS and PFS (AUC 0.96 at 24 months in OS and 0.86 at 21 months in PFS). This could potentially have implications on future imaging. Since PET and MR radiomic features appear to have prognostic value, combined PET/MR may have a clinical role in staging, prognostication and potentially future surveillance of patients with NPC.

T5B-SPIN-1 Artificial Intelligence in Detection of Submassive and Massive Pulmonary Embolism

Participants
Alexander Anavim, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Pulmonary embolism (PE) is a medical emergency representing the third most common cause of death worldwide, responsible for 100,000 deaths annually within the United States alone. PE has high mortality rates within the first few hours of presentation, thus, accurate and timely diagnosis is essential for initiating potentially lifesaving interventions. Management of PE has dramatically improved with recent advances in device technology, allowing improved percutaneous thrombectomy early on in management of select submassive and massive pulmonary emboli. Artificial Intelligence (AI) powered algorithms are becoming more integrated within diagnostic radiology. The use of AI across multiple modalities and specialties within radiology is gradually changing clinical practice by enhancing accuracy and efficiency, interrater reliability, and overall workflow for more timely recommendations. AI algorithms have been shows to have a high sensitivity in detection of PE on CT pulmonary angiograms. Algorithms have also been developed to estimate right heart strain associated with PE. The purpose of our study was to determine accuracy of AI in detecting right heart strain in patients with PE.

METHODS AND MATERIALS

This is a single center, retrospective study. CT pulmonary angiograms (CTPA) of patients presenting to an urban center emergency department between July 25, 2021 and October 16, 2021, were reviewed. A total of 74 patients with acute PE shown in CTPA were included. An AI algorithm was used to calculate right to left ventricular ratio. The calculated results of right ventricular strain by AI algorithm, the radiology reports, and echocardiogram results were collected. A right ventricle to left ventricle ratio of 1.2 was set as a trigger for the AI algorithm to detect right heart strain.

RESULTS

The result of right ventricular strain calculated by AI algorithm and radiology reports was concordant in 64 cases (20 positive, 44 negative cases) and discordant in 10 cases (6 positive and 4 negatives cases by AI). More than half of the patients (38/74 patients) had subsequent echocardiograms. Compared to the results of echocardiogram, the AI algorithm had a higher sensitivity (80% vs 73%) than the radiology reports with equivalent specificity (74%).

CONCLUSION

s AI algorithms are non-inferior to radiology reports in detecting right heart strain in patients with PE.

CLINICAL RELEVANCE/APPLICATION

Machine learning has the potential to play a key role in clinical management of PE and expedite thrombectomy and other treatments of submassive and massive PE.

T5B-SPIN-2 Self-Supervised Learning with MoCo v2 for Publicly Accessible Chest X-ray Pretrained Model and Its Evaluation

Participants
Kyungjin Cho, MSc, BS, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To propose the self-supervised learning with contrastive learning for publicly accessible pretrained model (SSAP) of chest X-rays (CXRs), which has been trained using a considerable amount of CXR images, and evaluate its performances.

METHODS AND MATERIALS

For training an upstream method, 4.8M CXR images were obtained retrospectively from a tertiary hospital in South Korea. We trained the self-supervised contrastive pretraining method with unlabeled images using MoCo v2 to learn visual representations of CXR. The upstream method maximizes the similarity between two views of the same CXR images and minimizes the similarity between different CXR images. In downstream tasks, CXR images with 6 class diseases (normal, nodule, consolidation, pneumothorax, interstitial opacity, and pleural effusion) which were confirmed with near computed tomography scans within one month were collected from the same hospital but independently of the upstream dataset for the multi-class classification. Second, we used the CheXpert dataset for the external validation test. Third, adult posterior-anterior CXR pairs of rib-preserved and rib-suppressed images, generated using the Bone Suppression™ software (Samsung Electronics Co., Ltd.) for the bone suppression were collected. Finally, we evaluated SSAP and ImageNet pretrained models with three downstream tasks.

RESULTS

In classification of 6 class diseases, accuracies of pretrained ImageNet and SSAP models, were 0.345, and 0.631, respectively. In external validation with CheXpert dataset, mean AUCs of pretrained ImageNet and SSAP models with 1%, 10%, 50%, and full datasets were 0.616, 0.700, 0.774, 0.795, and 0.638, 0.746, 0.790, 0.807, respectively. In bone suppression, PSNR, SSIM, RMSE of pretrained ImageNet and SSAP models were 34.99, 0.976, 4.410, and 37.77, 0.977, 3.301, respectively.

CONCLUSION

s The SSAP model showed the better performance and decent transferability in multiple datasets and data settings in multi-class and multi-label classification. SSAP can also be used for perceptual loss in image-to-image translation. This public model can help researchers overcome data imbalance, data shortage, and inaccessibility of medical image datasets.

CLINICAL RELEVANCE/APPLICATION

The SSAP model can help researchers develop a CXR related model with better performance and robustness to overcome data imbalance, data shortage, and inaccessibility of medical image datasets.

T5B-SPIN-3 Learning 2D Image-Level Annotations from 3D Exam-Level Annotations

Participants
Ian Pan, MD, Brookline, MA (*Presenter*) Consultant, MD.ai, Inc;Consultant, Centaur Labs Inc;Consultant, Diagnosticos da America SA;Consultant, CoRead AI

PURPOSE

Develop a deep learning-based approach to infer 2D image-level annotations from 3D exam-level annotations to reduce the annotation burden of developing image-level classification models.

METHODS AND MATERIALS

21,744 head CT scans (18,938 patients) from the RSNA Intracranial Hemorrhage (ICH) Detection Challenge and 7,279 CT pulmonary angiograms from the RSNA-STR Pulmonary Embolism (PE) Detection Challenge were used for this study. Datasets were divided into training/validation (80%) and test (20%) sets, by patient (if available) or exam. 3D CNN models based on the X3D architecture were trained, for ICH, to predict 6 ICH classes (epidural, subdural, subarachnoid, intraparenchymal, intraventricular, any), and, for PE, the binary class of PE (vs. no PE). The final linear classification layer of the X3D model was removed after training. Inference was then performed on the whole dataset, producing a 3D class activation map for each exam and class. The 3D map was converted to a 1D sequence, with dimension corresponding to the z-axis, by taking the max of each 2D axial map. The sequence was then resampled to the number of images in the original exam and rescaled to a max of 1. Image-level pseudolabels were generated by applying a threshold of 0.2 to the sequence values. 2D CNNs based on the EfficientNet-B4 architecture were then trained on the pseudolabels and original image-level ground truth ("gold standard") to predict the above labels at the image level. A "naive" approach, where all images in an exam were assigned the exam-level label, served as a baseline. Performance was compared using the area under the receiver operating characteristic curve (AUC) and classification (multi- and single-label binary cross-entropy) loss.

RESULTS

All values are calculated at the image level. For ICH, the naive approach achieved mean AUC 0.939, ranging from 0.911 for epidural hematoma to 0.962 for intraventricular hemorrhage, and a classification loss of 0.270. The pseudolabel approach achieved mean AUC 0.968, ranging from 0.949 to 0.989, and classification loss 0.075. The gold standard approach achieved mean AUC 0.977, ranging from 0.953 to 0.994, and a loss of 0.064. For PE, the naive approach achieved AUC 0.681 and loss 0.793, compared with AUC 0.895, loss 0.143 and AUC 0.929, loss 0.112 for the pseudolabel and gold standard approaches, respectively. All pairwise differences between approaches were statistically significant ($p<0.0001$).

CONCLUSION

s 3D CNN models can generate 2D image-level labels suitable for training accurate 2D classification models.

CLINICAL RELEVANCE/APPLICATION

Image-level pseudolabeling with 3D CNNs can considerably reduce the annotation effort required to develop deep learning models with 2D granularity.

T5B-SPIN-4 Multi-head Deep Learning Model for The Detection of Prostate Cancer Lesions in Bi-parametric MRI

Participants
Kourosh Jafari-Khouzani, Cambridge, MA (*Presenter*) Employee, IBM Corporation

PURPOSE

Prostate cancer is the second leading cause of cancer death in men in the United States. Bi-parametric MRI (bp-MRI), comprising T2-weighted (T2W) and diffusion-weighted imaging (DWI), plays an essential role in the assessment of prostate cancer. Prostate Imaging Reporting and Data System (PI-RADS) serves as a standardized scoring system to assess the risk of clinically significant prostate cancer using bp-MRI, but it suffers from high intra- and inter-reader variability. We have proposed a multi-head deep learning model to automatically detect clinically significant cancers as determined by PI-RADS guidelines.

METHODS AND MATERIALS

We collected a dataset of bp-MRI from 9 different providers and various scanners and imaging protocols in multiple sites in the United States, Europe, South America, and Asia. We selected a subset of 3076 studies for this project. A group of radiologists outlined and scored lesions in T2W and DWI volumes. In addition, they outlined the prostate gland and zones including the transitional zone (TZ), peripheral zone (PZ), central zone (CZ), and Anterior Fibromuscular Stroma (AFMS). We only included lesion masks that had PI-RADS scores 3, 4, and 5 in the training. Similarly, we annotated 341 studies from the publicly available dataset ProstateX for testing. A multi-head model was trained to simultaneously predict segmentation masks for lesions outlined in the T2W image and DWI, prostate, and zones, given the T2W image, apparent diffusion coefficient (ADC) map, and high b-value DWI. The model leveraged information from the prostate and zones by predicting their mask. In addition, we added convolutional LSTM blocks

to leverage information from the neighboring slices. We evaluated the network by 5-fold cross-validation and separately by the held-out test set. To evaluate performance, we report sensitivity and 3D Dice coefficients for the validation set as well as the test set.

RESULTS

For the validation and test sets, we obtained average 3D Dice coefficients of 0.35 and 0.42 for lesions outlined in T2W, 0.41 and 0.44 for lesions outlined in DWI, 0.94 and 0.94 for prostate, 0.88 and 0.86 for TZ, 0.76 and 0.70 for PZ, 0.51 and 0.45 for CZ, and 0.57 and 0.44 for AFMS, respectively. The average sensitivity at one false positive per case was 91%.

CONCLUSION

s The proposed model simultaneously detects clinically significant lesions in T2W and DWI volumes and segments the prostate gland and its zones. This is an important step toward fully automating prostate cancer assessment and subsequently reducing its subjectivity.

CLINICAL RELEVANCE/APPLICATION

PI-RADS assessment is subjective and time-consuming. Automatic detection of prostate cancer lesions is an important step toward making PI-RADS classification fully automated and more objective.

T5B-SPIN-5 Fully Automated, Fast, and Accurate Intracranial Arterial Narrowing Detection: A Deep Learning Approach

Participants
Maxime Chagnon, BEng, MSc, (*Presenter*) Nothing to Disclose

PURPOSE

Intracranial narrowing of the artery (INA) is a well-established cause of stroke worldwide. Radiologists routinely use computed tomography angiography (CTA) to manually analyze INA, yet this process is tedious and prone to inter-observer variability. We here present a novel approach using artificial intelligence (AI) and convolutional neural network (CNN) that rapidly locates INA on CTA without the need of user intervention. We believe that it was never done on CTA images before.

METHODS AND MATERIALS

192 consecutive patients (mean age 58 ± 16, 111 females) with CTA (0.3x0.3x0.5mm) were retrospectively analyzed for INA by a neuroradiologist (author JC) and a resident (author SG). 96 were identified as having at least one INA (1-18 per patient, average 4 ± 4), and 96 had no INA. To reduce computation complexity and to avoid training on unnecessary information, each image was divided into coarse patches (14.4x14.4x24mm) and each patch was labelled as INA positive or negative. We used 158 CTA to obtain a subset of patches with data augmentation (total patches = 3700, 50% positive) used to train a model (3d SE-RESNET). We used 12 new CTA images (90 patches, 50% positive) for testing and 16 new CTA (76 patches, 50% positive) for validation.

RESULTS

Across all validation set patches, the detection rate was 83%, the false negative rate was 16% and precision was 92%. Our model correctly found 32 of all 38 INA. In general, our model underestimated the true number of INA sites by 13% ± 17%, but the average detection score was still relatively high (85% ± 17 %).

CONCLUSION

s We successfully developed and validated an AI model capable of quickly (~2 min compute time per CTA) and accurately locating brain patches with INA. We believe this method may be helpful for providing a quick, but coarse analysis of INA topography without the need of user intervention. We are currently assessing the impact this method has in clinical evaluations.

CLINICAL RELEVANCE/APPLICATION

Preliminary results indicate that the model presented can accurately and automatically locate INA on CTA. It is expected to reduce the burden of manual INA detection and improve reliability.

T5B-SPIN-6 Transformer-Based Semi-Supervised Adversarial Learning for Liver Tumor Segmentation in Contrast-Enhanced MRI Images

Participants
Han Wen, Chengdu, China (*Presenter*) Nothing to Disclose

PURPOSE

This study aims to construct a semi-supervised segmentation model for contrast-enhanced MRI of liver tumors using a deep learning approach on a small amount of labeled data and a large amount of unlabeled data to assist physicians in annotating liver tumors and reduce physician workload.

METHODS AND MATERIALS

We retrospectively collected contrast-enhanced MRI of 126 patients with liver tumors. We randomly selected 20 MRI from the dataset as the test set. Our image preprocessing procedure was as follows. All MRI were resampled to 1×1×1mm. The dataset was normalized by subtracting the mean divided by the standard deviation. Each MRI was centrally cropped and the size of the cropped patch was 256×256×32mm.As shown in Figure 1, our semi-supervised segmentation model consists of a segmentation sub-network and an evaluation sub-network. The segmentation sub-network is a variant structure of Unet, where the encoder is a transformer and the decoder is a CNN, and features from multiple resolutions of the encoder are combined with the decoder to generate segmentation masks. The evaluation sub-network is a 5-layer CNN, each convolutional layer contains convolution, leaky_relu and dropout. During the training process, the segmentation sub-network generates segmentation masks for unlabeled images and labeled images, and the evaluation sub-network learns by distinguishing between the two. The loss function of our semi-supervised segmentation model is L=Lseg+Ladv ,where Lseg is used for labeled data, which consists of cross-entropy loss, dice loss and signed distance map loss. Ladv is used for both labeled data and unlabeled data, it is cross entropy loss.

RESULTS

As shown in Table 1, on the 40% labeled data set, our method achieves the best performance compared to other methods on Dice, Jaccard, ASD, and 95HD, reaching 74.09%,60.36%, 3.26,15.92, respectively. Even the segmentation results of 100% labeled data are almost the same. As can be seen in Figure 2, the segmentation results of our method are significantly better than other models and comparable to the manual descriptions of physicians.

CONCLUSION

s In this study, we present a Transformer-based semi-supervised segmentation model for contrast-enhanced MRI of liver tumors. The model was trained using an adversarial learning approach and achieved very excellent results on a small amount of labeled data and a large amount of unlabeled data, and was comparable to manual annotation by physicians.

CLINICAL RELEVANCE/APPLICATION

For medical images, it is an expensive and time-consuming process for clinical experts to perform pixel-by-pixel annotation of a large number of segmentation masks. If our method is used it can reduce the physician's annotation time significantly.

RESULTS

In classification of 6 class diseases, accuracies of pretrained ImageNet and SSAP models, were 0.345, and 0.631, respectively. In external validation with CheXpert dataset, mean AUCs of pretrained ImageNet and SSAP models with 1%, 10%, 50%, and full datasets were 0.616, 0.700, 0.774, 0.795, and 0.638, 0.746, 0.790, 0.807, respectively. In bone suppression, PSNR, SSIM, RMSE of pretrained ImageNet and SSAP models were 34.99, 0.976, 4.410, and 37.77, 0.977, 3.301, respectively.

CONCLUSION

s The SSAP model showed the better performance and decent transferability in multiple datasets and data settings in multi-class and multi-label classification. SSAP can also be used for perceptual loss in image-to-image translation. This public model can help researchers overcome data imbalance, data shortage, and inaccessibility of medical image datasets.

CLINICAL RELEVANCE/APPLICATION

The SSAP model can help researchers develop a CXR related model with better performance and robustness to overcome data imbalance, data shortage, and inaccessibility of medical image datasets.

Learning 2D Image-Level Annotations from 3D Exam-Level Annotations

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - IN DPS

Participants
Ian Pan, MD, Brookline, MA (*Presenter*) Consultant, MD.ai, Inc;Consultant, Centaur Labs Inc;Consultant, Diagnosticos da America SA;Consultant, CoRead AI

PURPOSE

Develop a deep learning-based approach to infer 2D image-level annotations from 3D exam-level annotations to reduce the annotation burden of developing image-level classification models.

METHODS AND MATERIALS

21,744 head CT scans (18,938 patients) from the RSNA Intracranial Hemorrhage (ICH) Detection Challenge and 7,279 CT pulmonary angiograms from the RSNA-STR Pulmonary Embolism (PE) Detection Challenge were used for this study. Datasets were divided into training/validation (80%) and test (20%) sets, by patient (if available) or exam. 3D CNN models based on the X3D architecture were trained, for ICH, to predict 6 ICH classes (epidural, subdural, subarachnoid, intraparenchymal, intraventricular, any), and, for PE, the binary class of PE (vs. no PE). The final linear classification layer of the X3D model was removed after training. Inference was then performed on the whole dataset, producing a 3D class activation map for each exam and class. The 3D map was converted to a 1D sequence, with dimension corresponding to the z-axis, by taking the max of each 2D axial map. The sequence was then resampled to the number of images in the original exam and rescaled to a max of 1. Image-level pseudolabels were generated by applying a threshold of 0.2 to the sequence values. 2D CNNs based on the EfficientNet-B4 architecture were then trained on the pseudolabels and original image-level ground truth ("gold standard") to predict the above labels at the image level. A "naive" approach, where all images in an exam were assigned the exam-level label, served as a baseline. Performance was compared using the area under the receiver operating characteristic curve (AUC) and classification (multi- and single-label binary cross-entropy) loss.

RESULTS

All values are calculated at the image level. For ICH, the naive approach achieved mean AUC 0.939, ranging from 0.911 for epidural hematoma to 0.962 for intraventricular hemorrhage, and a classification loss of 0.270. The pseudolabel approach achieved mean AUC 0.968, ranging from 0.949 to 0.989, and classification loss 0.075. The gold standard approach achieved mean AUC 0.977, ranging from 0.953 to 0.994, and a loss of 0.064. For PE, the naive approach achieved AUC 0.681 and loss 0.793, compared with AUC 0.895, loss 0.143 and AUC 0.929, loss 0.112 for the pseudolabel and gold standard approaches, respectively. All pairwise differences between approaches were statistically significant ($p<0.0001$).

CONCLUSION

s 3D CNN models can generate 2D image-level labels suitable for training accurate 2D classification models.

CLINICAL RELEVANCE/APPLICATION

Image-level pseudolabeling with 3D CNNs can considerably reduce the annotation effort required to develop deep learning models with 2D granularity.

T5B-SPIN-4

Multi-head Deep Learning Model for The Detection of Prostate Cancer Lesions in Bi-parametric MRI

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - IN DPS

Participants
Kourosh Jafari-Khouzani, Cambridge, MA (*Presenter*) Employee, IBM Corporation

PURPOSE

Prostate cancer is the second leading cause of cancer death in men in the United States. Bi-parametric MRI (bp-MRI), comprising T2-weighted (T2W) and diffusion-weighted imaging (DWI), plays an essential role in the assessment of prostate cancer. Prostate Imaging Reporting and Data System (PI-RADS) serves as a standardized scoring system to assess the risk of clinically significant prostate cancer using bp-MRI, but it suffers from high intra- and inter-reader variability. We have proposed a multi-head deep learning model to automatically detect clinically significant cancers as determined by PI-RADS guidelines.

METHODS AND MATERIALS

We collected a dataset of bp-MRI from 9 different providers and various scanners and imaging protocols in multiple sites in the United States, Europe, South America, and Asia. We selected a subset of 3076 studies for this project. A group of radiologists outlined and scored lesions in T2W and DWI volumes. In addition, they outlined the prostate gland and zones including the transitional zone (TZ), peripheral zone (PZ), central zone (CZ), and Anterior Fibromuscular Stroma (AFMS). We only included lesion masks that had PI-RADS scores 3, 4, and 5 in the training. Similarly, we annotated 341 studies from the publicly available dataset ProstateX for testing. A multi-head model was trained to simultaneously predict segmentation masks for lesions outlined in the T2W image and DWI, prostate, and zones, given the T2W image, apparent diffusion coefficient (ADC) map, and high b-value DWI. The model leveraged information from the prostate and zones by predicting their mask. In addition, we added convolutional LSTM blocks to leverage information from the neighboring slices. We evaluated the network by 5-fold cross-validation and separately by the held-out test set. To evaluate performance, we report sensitivity and 3D Dice coefficients for the validation set as well as the test set.

RESULTS

For the validation and test sets, we obtained average 3D Dice coefficients of 0.35 and 0.42 for lesions outlined in T2W, 0.41 and 0.44 for lesions outlined in DWI, 0.94 and 0.94 for prostate, 0.88 and 0.86 for TZ, 0.76 and 0.70 for PZ, 0.51 and 0.45 for CZ, and 0.57 and 0.44 for AFMS, respectively. The average sensitivity at one false positive per case was 91%.

CONCLUSION

s The proposed model simultaneously detects clinically significant lesions in T2W and DWI volumes and segments the prostate gland and its zones. This is an important step toward fully automating prostate cancer assessment and subsequently reducing its subjectivity.

CLINICAL RELEVANCE/APPLICATION

PI-RADS assessment is subjective and time-consuming. Automatic detection of prostate cancer lesions is an important step toward making PI-RADS classification fully automated and more objective.

T5B-SPIN-5

Fully Automated, Fast, and Accurate Intracranial Arterial Narrowing Detection: A Deep Learning Approach

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - IN DPS

Participants
Maxime Chagnon, BEng, MSc, (*Presenter*) Nothing to Disclose

PURPOSE

Intracranial narrowing of the artery (INA) is a well-established cause of stroke worldwide. Radiologists routinely use computed tomography angiography (CTA) to manually analyze INA, yet this process is tedious and prone to inter-observer variability. We here present a novel approach using artificial intelligence (AI) and convolutional neural network (CNN) that rapidly locates INA on CTA without the need of user intervention. We believe that it was never done on CTA images before.

METHODS AND MATERIALS

192 consecutive patients (mean age 58 ± 16, 111 females) with CTA (0.3x0.3x0.5mm) were retrospectively analyzed for INA by a neuroradiologist (author JC) and a resident (author SG). 96 were identified as having at least one INA (1-18 per patient, average 4 ± 4), and 96 had no INA. To reduce computation complexity and to avoid training on unnecessary information, each image was divided into coarse patches (14.4x14.4x24mm) and each patch was labelled as INA positive or negative. We used 158 CTA to obtain a subset of patches with data augmentation (total patches = 3700, 50% positive) used to train a model (3d SE-RESNET). We used 12 new CTA images (90 patches, 50% positive) for testing and 16 new CTA (76 patches, 50% positive) for validation.

RESULTS

Across all validation set patches, the detection rate was 83%, the false negative rate was 16% and precision was 92%. Our model correctly found 32 of all 38 INA. In general, our model underestimated the true number of INA sites by 13% ± 17%, but the average detection score was still relatively high (85% ± 17 %).

CONCLUSION

s We successfully developed and validated an AI model capable of quickly (~2 min compute time per CTA) and accurately locating brain patches with INA. We believe this method may be helpful for providing a quick, but coarse analysis of INA topography without the need of user intervention. We are currently assessing the impact this method has in clinical evaluations.

CLINICAL RELEVANCE/APPLICATION

Preliminary results indicate that the model presented can accurately and automatically locate INA on CTA. It is expected to reduce the burden of manual INA detection and improve reliability.

T5B-SPIN-6

Transformer-Based Semi-Supervised Adversarial Learning for Liver Tumor Segmentation in Contrast-Enhanced MRI Images

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - IN DPS

Participants
Han Wen, Chengdu, China (*Presenter*) Nothing to Disclose

PURPOSE

This study aims to construct a semi-supervised segmentation model for contrast-enhanced MRI of liver tumors using a deep learning approach on a small amount of labeled data and a large amount of unlabeled data to assist physicians in annotating liver tumors and reduce physician workload.

METHODS AND MATERIALS

We retrospectively collected contrast-enhanced MRI of 126 patients with liver tumors. We randomly selected 20 MRI from the dataset as the test set. Our image preprocessing procedure was as follows. All MRI were resampled to 1×1×1mm. The dataset was normalized by subtracting the mean divided by the standard deviation. Each MRI was centrally cropped and the size of the cropped patch was 256×256×32mm.As shown in Figure 1, our semi-supervised segmentation model consists of a segmentation sub-network and an evaluation sub-network. The segmentation sub-network is a variant structure of Unet, where the encoder is a transformer and the decoder is a CNN, and features from multiple resolutions of the encoder are combined with the decoder to generate segmentation masks. The evaluation sub-network is a 5-layer CNN, each convolutional layer contains convolution, leaky_relu and dropout. During the training process, the segmentation sub-network generates segmentation masks for unlabeled images and labeled images, and the evaluation sub-network learns by distinguishing between the two. The loss function of our semi-supervised segmentation model is L=Lseg+Ladv ,where Lseg is used for labeled data, which consists of cross-entropy loss, dice loss and signed distance map loss. Ladv is used for both labeled data and unlabeled data, it is cross entropy loss.

RESULTS

As shown in Table 1, on the 40% labeled data set, our method achieves the best performance compared to other methods on Dice, Jaccard, ASD, and 95HD, reaching 74.09%,60.36%, 3.26,15.92, respectively. Even the segmentation results of 100% labeled data are almost the same. As can be seen in Figure 2, the segmentation results of our method are significantly better than other models and comparable to the manual descriptions of physicians.

CONCLUSION

s In this study, we present a Transformer-based semi-supervised segmentation model for contrast-enhanced MRI of liver tumors. The model was trained using an adversarial learning approach and achieved very excellent results on a small amount of labeled data and a large amount of unlabeled data, and was comparable to manual annotation by physicians.

CLINICAL RELEVANCE/APPLICATION

For medical images, it is an expensive and time-consuming process for clinical experts to perform pixel-by-pixel annotation of a large number of segmentation masks. If our method is used it can reduce the physician's annotation time significantly.

Interventional Tuesday Poster Discussions - B

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - IR DPS

Sub-Events

T5B-SPIR-1 Bare Metallic Stent as Salvage Treatment for Refractory Benign Biliary Strictures After Pediatric Liver Transplantation: Preliminary Experience in A Single-center Cohort

Participants
Ludovico Dulcetta, MD, Bergamo, Italy (*Presenter*) Nothing to Disclose

PURPOSE

Liver transplant (LT) is the standard of care for pediatric patients with end-stage liver disease or congenital metabolic disorders. Biliary complications, in particular benign strictures, are a common cause of morbidity and graft dysfunction. Anastomotic and intrahepatic strictures frequently relapse after the standard percutaneous management with bilioplasty and surgical revision.The aim is to describe preliminary experience with metallic stent as salvage treatment in selected patients before relisting for retransplantation.

METHODS AND MATERIALS

Eight pediatric patients (3 female; mean age 20 months) after split left LT with refractory biliary strictures were treated with percutaneous transhepatic implantation of vascular balloon-expandable or biliary self-expandable bare metallic stents. Indications for stenting were signs of mechanical cholestasis and fibrosis at liver biopsy and failure of standard management with percutaneous transhepatic bilioplasty and/or surgical revision.

RESULTS

A total of 18 stents (3 biliary, 15 vascular) were implanted. Technical success was 100% without adverse events. A single anastomotic stent was used in 3 patients. Two parallel stents with the kissing-balloon technique to cover the confluence between segments 2 and 3 were implanted in 6 patients. In 1 patient 3 stents were imbricated due to incomplete coverage of the stenosis. Before stents implantation a mean of 3.6 PTC per patient was performed (7.8 months follow-up); after stents implantation a mean of 0.6 PTC (13.1 months follow-up). In one case stent patency was observed after 9 years.

CONCLUSION

s Preliminary data suggest that after pediatric LT, relapsing biliary strictures could be safely treated with metallic stents to reduce numbers of interventional procedures before surgical anastomosis revision or retransplantation.

CLINICAL RELEVANCE/APPLICATION

Although metal stents are intended for palliation in malignant biliary pathology, they could be considered to improve cholestatic symptoms in retransplantation waitlist.

T5B-SPIR-2 Combined Microwave Ablation plus Osteosynthesis for Long Bone Metastases

Participants
Claudio Pusceddu, MD, (*Presenter*) Nothing to Disclose

PURPOSE

to evaluate the feasibility, safety and efficacy of microwave ablation (MWA) in combination with open surgery nail positioning for the treatment of fractures or impending fractures of long bone metastases.

METHODS AND MATERIALS

Eleven patients (four men, seven women) with painful bone metastases of the humerus, femur ortibia with non-displaced fractures (one case) or impending fractures (10 cases) underwent open MWA in combination with osteosynthesis by locked nail positioning. Pain intensity was measured using a VAS score before and after treatment. CT or MRI were acquired at one month before and 1, 3, 6, 12 and 18 months after treatment.

RESULTS

All procedures were successfully completed without major complications. The level of pain was significantly reduced one month after treatment. For the patients with humerus metastases, the complete recovery of arm use took 8 weeks, while for the patients with femoral metastases the complete recovery of walking capacity took 11 weeks. The VAS score ranged from 7 (4-9) before treatment to 1.5 (0-2.5) after treatment. During a mid-term follow-up of 18 months (range 4-29 months), none of the patients showed tumor relapse or new fractures in the treated site. Two patients died due to tumor disease progression.

CONCLUSION

s Results of this preliminary study suggest that combined MWA and surgical osteosynthesis with locked nails is a safe and effective treatment for pathological fractures or malignant impending fractures of long bone metastases of the humerus, femur and tibia. Further analyses with larger cohorts are warranted to confirm these findings.

CLINICAL RELEVANCE/APPLICATION

Combined ablation and osteosynthesis treatment of long bone metastases may improve survival in patients with cancer

T5B-SPIR-3 CT-based Radiomics Models May Predict the Early Efficacy of Microwave Ablation in Malignant Lung Tumors

Participants
Fandong Zhu, Shaoxing, China (*Presenter*) Nothing to Disclose

PURPOSE

To establish and validate a radiomics model for predicting the early efficacy of microwave ablation (MWA) in malignant lung tumors.

METHODS AND MATERIALS

The study enrolled 104 malignant lung tumor patients (72 in the training cohort and 32 in the validation cohort) treated with MWA. Post-operation CT images were analyzed. To evaluate the therapeutic effect of ablation, three models were constructed by least absolute shrinkage and selection operator and logistic regression: the tumoral radiomics (T-RO), peritumoral radiomics (P-RO), and tumoral-peritumoral radiomics (TP-RO) models. Univariate and multivariate analyses were performed to identify clinical variables and radiomics features associated with early efficacy, which were incorporated into the combined nomogram (C-RO). The performance of the C-RO model was evaluated by the area under the receiver operating characteristic curve (AUC), calibration curve, and decision curve analysis. The efficacy of the C-RO model was quantified using the Cox regression model.

RESULTS

Four radiomics features were selected from the region of interest of tumor and peritumor CT images, which showed good performance for evaluating prognosis and early efficacy in two cohorts. The C-RO model was better than the T-RO model (AUC in training, 0.913 vs. 0.784; P = 0.055), P-RO model (AUC in training, 0.913 vs. 0.740; P = 0.027) and the TP-RO model (AUC in training, 0.913 vs. 0.814; P=0.130). Decision curve analysis (DCA) confirmed the clinical benefit of the radiomics nomogram. Survival analysis revealed that in the C-RO model, the low-risk groups defined by best cutoff value had significantly better progression-free survival than the high-risk groups (P<0.05).

CONCLUSION

s CT-based radiomics in malignant lung tumor patients after MWA could be useful for individualized risk classification and treatment.

CLINICAL RELEVANCE/APPLICATION

Traditional imaging methods lack sensitivity and specificity to evaluate the early efficacy of microwave ablation. The aim of this study was to evaluate tumor and peritumor radiomics-based models and their potential to predict the early efficacy of MWA in malignant lung tumors. The model constructed by integrating radiomics features extracted from the ROI in tumoral and peritumoral areas and clinical risk factors showed a stable and excellent predictive performance, providing a non-invasive and repeatable method to evaluate the outcomes of MWA.

T5B-SPIR-4 Ability of the Renal Ablation-Specific (MC)2 Risk Scoring System to Predict Major Complications from Percutaneous Renal Microwave Ablation

Participants
Cody Savage, BS, Tuscaloosa, AL (*Presenter*) Nothing to Disclose

PURPOSE

The (MC)2 score is a renal-ablation specific risk scoring system originally developed to predict major complications from percutaneous renal cryoablation. However, this scoring system has not been applied to patients undergoing percutaneous renal microwave ablation (MWA). The aim of this study is to access the ability of the (MC)2 scoring system to identify patients at risk for major complications of percutaneous renal MWA.

METHODS AND MATERIALS

Retrospective review of all adult patients who underwent percutaneous renal MWA at two centers from 2009-2018. Patient demographics, medical histories, laboratory work, technical details of the procedure, tumor characteristics, and clinical outcomes were collected. The (MC)2 score was calculated for each patients. Patients were assigned to low-risk (<5), moderate-risk (5-8) and high-risk (>8) groups. Complications were graded according to CIRSE guidelines.

RESULTS

A total of 116 patients (M=66; F=50; median age=63 (range: 34-81)) were included. 11 (9.5%) and 23 (19.8%) experienced major or minor complications, respectively. Patients who developed major complications had a mean tumor diameter of 3.0 mm (± 1.4). In this group, 21 patients (18.1%) had a central tumor, 20 patients (17.2%) had complicated diabetes, and 14 patient (12.1%) had a prior myocardial infarction. Among the low-risk, moderate-risk, and high-risk groups, the major complication rate was 7.8%, 13.2%, and 0%, respectively. The mean (MC)2 score for patients with major complications (4.8 (± 1.8)) was not higher than those with either minor complications (4.1 (± 1.6)) (p= 0.49) or no complications (3.7 (± 1.5)) (p= 0.10). The area under the ROC curve to predict major complications was 0.64, indicating a poor ability to predict major complications in this cohort. However, mean tumor size was greater in patients with major complications than those with minor complications (p=0.01).

CONCLUSION

s The (MC)2 risk scoring system does not accurately identify patients at risk for major complications from percutaneous renal MWA. The mean tumor size alone may serve as a better indicator for risk assessment of major complications.

CLINICAL RELEVANCE/APPLICATION

Unlike in percutaneous renal cryoablation, the (MC)2 scoring system is not effective at predicting which patients will develop major complications following percutaneous renal MWA. As such, risk stratification systems specific to the treatment modality need to be developed to accurately predict a patient's risk of major complications.

T5B-SPIR-5 Preliminary Results Developing a Novel Ex Vivo Human Liver Model to Investigate Microwave Ablation

Participants
Carlos Ortiz, MD, San Antonio, TX (*Presenter*) Consultant, Argon Medical Devices, Inc

PURPOSE

We aim to develop a novel dual-perfused ex vivo model using explanted human research livers to investigate microwave ablation (MWA).

METHODS AND MATERIALS

Five explanted research livers (3 cirrhotic and 2 > 50% steatosis) were obtained under research consent. Each organ was recovered from a brain-dead human deceased donor by a transplant surgeon using standard surgical and preservation techniques. This study consists of three components: 1) develop a physiologic ex vivo model to perfuse human research livers, 2) use the model to assess the impact of perfusion mediated tissue cooling on MWA ablation measurements in a human model, and 3) compare observed ex vivo results to manufacturer reference data from nonperfused animal organs. A total of 27 ablations (12 perfused and 15 nonperfused) were performed at 140W for 6 minutes using a MWA system (Angiodynamics Solero). Pre- and post-ablation arteriogram, portal venogram, and cholangiogram were obtained. Ablations were sectioned along the probe trajectory to obtain maximal long axis diameter (LAD) and short axis diameter (SAD) for the zone of coagulation. Ellipsoid volume and sphericity were calculated. Standard statistical analysis was performed.

RESULTS

Continuous bile production was observed in three viable livers (60%), including one cirrhotic liver. Perfused ablations resulted in significantly smaller ablation dimensions than nonperfused ablations with average gross specimen MWA comparisons as follows (12 perfused ablations vs 15 nonperfused ablations, two-tailed t-test): SAD, 3.2 ± 0.4 cm vs 4.1 + 0.5 cm ($p < 0.001$); LAD, 5.1 ± 0.3 cm vs 6.1 ± 0.4 cm ($p < 0.001$); volume, 27.3 ± 8.6 mL vs 54.3 ± 12.7 mL ($p < 0.001$); sphericity, 0.40 ± 0.10 vs 0.45 ± 0.10 ($p = 0.19$). No significant differences were observed in organ temperature and maximal probe wattage for perfused and nonperfused ablations. Comparing nonperfused ablations to manufacturer data, there were significant differences in LAD, SAD, and sphericity (one sample t-test, $p < 0.05$). Comparing perfused ablations to manufacturer data, there were significant differences in LAD, SAD, volume, and sphericity (one sample t-test, all $p < 0.001$). Post-ablation arteriograms demonstrated no contrast extravasation and a new arteriovenous fistula in a single organ.

CONCLUSION

s The presence of perfusion significantly decreases MWA measurements in human livers. At a single device setting, significant differences in MWA measurements are seen in human livers compared to nonperfused manufacturer data.

CLINICAL RELEVANCE/APPLICATION

This ex vivo model allows for improved characterization of ablation measurements utilizing organs donated for medical research. An ex vivo human model could decrease variability between MWA reference data and clinical results.

T5B-SPIR-6 Specific Inhibitor of MMP Decrease Tumor Invasiveness After Radiofrequency Ablation in Liver Tumor Animal Model

Participants
Bing Wang, (*Presenter*) Nothing to Disclose

PURPOSE

To determine whether matrix metalloproteinase (MMP) inhibitor batimastat (BB-94) could inhibit the progression of liver tumor after radiofrequency ablation (RFA) and achieve better therapeutic efficacy in an animal model.

METHODS AND MATERIALS

In vitro experiments, the proliferation of H22 cells was detected by CCK8 method and cell migration was detected by Transwell method. Next, H22 murine liver tumors were used for in vivo experiments. First, 32 mice with one tumor were randomized into four groups (n=8 each group): control (PBS only), RFA alone (65?, 5min), BB-94 (30 mg/kg), RFA+BB-94. The growth rate of the residual tumor and the end point survival were estimated and the pathologic changes were compared. Secondly, a total of 48 tumors in 24 animals were randomized into three groups (n= 8 each group): control (PBS only), RFA alone, RFA+BB-94. Each mouse was implanted two tumors subcutaneously, one tumor was ablated and the other was evaluated for distant metastasis after applying BB-94.

RESULTS

In vitro, the proliferation assay demonstrated that the H22 cells had significantly higher proliferation rate in the heat group than the control group (1.27±0.08 vs 0.82±0.07, P=0.008), and it could be inhibited by BB-94 (0.67±0.06 vs 0.37±0.01, P=0.015). In the cell migration assay, the H22 cells demonstrated enhanced invasive ability after heat experiment (33.7±2.1 vs 19.7±4.9, P=0.011). And it could be significantly suppressed after treated with BB-94 (32.3±3.5 vs 23.0±4.6, P=0.009). With one tumor animal, the growth rate of the residual tumor in the BB-94+RFA group was slower than that in the RFA alone group (P=0.003). And combination of BB-94 could significantly prolong the survival of the mice (40.3±1.4d vs 47.1±1.3d, P =0.002). The expression of MM9, Collagen I and VEGF at the coagulation margin were decreased after combined with BB-94. With two tumors animal, the tumor growth rate of metastasis tumor in the BB-94+RFA group was lower than that in the RFA group (P<0.001).

CONCLUSION

s BB-94 combined with RFA reduced the invasiveness of the tumor and improved the endpoint survival. It also helped to suppress the growth rate of metastasis tumor after RFA.

CLINICAL RELEVANCE/APPLICATION

Our data suggested that targeting the MMP process with the specific inhibition could increase overall ablation efficacy.

T5B-SPIR-7 Can Two-step Ablation Combined with Chemotherapeutic Liposomes Achieve Better Outcome Than Traditional RF Ablation? A Solid Tumor Animal Study

Participants
Kun Zhao, (*Presenter*) Nothing to Disclose

PURPOSE

To determine whether two-step ablation using sequential low and high temperature heating can achieve improved outcomes in animal tumor models when combined with chemotherapeutic liposomes (LP).

METHODS AND MATERIALS

Balb/c mice bearing 4T1 tumor received paclitaxel-loaded liposomes followed 24hr later by either traditional RFA (70°C, 5min) or a low temperature RFA (45°C, 5min), or two-step RFA (45°C 2min+70°C 3min). Intratumoral drug accumulation and bio-distribution in major organs were evaluated. Periablational drug penetration was evaluated by pathologic staining and intratumoral interstitial fluid pressure (IFP) measured directly. For long-term outcomes, mice bearing 4T1 or H22 tumors were randomized into five groups (n = 8/group): control (no treatment), RFA alone, LP+RFA (45°C), LP+RFA (70°C) and LP+RFA (45+70°C). End-point survivals were compared among the different groups.

RESULTS

The greater intratumoral drug accumulation (3.35±0.32 vs 3.79±0.29 x108phot/cm2/s at 24hr, p=0.09), deeper periablational drug penetration (45.7±5.0 vs 1.6±0.5, p<0.001), and reduced off-target drug deposition in major organs (liver 96.1±31.6 vs 47.4±1.5 x106phot/cm2/s, p<0.001) were found when combined with RFA (45°C) compared to drug alone. For long-term outcomes, 4T1 tumor growth rates for LP+ two-step RFA (45+70°C) were significantly slower than LP+RFA (70°C), LP+RFA (45°C), and RFA alone (P<0.01 for all comparisons). End point survival for LP+ RFA (45+70°C) was also longer than for LP+RFA (70°C) (median 16 vs 10 days, p=0.003) or LP+RFA 45°C (11 days, p=0.009), RFA alone (8.3 days, p<0.001) in H22 tumor models. The intratumoral IFP after RFA (45°C) was significantly lower than baseline RFA (5.4±3.6 vs 23.0±8.0 mmHg, p<0.001), but was not measurable after RFA (70°C).

CONCLUSION

s A two-step ablation combined with chemotherapeutic liposomes can achieve better survival benefit compared to traditional RFA in animal models.

CLINICAL RELEVANCE/APPLICATION

Two-step ablation of initial moderate hyperthermia followed by coagulative ablation temperatures combined with intravenous administration of chemotherapeutic liposomes can achieve a better outcome over single dose traditional high temperature ablation based upon the premise of greater drug accumulation and penetration. These results may provide a useful method for improving therapy outcome in clinical practice.

T5B-SPIR-8 Visualizing Recovery: Feasibility of Accelerometer-based Biometric Data Collection Among Interventional Oncology Patients

Participants
Nicole Kim, BS, (*Presenter*) Nothing to Disclose

PURPOSE

The use of image-guided locoregional therapies (LRT) for the treatment of cancer holds several advantages over surgical interventions, including fewer hospitalizations and low complication rates. While shorter time to recovery is another theoretical benefit, recovery following LRT often takes place in the outpatient setting and patient health trajectories during this period are not well understood. This pilot study tested the feasibility of measuring post-LRT patient recovery using wearable accelerometer technology (WAT).

METHODS AND MATERIALS

Adult cancer patients referred to undergo LRT procedures were enrolled during their pre-procedural consultation visits in a dedicated interventional oncology clinic. All patients were provided with a Fitbit® Inspire 2 device to wear for 7-14 days prior to their interventional oncology procedure (baseline phase) and for 30 days thereafter (recovery phase). WAT-derived step count was continuously recorded throughout the study period. Post-procedure "recovery" was defined as a return to the baseline daily step count during the recovery phase after LRT. Patient responses to the RAND 36-Item Short Form (SF-36) Health Survey were also collected at enrollment, on the procedure day, and at 30-day follow-up to assess for changes over time. An interrupted time series design was used wherein pre- and post-LRT step count and SF-36 metrics were compared using cubic spline mixed modeling. Significance was set at p<0.05.

RESULTS

Twenty adult cancer patients were enrolled, and 18 completed the study (14 ablation, 4 embolization). Median age was 73 years (range 59-89 years; 67% male). Most patients wore the Fitbit devices without significant interruptions for the duration of the study period, and all completed the SF-36 surveys. Analysis of WAT-derived biometric data demonstrated a mean of 4850 (95% CI [4080, 5621]) steps taken during the baseline phase across all patients. Step count decreased to 2000 immediately following LRT, then steadily increased to 4568 (95% CI [3715, 5421]) steps, achieving a "recovery" plateau after an average of 10 days (p<0.001). The SF-36 survey did not reliably capture patient recovery data; no significant change was observed between initial and follow-up assessments (p>0.10).

CONCLUSION

s WAT effectively captures dynamic peri-procedural biophysical parameters not reflected in standard survey-based monitoring and can be reliably implemented to monitor patient recovery following interventional oncology procedures.

CLINICAL RELEVANCE/APPLICATION

Characterization of recovery following various interventional oncology procedures could facilitate appropriate intervention in patients with poor post-procedural progression and better inform treatment recommendations.

T5B-SPIR-9 MR-guided High Intensity Focused Ultrasound (MRgHIFU) in The treatment of Bone Metastases: Safety of Sensitive Structures Within 1 cm from Target Lesion

Awards
Trainee Research Prize - Resident

Participants
Valerio D'Agostino, MD, (*Presenter*) Nothing to Disclose

PURPOSE

A distance greater than 1 cm between the target lesion and sensitive structures is highly recommended in MRgHIFU treatments of bone lesions. The aim of this work was to evaluate the safety of MRgHIFU treatment for pain palliation of bone metastases involving regions close to (lt1cm) sensitive structures.

METHODS AND MATERIALS

101 patients (56% female, 44% male; mean age 55±15,4) with 141 bone metastases were treated by MRgHIFU. Close proximity between the target lesion and sensitive structures (skin, nerves, vessels, sensitive organs) was measured on pre-treatment MR images, and metastases were divided in two groups according to this (> 1 cm distance - group A, < 1 cm - group B). VAS score at baseline, and at 3 and 6 months after treatment was assessed in all patients. MR/CT imaging was performed before and 3-6 months after treatment, in order to assess local tumour control according to MD Anderson criteria. Primary endpoint was the rate of major and minor complications on sensitive structures, according to the common terminology criteria for adverse events, version 5.0. Secondary endpoints included the assessment of the impact of such proximity (lesion to sensitive structures) on response to treatment - treatment efficacy.

RESULTS

141 metastases were submitted to MRgHIFU (primary tumors: 33,5% breast, 13% prostate, 12,7% kidney, 40,8% others). 85 metastases were included in group A. Close proximity between the target lesion and sensitive structures was recorded for 56 metastases (6 skin, 22 nerves, 17 vessels, 6 sensitive organs - 11 with combined conditions) - group B. 1 case of Grade 1 Burn (group A) and 1 case of Grade 1 Prostatic Pain (group B) were observed. VAS at baseline was 5.9±2,7, with a significant reduction at 3 months (2,57±2.5, p lt0.0001) and at 6 months (2,82±2,83, p lt0.0001). Complete follow-up at 3 and 6 months after treatment was available for 61 patients. Complete response was observed in 16 cases, partial response in 18, stability in 23 and progression in 4 patients. Location in proximity of sensitive structures did not affect the outcome of treatments, as there was no statistically significant difference in both safety and efficacy between the two groups of patients.

CONCLUSION

s MRgHIFU can be safely and effective performed even on lesions located at lt1 cm from sensitive structures.

CLINICAL RELEVANCE/APPLICATION

A distance lt1 cm from sensitive structures of the target lesion is considered an exclusion criterion for MRgHIFU treatment.The results of this study suggest the need for revision of MRgHIFU's exclusion criteria, in clinical practice and research.

Bare Metallic Stent as Salvage Treatment for Refractory Benign Biliary Strictures After Pediatric Liver Transplantation: Preliminary Experience in A Single-center Cohort

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - IR DPS

Participants
Ludovico Dulcetta, MD, Bergamo, Italy (*Presenter*) Nothing to Disclose

PURPOSE

Liver transplant (LT) is the standard of care for pediatric patients with end-stage liver disease or congenital metabolic disorders. Biliary complications, in particular benign strictures, are a common cause of morbidity and graft dysfunction. Anastomotic and intrahepatic strictures frequently relapse after the standard percutaneous management with bilioplasty and surgical revision.The aim is to describe preliminary experience with metallic stent as salvage treatment in selected patients before relisting for retransplantation.

METHODS AND MATERIALS

Eight pediatric patients (3 female; mean age 20 months) after split left LT with refractory biliary strictures were treated with percutaneous transhepatic implantation of vascular balloon-expandable or biliary self-expandable bare metallic stents. Indications for stenting were signs of mechanical cholestasis and fibrosis at liver biopsy and failure of standard management with percutaneous transhepatic bilioplasty and/or surgical revision.

RESULTS

A total of 18 stents (3 biliary, 15 vascular) were implanted. Technical success was 100% without adverse events. A single anastomotic stent was used in 3 patients. Two parallel stents with the kissing-balloon technique to cover the confluence between segments 2 and 3 were implanted in 6 patients. In 1 patient 3 stents were imbricated due to incomplete coverage of the stenosis. Before stents implantation a mean of 3.6 PTC per patient was performed (7.8 months follow-up); after stents implantation a mean of 0.6 PTC (13.1 months follow-up). In one case stent patency was observed after 9 years.

CONCLUSION

s Preliminary data suggest that after pediatric LT, relapsing biliary strictures could be safely treated with metallic stents to reduce numbers of interventional procedures before surgical anastomosis revision or retransplantation.

CLINICAL RELEVANCE/APPLICATION

Although metal stents are intended for palliation in malignant biliary pathology, they could be considered to improve cholestatic symptoms in retransplantation waitlist.

Combined Microwave Ablation plus Osteosynthesis for Long Bone Metastases

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - IR DPS

Participants
Claudio Pusceddu, MD, (*Presenter*) Nothing to Disclose

PURPOSE

to evaluate the feasibility, safety and efficacy of microwave ablation (MWA) in combination with open surgery nail positioning for the treatment of fractures or impending fractures of long bone metastases.

METHODS AND MATERIALS

Eleven patients (four men, seven women) with painful bone metastases of the humerus, femur ortibia with non-displaced fractures (one case) or impending fractures (10 cases) underwent open MWA in combination with osteosynthesis by locked nail positioning. Pain intensity was measured using a VAS score before and after treatment. CT or MRI were acquired at one month before and 1, 3, 6, 12 and 18 months after treatment.

RESULTS

All procedures were successfully completed without major complications. The level of pain was significantly reduced one month after treatment. For the patients with humerus metastases, the complete recovery of arm use took 8 weeks, while for the patients with femoral metastases the complete recovery of walking capacity took 11 weeks. The VAS score ranged from 7 (4-9) before treatment to 1.5 (0-2.5) after treatment. During a mid-term follow-up of 18 months (range 4-29 months), none of the patients showed tumor relapse or new fractures in the treated site. Two patients died due to tumor disease progression.

CONCLUSION

s Results of this preliminary study suggest that combined MWA and surgical osteosynthesis with locked nails is a safe and effective treatment for pathological fractures or malignant impending fractures of long bone metastases of the humerus, femur and tibia. Further analyses with larger cohorts are warranted to confirm these findings.

CLINICAL RELEVANCE/APPLICATION

Combined ablation and osteosynthesis treatment of long bone metastases may improve survival in patients with cancer

CT-based Radiomics Models May Predict the Early Efficacy of Microwave Ablation in Malignant Lung Tumors

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - IR DPS

Participants
Fandong Zhu, Shaoxing, China (*Presenter*) Nothing to Disclose

PURPOSE

To establish and validate a radiomics model for predicting the early efficacy of microwave ablation (MWA) in malignant lung tumors.

METHODS AND MATERIALS

The study enrolled 104 malignant lung tumor patients (72 in the training cohort and 32 in the validation cohort) treated with MWA. Post-operation CT images were analyzed. To evaluate the therapeutic effect of ablation, three models were constructed by least absolute shrinkage and selection operator and logistic regression: the tumoral radiomics (T-RO), peritumoral radiomics (P-RO), and tumoral-peritumoral radiomics (TP-RO) models. Univariate and multivariate analyses were performed to identify clinical variables and radiomics features associated with early efficacy, which were incorporated into the combined nomogram (C-RO). The performance of the C-RO model was evaluated by the area under the receiver operating characteristic curve (AUC), calibration curve, and decision curve analysis. The efficacy of the C-RO model was quantified using the Cox regression model.

RESULTS

Four radiomics features were selected from the region of interest of tumor and peritumor CT images, which showed good performance for evaluating prognosis and early efficacy in two cohorts. The C-RO model was better than the T-RO model (AUC in training, 0.913 vs. 0.784; P = 0.055), P-RO model (AUC in training, 0.913 vs. 0.740; P = 0.027) and the TP-RO model (AUC in training, 0.913 vs. 0.814; P=0.130). Decision curve analysis (DCA) confirmed the clinical benefit of the radiomics nomogram. Survival analysis revealed that in the C-RO model, the low-risk groups defined by best cutoff value had significantly better progression-free survival than the high-risk groups (P<0.05).

CONCLUSION

s CT-based radiomics in malignant lung tumor patients after MWA could be useful for individualized risk classification and treatment.

CLINICAL RELEVANCE/APPLICATION

Traditional imaging methods lack sensitivity and specificity to evaluate the early efficacy of microwave ablation. The aim of this study was to evaluate tumor and peritumor radiomics-based models and their potential to predict the early efficacy of MWA in malignant lung tumors. The model constructed by integrating radiomics features extracted from the ROI in tumoral and peritumoral areas and clinical risk factors showed a stable and excellent predictive performance, providing a non-invasive and repeatable method to evaluate the outcomes of MWA.

T5B-SPIR-4

Ability of the Renal Ablation-Specific (MC)2 Risk Scoring System to Predict Major Complications from Percutaneous Renal Microwave Ablation

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - IR DPS

Participants
Cody Savage, BS, Tuscaloosa, AL (*Presenter*) Nothing to Disclose

PURPOSE

The (MC)2 score is a renal-ablation specific risk scoring system originally developed to predict major complications from percutaneous renal cryoablation. However, this scoring system has not been applied to patients undergoing percutaneous renal microwave ablation (MWA). The aim of this study is to access the ability of the (MC)2 scoring system to identify patients at risk for major complications of percutaneous renal MWA.

METHODS AND MATERIALS

Retrospective review of all adult patients who underwent percutaneous renal MWA at two centers from 2009-2018. Patient demographics, medical histories, laboratory work, technical details of the procedure, tumor characteristics, and clinical outcomes were collected. The (MC)2 score was calculated for each patients. Patients were assigned to low-risk (<5), moderate-risk (5-8) and high-risk (>8) groups. Complications were graded according to CIRSE guidelines.

RESULTS

A total of 116 patients (M=66; F=50; median age=63 (range: 34-81)) were included. 11 (9.5%) and 23 (19.8%) experienced major or minor complications, respectively. Patients who developed major complications had a mean tumor diameter of 3.0 mm (± 1.4). In this group, 21 patients (18.1%) had a central tumor, 20 patients (17.2%) had complicated diabetes, and 14 patient (12.1%) had a prior myocardial infarction. Among the low-risk, moderate-risk, and high-risk groups, the major complication rate was 7.8%, 13.2%, and 0%, respectively. The mean (MC)2 score for patients with major complications (4.8 (± 1.8)) was not higher than those with either minor complications (4.1 (± 1.6)) (p= 0.49) or no complications (3.7 (± 1.5)) (p= 0.10). The area under the ROC curve to predict major complications was 0.64, indicating a poor ability to predict major complications in this cohort. However, mean tumor size was greater in patients with major complications than those with minor complications (p=0.01).

CONCLUSION

s The (MC)2 risk scoring system does not accurately identify patients at risk for major complications from percutaneous renal MWA. The mean tumor size alone may serve as a better indicator for risk assessment of major complications.

CLINICAL RELEVANCE/APPLICATION

Unlike in percutaneous renal cryoablation, the (MC)2 scoring system is not effective at predicting which patients will develop major complications following percutaneous renal MWA. As such, risk stratification systems specific to the treatment modality need to be developed to accurately predict a patient's risk of major complications.

Preliminary Results Developing a Novel Ex Vivo Human Liver Model to Investigate Microwave Ablation

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - IR DPS

Participants
Carlos Ortiz, MD, San Antonio, TX (*Presenter*) Consultant, Argon Medical Devices, Inc

PURPOSE

We aim to develop a novel dual-perfused ex vivo model using explanted human research livers to investigate microwave ablation (MWA).

METHODS AND MATERIALS

Five explanted research livers (3 cirrhotic and 2 > 50% steatosis) were obtained under research consent. Each organ was recovered from a brain-dead human deceased donor by a transplant surgeon using standard surgical and preservation techniques. This study consists of three components: 1) develop a physiologic ex vivo model to perfuse human research livers, 2) use the model to assess the impact of perfusion mediated tissue cooling on MWA ablation measurements in a human model, and 3) compare observed ex vivo results to manufacturer reference data from nonperfused animal organs. A total of 27 ablations (12 perfused and 15 nonperfused) were performed at 140W for 6 minutes using a MWA system (Angiodynamics Solero). Pre- and post-ablation arteriogram, portal venogram, and cholangiogram were obtained. Ablations were sectioned along the probe trajectory to obtain maximal long axis diameter (LAD) and short axis diameter (SAD) for the zone of coagulation. Ellipsoid volume and sphericity were calculated. Standard statistical analysis was performed.

RESULTS

Continuous bile production was observed in three viable livers (60%), including one cirrhotic liver. Perfused ablations resulted in significantly smaller ablation dimensions than nonperfused ablations with average gross specimen MWA comparisons as follows (12 perfused ablations vs 15 nonperfused ablations, two-tailed t-test): SAD, 3.2 ± 0.4 cm vs 4.1 + 0.5 cm ($p < 0.001$); LAD, 5.1 ± 0.3 cm vs 6.1 ± 0.4 cm ($p < 0.001$); volume, 27.3 ± 8.6 mL vs 54.3 ± 12.7 mL ($p < 0.001$); sphericity, 0.40 ± 0.10 vs 0.45 ± 0.10 ($p = 0.19$). No significant differences were observed in organ temperature and maximal probe wattage for perfused and nonperfused ablations. Comparing nonperfused ablations to manufacturer data, there were significant differences in LAD, SAD, and sphericity (one sample t-test, $p < 0.05$). Comparing perfused ablations to manufacturer data, there were significant differences in LAD, SAD, volume, and sphericity (one sample t-test, all $p < 0.001$). Post-ablation arteriograms demonstrated no contrast extravasation and a new arteriovenous fistula in a single organ.

CONCLUSION

s The presence of perfusion significantly decreases MWA measurements in human livers. At a single device setting, significant differences in MWA measurements are seen in human livers compared to nonperfused manufacturer data.

CLINICAL RELEVANCE/APPLICATION

This ex vivo model allows for improved characterization of ablation measurements utilizing organs donated for medical research. An ex vivo human model could decrease variability between MWA reference data and clinical results.

T5B-SPIR-6

Specific Inhibitor of MMP Decrease Tumor Invasiveness After Radiofrequency Ablation in Liver Tumor Animal Model

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - IR DPS

Participants
Bing Wang, (*Presenter*) Nothing to Disclose

PURPOSE

To determine whether matrix metalloproteinase (MMP) inhibitor batimastat (BB-94) could inhibit the progression of liver tumor after radiofrequency ablation (RFA) and achieve better therapeutic efficacy in an animal model.

METHODS AND MATERIALS

In vitro experiments, the proliferation of H22 cells was detected by CCK8 method and cell migration was detected by Transwell method. Next, H22 murine liver tumors were used for in vivo experiments. First, 32 mice with one tumor were randomized into four groups (n=8 each group): control (PBS only), RFA alone (65?, 5min), BB-94 (30 mg/kg), RFA+BB-94. The growth rate of the residual tumor and the end point survival were estimated and the pathologic changes were compared. Secondly, a total of 48 tumors in 24 animals were randomized into three groups (n= 8 each group): control (PBS only), RFA alone, RFA+BB-94. Each mouse was implanted two tumors subcutaneously, one tumor was ablated and the other was evaluated for distant metastasis after applying BB-94.

RESULTS

In vitro, the proliferation assay demonstrated that the H22 cells had significantly higher proliferation rate in the heat group than the control group (1.27±0.08 vs 0.82±0.07, P=0.008), and it could be inhibited by BB-94 (0.67±0.06 vs 0.37±0.01, P=0.015). In the cell migration assay, the H22 cells demonstrated enhanced invasive ability after heat experiment (33.7±2.1 vs 19.7±4.9, P=0.011). And it could be significantly suppressed after treated with BB-94 (32.3±3.5 vs 23.0±4.6, P=0.009). With one tumor animal, the growth rate of the residual tumor in the BB-94+RFA group was slower than that in the RFA alone group (P=0.003). And combination of BB-94 could significantly prolong the survival of the mice (40.3±1.4d vs 47.1±1.3d, P =0.002). The expression of MM9, Collagen I and VEGF at the coagulation margin were decreased after combined with BB-94. With two tumors animal, the tumor growth rate of metastasis tumor in the BB-94+RFA group was lower than that in the RFA group (P<0.001).

CONCLUSION

s BB-94 combined with RFA reduced the invasiveness of the tumor and improved the endpoint survival. It also helped to suppress the growth rate of metastasis tumor after RFA.

CLINICAL RELEVANCE/APPLICATION

Our data suggested that targeting the MMP process with the specific inhibition could increase overall ablation efficacy.

T5B-SPIR-7

Can Two-step Ablation Combined with Chemotherapeutic Liposomes Achieve Better Outcome Than Traditional RF Ablation? A Solid Tumor Animal Study

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - IR DPS

Participants
Kun Zhao, (*Presenter*) Nothing to Disclose

PURPOSE

To determine whether two-step ablation using sequential low and high temperature heating can achieve improved outcomes in animal tumor models when combined with chemotherapeutic liposomes (LP).

METHODS AND MATERIALS

Balb/c mice bearing 4T1 tumor received paclitaxel-loaded liposomes followed 24hr later by either traditional RFA (70°C, 5min) or a low temperature RFA (45°C, 5min), or two-step RFA (45°C 2min+70°C 3min). Intratumoral drug accumulation and bio-distribution in major organs were evaluated. Periablational drug penetration was evaluated by pathologic staining and intratumoral interstitial fluid pressure (IFP) measured directly. For long-term outcomes, mice bearing 4T1 or H22 tumors were randomized into five groups (n = 8/group): control (no treatment), RFA alone, LP+RFA (45°C), LP+RFA (70°C) and LP+RFA (45+70°C). End-point survivals were compared among the different groups.

RESULTS

The greater intratumoral drug accumulation (3.35±0.32 vs 3.79±0.29 x108phot/cm2/s at 24hr, p=0.09), deeper periablational drug penetration (45.7±5.0 vs 1.6±0.5, p<0.001), and reduced off-target drug deposition in major organs (liver 96.1±31.6 vs 47.4±1.5 x106phot/cm2/s, p<0.001) were found when combined with RFA (45°C) compared to drug alone. For long-term outcomes, 4T1 tumor growth rates for LP+ two-step RFA (45+70°C) were significantly slower than LP+RFA (70°C), LP+RFA (45°C), and RFA alone (P<0.01 for all comparisons). End point survival for LP+ RFA (45+70°C) was also longer than for LP+RFA (70°C) (median 16 vs 10 days, p=0.003) or LP+RFA 45°C (11 days, p=0.009), RFA alone (8.3 days, p<0.001) in H22 tumor models. The intratumoral IFP after RFA (45°C) was significantly lower than baseline RFA (5.4±3.6 vs 23.0±8.0 mmHg, p<0.001), but was not measurable after RFA (70°C).

CONCLUSION

s A two-step ablation combined with chemotherapeutic liposomes can achieve better survival benefit compared to traditional RFA in animal models.

CLINICAL RELEVANCE/APPLICATION

Two-step ablation of initial moderate hyperthermia followed by coagulative ablation temperatures combined with intravenous administration of chemotherapeutic liposomes can achieve a better outcome over single dose traditional high temperature ablation based upon the premise of greater drug accumulation and penetration. These results may provide a useful method for improving therapy outcome in clinical practice.

Visualizing Recovery: Feasibility of Accelerometer-based Biometric Data Collection Among Interventional Oncology Patients

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - IR DPS

Participants
Nicole Kim, BS, (*Presenter*) Nothing to Disclose

PURPOSE

The use of image-guided locoregional therapies (LRT) for the treatment of cancer holds several advantages over surgical interventions, including fewer hospitalizations and low complication rates. While shorter time to recovery is another theoretical benefit, recovery following LRT often takes place in the outpatient setting and patient health trajectories during this period are not well understood. This pilot study tested the feasibility of measuring post-LRT patient recovery using wearable accelerometer technology (WAT).

METHODS AND MATERIALS

Adult cancer patients referred to undergo LRT procedures were enrolled during their pre-procedural consultation visits in a dedicated interventional oncology clinic. All patients were provided with a Fitbit® Inspire 2 device to wear for 7-14 days prior to their interventional oncology procedure (baseline phase) and for 30 days thereafter (recovery phase). WAT-derived step count was continuously recorded throughout the study period. Post-procedure "recovery" was defined as a return to the baseline daily step count during the recovery phase after LRT. Patient responses to the RAND 36-Item Short Form (SF-36) Health Survey were also collected at enrollment, on the procedure day, and at 30-day follow-up to assess for changes over time. An interrupted time series design was used wherein pre- and post-LRT step count and SF-36 metrics were compared using cubic spline mixed modeling. Significance was set at $p<0.05$.

RESULTS

Twenty adult cancer patients were enrolled, and 18 completed the study (14 ablation, 4 embolization). Median age was 73 years (range 59-89 years; 67% male). Most patients wore the Fitbit devices without significant interruptions for the duration of the study period, and all completed the SF-36 surveys. Analysis of WAT-derived biometric data demonstrated a mean of 4850 (95% CI [4080, 5621]) steps taken during the baseline phase across all patients. Step count decreased to 2000 immediately following LRT, then steadily increased to 4568 (95% CI [3715, 5421]) steps, achieving a "recovery" plateau after an average of 10 days ($p<0.001$). The SF-36 survey did not reliably capture patient recovery data; no significant change was observed between initial and follow-up assessments ($p>0.10$).

CONCLUSION

s WAT effectively captures dynamic peri-procedural biophysical parameters not reflected in standard survey-based monitoring and can be reliably implemented to monitor patient recovery following interventional oncology procedures.

CLINICAL RELEVANCE/APPLICATION

Characterization of recovery following various interventional oncology procedures could facilitate appropriate intervention in patients with poor post-procedural progression and better inform treatment recommendations.

MR-guided High Intensity Focused Ultrasound (MRgHIFU) in The treatment of Bone Metastases: Safety of Sensitive Structures Within 1 cm from Target Lesion

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - IR DPS

Awards
Trainee Research Prize - Resident

Participants
Valerio D'Agostino, MD, (*Presenter*) Nothing to Disclose

PURPOSE

A distance greater than 1 cm between the target lesion and sensitive structures is highly recommended in MRgHIFU treatments of bone lesions. The aim of this work was to evaluate the safety of MRgHIFU treatment for pain palliation of bone metastases involving regions close to (lt1cm) sensitive structures.

METHODS AND MATERIALS

101 patients (56% female, 44% male; mean age 55±15,4) with 141 bone metastases were treated by MRgHIFU. Close proximity between the target lesion and sensitive structures (skin, nerves, vessels, sensitive organs) was measured on pre-treatment MR images, and metastases were divided in two groups according to this (> 1 cm distance - group A, < 1 cm - group B). VAS score at baseline, and at 3 and 6 months after treatment was assessed in all patients. MR/CT imaging was performed before and 3-6 months after treatment, in order to assess local tumour control according to MD Anderson criteria. Primary endpoint was the rate of major and minor complications on sensitive structures, according to the common terminology criteria for adverse events, version 5.0. Secondary endpoints included the assessment of the impact of such proximity (lesion to sensitive structures) on response to treatment - treatment efficacy.

RESULTS

141 metastases were submitted to MRgHIFU (primary tumors: 33,5% breast, 13% prostate, 12,7% kidney, 40,8% others). 85 metastases were included in group A. Close proximity between the target lesion and sensitive structures was recorded for 56 metastases (6 skin, 22 nerves, 17 vessels, 6 sensitive organs - 11 with combined conditions) - group B. 1 case of Grade 1 Burn (group A) and 1 case of Grade 1 Prostatic Pain (group B) were observed. VAS at baseline was 5.9±2,7, with a significant reduction at 3 months (2,57±2.5, p lt0.0001) and at 6 months (2,82±2,83, p lt0.0001). Complete follow-up at 3 and 6 months after treatment was available for 61 patients. Complete response was observed in 16 cases, partial response in 18, stability in 23 and progression in 4 patients. Location in proximity of sensitive structures did not affect the outcome of treatments, as there was no statistically significant difference in both safety and efficacy between the two groups of patients.

CONCLUSION

s MRgHIFU can be safely and effective performed even on lesions located at lt1 cm from sensitive structures.

CLINICAL RELEVANCE/APPLICATION

A distance lt1 cm from sensitive structures of the target lesion is considered an exclusion criterion for MRgHIFU treatment.The results of this study suggest the need for revision of MRgHIFU's exclusion criteria, in clinical practice and research.

T5B-SPMK-2 Voriconazole-induced Periostitis: Clinical, Laboratory and Imaging Features

Participants
Alwalid Ashmeik, MD, San Francisco, CA (*Presenter*) Nothing to Disclose

PURPOSE

There are several case reports of voriconazole-induced periostitis (VIP) developing in patients on chronic voriconazole therapy. However, studies have been limited by small sample sizes and variable radiological findings between cases. The goal of this study is to better characterize the clinical, laboratory and radiologic findings of VIP.

METHODS AND MATERIALS

100 participants with voriconazole use were identified using a PACS search tool. Health record data including age, gender, alkaline phosphatase (ALP) and voriconazole dose and treatment duration were collected. All imaging studies during the duration of treatment were reviewed by two radiology trainees and imaging features of VIP were confirmed by a board-certified musculoskeletal radiologist. Size, location and morphology of VIP lesions were recorded. Incident VIP was defined as new periostitis or enthesitis on imaging after 28 days or more of voriconazole treatment in the absence of an alternative diagnosis. Cumulative dose was calculated as the summation of daily dose from the date of initiation until the date of incident VIP. Differences in group characteristics were assessed using independent t-tests for continuous variables or chi-square tests for categorical variables. Firth's logistic regression models were performed using standardized values for cumulative voriconazole dose, treatment duration and ALP as predictors and incident VIP as the outcome.

RESULTS

Compared to participants without VIP (N = 91), participants with VIP (N = 9) had higher age (61.2 vs 42.0 years, P = 0.02), cumulative voriconazole dose (356.5 vs 136.4 g, P = 0.005), treatment duration (884.6 vs 322.6 days, P = 0.002) and ALP (300.8 vs 159.1 U/L, P = 0.003). There were 97 lesions with a mean length of 33.8 (SD 26.2) mm. The most common lesion location in the body was the hand (28.9%) and morphology was solid (37%). A one standard deviation increase in cumulative voriconazole dose (225.2 g) was associated with 80% higher odds of VIP (P = 0.01). A one standard deviation increase in treatment duration (537 days) was associated with 82% higher odds of VIP (P = 0.008). A one standard deviation increase in ALP (214.4 U/L) was associated with 88% higher odds of VIP (P = 0.01).

CONCLUSION

s Participants with VIP were older and had higher cumulative voriconazole dose, treatment duration and ALP compared with those that did not have VIP. Furthermore, increased cumulative voriconazole dose, treatment duration and ALP were associated with higher odds of VIP.

CLINICAL RELEVANCE/APPLICATION

VIP is an important entity for radiologists to recognize. A greater understanding of the clinical, laboratory and imaging features of this condition is essential given that voriconazole discontinuation is effective at reversing the disease course.

T5B-SPMK-3 Automated Deep Learning Tool for Volumetric Assessment of Abdominal Muscle Mass on CT

Participants
Phuong Vu, Philadelphia, PA (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this study was to develop a convolutional neural network (CNN) to automatically determine lean abdominal muscle volume for individual muscle groups using computed tomography (CT) for the diagnosis and assessment of sarcopenia.

METHODS AND MATERIALS

This retrospective study was conducted using the Penn Medicine BioBank (PMBB), a single-institutional research protocol that recruits adult participants during outpatient visits, including 34,150 patients for whom 186,721 CTs and years of detailed electronic health record, genomic, and laboratory data were collected. We developed a deep residual U-Net (ResUNet) using Pytorch to segment 12 abdominal muscle groups and determine lean muscle volume from CT scans. 105 CT studies were randomly selected to train the network; of these, 10 were used to teach Penn undergraduate students to label muscle groups. This dataset was enriched with 20 sets of 3 studies specific to different intra-abdominal pathologies (ventral hernia, abdominal abscess, etc.). Students labeled all 165 studies, encompassing 3300 axial CT slices and 980 labels, later verified and revised by a board-certified abdominal radiologist and physicist (H.S. and W.R.W.). The 165 accessions were divided into non-overlapping training (70%), validation (20%) and testing (10%) sets. Model performance was evaluated using the Sørensen-Dice coefficient.

RESULTS

The model's performance (Dice scores) on the test data was (P, psoas): 0.85±0.12, (QL, quadratus lumborum): 0.72±0.14, (ES, erector spinae): 0.91±0.07, (GM, gluteus medius): 0.90±0.08, (RA, rectus abdominus): 0.85±0.08, (LA, lateral abdominals): 0.85±0.09. The average Dice score across all muscle groups was 0.86±0.05. The addition of residual units to the CNN significantly reduced the time to model convergence and increased the validation Dice scores.

CONCLUSION

s These preliminary findings show that our CNN can automate detailed abdominal muscle volume measurement. Unlike prior efforts which only provided 2D information and did not distinguish between muscle groups, this technique provides 3D muscle segmentations of individual muscles

CLINICAL RELEVANCE/APPLICATION

Sarcopenia is a prevalent but challenging diagnosis with far-reaching clinical and public health implications. There are currently no tools for direct 3D volumetric assessment of individual abdominal muscle mass.The CNN model we developed will dramatically impact sarcopenia diagnosis and research, elucidating its clinical and public health implications. Our overarching goal is to investigate genetic variants for sarcopenia and malnutrition, while describing genotype—phenotype associations of muscle mass in healthy humans using imaging-derived phenotypes

T5B-SPMK-4 Femoral Version: Reliable and Reproducible MRI Measurement Compared to CT Using Fast 3D T1 Images Without Leg Holder

Awards
Trainee Research Prize - Resident

Participants
Till Lerch, MD, PhD, Bern, Switzerland (*Presenter*) Nothing to Disclose

PURPOSE

Femoroacetabular Impingement (FAI) is a known cause for hip pain in young patients. Abnormal femoral version(FV) has been associated with extraarticular hip impingement. Variations in acquisition technique were subject of controversy for MRI-based measurement of FV. Knee bolstering is commonly used for MRI but could introduce bias to FV measurement.MRI- and CT-based measurements of FV were compared.Purposes (1)What is the reliability in terms of mean difference and correlation with and without bolstering? (2)What is the mean difference and correlation between two readers?

METHODS AND MATERIALS

A retrospective IRB approved comparative radiologic study involving a total of 100 hips was performed. Of them, 52 hips (46 patients) underwent standard MRI with a knee bolstering, while 48 hips had no knee bolstering and additional MRI sequence.All patients (100 hips) had symptomatic FAI (mean age of 28±10 years). All patients underwent pelvic CT scan and MRI of the same hip joint (2016-2019). Mean interval time between CT and MRI was 20 days. In addition to the routine unilateral, multiplanar protocol for chondrolabral lesions, bilateral fast T1 VIBE Dixon of the pelvis and of the knee was acquired (acquisition time less than 1 minute) for 48 hips without bolstering to measure FV. Two readers independently measured FV on both CT and MRI scans on two separate sessions (Murphy method). Correlation between CT and MRI was assessed using Pearson correlation coefficient.

RESULTS

(1) Mean absolute difference between MRI with bolstering and CT-based measurements of FV of 52 hips was 6.0°±3 (-10-7) for Reader 1 and 8.4°±5 (-21-12) for Reader 2 . Mean absolute difference between MRI without bolstering and CT- based measurements of FV of 48 hips decreased to 1.3°±0.8(0.2-3.0) for Reader 1 and 2.3°±1.9(0-10) for Reader 2. Correlation of FV between MRI without bolstering and CT-based measurements was r=0.993 ($p<0.001$) for reader 1 and was r=0.975 ($p<0.001$) for reader 2. (2) Mean absolute difference of CT-based measurements of FV between two readers was 2.9°±2 (-0-8) and correlation was r=0.969 ($p<0.001$). Mean difference of MRI-based measurements without bolstering of FV between two readers was 3.3°±3 (0-10) and correlation was r=0.943 ($p<0.001$).

CONCLUSION

s MRI-based measurement of FV is as accurate and reliable as CT-based measurements when using T1 VIBE DIXON and in patients with FAI. Shorter MRI acquisition time and no bolstering during MRI decreased measurement errors in FV, leading to less misdiagnosis of FV.

CLINICAL RELEVANCE/APPLICATION

We changed our clinical practice and use MRI with VIBE Dixon without knee bolstering for preoperative measurement of FV. This could reduce radiation dose for typically young patients of childbearing age compared to CT scans.

T5B-SPNMMI-1 Additional Value of 18F-DCFPyL PET/MRI Radiomic Features for Nodal and Distant Metastases Detection of Prostate Cancer

Participants
Adriano Basso Dias, MD, MSc, Toronto, ON (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the performance of combined PET and multiparametric MRI (mpMRI) radiomics for the prediction of nodal and distant metastases in patients with suspicion of prostate cancer (PCa), or patients being considered for focal ablative therapies (FT), or patients with unfavorable intermediate/high-risk PCa.

METHODS AND MATERIALS

This ethics review board-approved, retrospective analysis of two prospective clinical trials, included 103 men, with suspicion of PCa and negative systematic biopsies or clinically discordant low-risk PCa (n=20), those being considered for FT (n=31) and those with unfavorable intermediate or high-risk prostate cancer (n=52). All patients received 18F-DCFPyL PET/MRI. All suspicious lesions underwent biopsy. Whole-prostate segmentations were performed on each modality separately, including the whole-gland T2-weighted sequence, whole-gland apparent diffusion coefficient (ADC) map, and whole-gland PET images. Then, image biomarker standardization initiative (IBSI)-compliant radiomic features were extracted. A total of 307 features based on the PET and MRI images were calculated. Univariate Logistic Regression was done to find the predictive value of the extracted features.

RESULTS

A total of 103 patients (mean age= 65; mean PSA level= 23.4) were studied. Based on the PET/MRI findings, 22 (21%) patients had metastatic disease, including 14 patients with only nodal metastasis and 8 patients with both nodal and distant metastases. PCa was confirmed in 93 (90%) patients after the histopathologic evaluation, and 10 patients were negative for malignancy according to biopsy. Among the proven PCa patients, 37 (36%) patients were grouped in ISUP 1 and 2, and 56 (64%) patients were in ISUP 3,4 and 5. The calculated radiomic features extracted from the segmented prostate glands were associated with the metastatic status (nodal and/or distant metastases). DISCRETIZED, GLCM, and GLZLM were the most significant variables in the prediction, with odds ratios ranging from 3.49 (95% CI: 1.86-6.55) to 5.15 (95% CI: 2.42-10.95).

CONCLUSION

s A whole-gland feature extraction could possibly predict the extraprostatic status of the PCa patients, showing the potential in prediction of metastatic disease (nodal and/or distant metastases). These findings indicate that by assessing the prostate gland as a whole could be potentially used for further treatment approach personalization in PCa patients.

CLINICAL RELEVANCE/APPLICATION

Detection of metastatic disease (nodal and/or distant metastases) is crucial for management of men with prostate cancer. 18F-DCFPyL PET/MRI Radiomics showed promising results as a predictor of metastases in patients with prostate cancer.

T5B-SPNMMI-2 Preliminary Investigation on Adenovirus-Mediated Transferrin Receptor Reporter Gene in Colorectal Cell MRI Imaging

Participants
Hua He, MMedSc, MMedSc, Yinchuan, China (*Presenter*) Nothing to Disclose

PURPOSE

To explore the best multiplicities of inflection (MOI), the expression of the target gene and in vitro MRI imaging of adenovirus vector-mediated transferrin receiver (TFRC) reporter gene transfer of human colorcancer Lovo cells.

METHODS AND MATERIALS

Lovo cells were transfected with recombinan tadenovirus (Ad-TFRC) at5, 10, 50, 100MOI to determine the best MOI, and quantitative real-time PCR was performed to detect the cDNA of TFRC. The transfectedcells were incubated in the culture medium including Tf-USPIO of variance concepts, and were observed by Prussian blue staining, then the cell viability was evaluated via Trypan blue staining. The labeled cells were scanned with 7.0T MR T2W, T2 map, T2*map sequences, and the signatures were analyzed.

RESULTS

Ad-TFRC were successfully transfected into Lovo cells. The best MOI was 50, and the efficiency of innovation was more than 90%. The relative expression amount of TFRC in transfected cells wash higher than that in control Lovo cells by real-time quantitative PCR (P<0.01). Prussian blue staining numerous blue iron parts in transfected cells when the best labelling conception was 1.5 μg/ml. Trypan blue staining results of transfected Lovo cells and control Lovo cells was (93.80±1.60)% and (95.10±2.30)%, respectively (P>0.05). MRI Imaging in vitro shown that compiled with control Lovo cells, the signal Intensity Decreased on T2WI, T2map and T2*map sequences in transfected Lovocells (P<0.05).

CONCLUSION

s TFRC reporter gene can be efficiently mediated by adenovirus for expression in Lovo cells. After magnetization labeling, 7.0T MRI Imaging of Lovo cells can be success fully achieved in vitro.

CLINICAL RELEVANCE/APPLICATION

Provide basic research basis for the occurrence and development mechanism of colorectal cancer.

T5B-SPNMMI-3 Accurate PET Quantification Using 3D Recovery Coefficient for Small or Irregular Shaped Objects

Participants
Matthew Smith, MD, PhD, Nashville, TN (*Presenter*) Nothing to Disclose

PURPOSE

Quantitation using SUVmax is an approximation with known limitations in small objects. The purpose of this work is to investigate a method to accurately calculate the 3D recovery coefficient (3D-RC) in an object of any shape or size to provide accurate PET quantification.

METHODS AND MATERIALS

The FHWMs of the PET/CT scanner (Philips Vereos) were measured in the radial (R), tangential (T), and axial (A) dimensions at isocenter and at 8 cm from the scanner centerline using point sources to determine the 3D point-spread function (3D-PSF) using a typical clinical reconstruction algorithm. Using Matlab, cylinders and spheres with diameters ranging from 1 mm to 40 mm and length of 400 mm were simulated with 0.625 mm pixel resolution. Each object was convolved with the measured 3D-PSF using a 3D-FFT to produce a 3D recovery coefficient (3D-RC) map. For each 3D-RC map, the max and mean recovery coefficients were recorded within the bounds of the object and plotted against object size.

RESULTS

Measured FWHMs in water for R, A, and T directions were 4.5, 4.5, and 4.5 mm, respectively. Radial FWHM did not vary for objects up to 8 cm from the centerline. Simulated 3D-RC values were lower for spheres compared to cylinders and decreased with smaller object size, consistent with prior published data for cylinders and spheres.

CONCLUSION

s A new approach to calculating an accurate 3D recovery coefficient for PET is presented and validated with prior published results. Unlike prior methods using lookup tables to estimate 3D-RC's for clinical PET, this method can easily be extended to irregularly shaped objects by simple 3D convolution. Future work includes phantom validation and application to clinical data.

CLINICAL RELEVANCE/APPLICATION

Improved PET ROI quantification is needed for assessing tumor SUV response for small lesions as well as providing accurate measurements for quantitative PET. This method utilizes a new approach to accurately measure PET activity in small or irregularly-shaped objects (e.g. F-18 DOPA imaging of the putamen, lymph node conglomerates, or lung masses). For objects adjacent to high activity structures, this method can also generate spillover factors. This method can be easily incorporated into clinical practice using existing technology.

T5B-SPNMMI-3

Accurate PET Quantification Using 3D Recovery Coefficient for Small or Irregular Shaped Objects

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - NMMI DPS

Participants
Matthew Smith, MD, PhD, Nashville, TN (*Presenter*) Nothing to Disclose

PURPOSE

Quantitation using SUVmax is an approximation with known limitations in small objects. The purpose of this work is to investigate a method to accurately calculate the 3D recovery coefficient (3D-RC) in an object of any shape or size to provide accurate PET quantification.

METHODS AND MATERIALS

The FHWMs of the PET/CT scanner (Philips Vereos) were measured in the radial (R), tangential (T), and axial (A) dimensions at isocenter and at 8 cm from the scanner centerline using point sources to determine the 3D point-spread function (3D-PSF) using a typical clinical reconstruction algorithm. Using Matlab, cylinders and spheres with diameters ranging from 1 mm to 40 mm and length of 400 mm were simulated with 0.625 mm pixel resolution. Each object was convolved with the measured 3D-PSF using a 3D-FFT to produce a 3D recovery coefficient (3D-RC) map. For each 3D-RC map, the max and mean recovery coefficients were recorded within the bounds of the object and plotted against object size.

RESULTS

Measured FWHMs in water for R, A, and T directions were 4.5, 4.5, and 4.5 mm, respectively. Radial FWHM did not vary for objects up to 8 cm from the centerline. Simulated 3D-RC values were lower for spheres compared to cylinders and decreased with smaller object size, consistent with prior published data for cylinders and spheres.

CONCLUSION

s A new approach to calculating an accurate 3D recovery coefficient for PET is presented and validated with prior published results. Unlike prior methods using lookup tables to estimate 3D-RC's for clinical PET, this method can easily be extended to irregularly shaped objects by simple 3D convolution. Future work includes phantom validation and application to clinical data.

CLINICAL RELEVANCE/APPLICATION

Improved PET ROI quantification is needed for assessing tumor SUV response for small lesions as well as providing accurate measurements for quantitative PET. This method utilizes a new approach to accurately measure PET activity in small or irregularly-shaped objects (e.g. F-18 DOPA imaging of the putamen, lymph node conglomerates, or lung masses). For objects adjacent to high activity structures, this method can also generate spillover factors. This method can be easily incorporated into clinical practice using existing technology.

T5B-SPNPM-1 Evaluating Faculty Teaching Skills in Diagnostic Imaging: Can We Ask Better Questions to Get More Useful Answers?

Participants
Daria Manos, FRCPC, Halifax, NS (*Presenter*) Speakers Bureau, Boehringer Ingelheim GmbH;Advisory Board, AstraZeneca PLC

PURPOSE

Faculty evaluation by residents is an important component of resident responsibility and professionalism. Unfortunately, many programs note difficulty obtaining quality feedback. Teaching evaluations in our department suffered from low response rates and poor utility. We sought to explore the limitations of the current process and to redesign it recognizing teaching activity specific to Diagnostic Imaging.

METHODS AND MATERIALS

The current evaluation process was assessed through feedback obtained from two focus groups (residents and members of the department education council) and interviews with the department chair. Several themes emerged. Residents noted evaluation-fatigue, insufficient time to complete evaluations, and concern evaluation was ineffectual. The department chair noted the number and quality of evaluations was insufficient to provide faculty support or to recognize excellence. Faculty expressed underappreciation related to low scores and/or low response rate, and noted poor utility of feedback.The evaluation form was redesigned based on focus group discussion and literature review of best practices. A department council including resident and faculty representatives reiteratively revised the form. The new process was trialed with 22 residents evaluating 47 faculty. Mixed methods were used to assess the intervention including quantity of responses and qualitative review of changes from the perspective of the residents, faculty, and departmental leadership.

RESULTS

The new form included DI-specific teaching activity, narrative scales, and an explanatory preamble. Residents were provided protected time to complete evaluations. Quality and quantity of faculty teaching evaluations improved with discipline-specific assessment, narrative scales, and protected time for evaluation. Overall response rate increased from 69% to 91% with individual faculty receiving up to 3.6 times the number of responses. Faculty felt better appreciated, particularly related to free-form resident comments. Initial feedback suggested small changes that will be incorporated in the future.

CONCLUSION

s Developing a specific and practical faculty teaching evaluation form in DI allowed a more effective, efficient and supportive feedback process. The form was designed for use in any diagnostic imaging program, but further study is needed to confirm generalizability.

CLINICAL RELEVANCE/APPLICATION

Faculty teaching evaluations in Diagnostic Imaging were optimized by providing a form specific to Diagnostic Imaging, by using narrative anchored scores, and by better explaining the process to the residents.

T5B-SPNPM-2 The Association Between Radiology Research Funding and Community Inclusion and Investment

Participants
Antonio Lopez, BA, Philadelphia, PA (*Presenter*) Nothing to Disclose

PURPOSE

The recent COVID-19 pandemic highlighted substantial health inequities that will require a multifaceted approach to address. One component necessitates appropriate representation of underserved populations in imaging research. The purpose of this study was to determine the relationship between NIH research funding for radiology departments/hospital systems and their contribution toward health equity.

METHODS AND MATERIALS

This study used publicly available de-identified data and was deemed exempt by the institutional review board. The dependent variable was aggregate radiology research funding from 2017 - 2021 by Radiology Department, derived from the NIH Reporter. Independent variables were outcomes focused on equity measures captured in the 2021 Lown Institute Hospitals Index, which

evaluates hospital social responsibility by examining performance across health outcomes, value, and equity. The community benefit metric measures hospital spending on community health initiatives, including charity care, and their service of Medicaid patients. The inclusivity metric evaluates how a hospital's patient population reflects the demographics of their local community based on race, income, and education levels. Bivariable linear regression and Pearson's correlation coefficients (CC) were used to evaluate the association between Radiology research funding and measures of hospital community benefit and inclusivity.

RESULTS

78 radiology departments received NIH funding between 2017-2021 ranging from $195,000 to $216,879,079 (median $12,603,918). On measures of inclusivity, Radiology departments that received more funding were less likely to serve low-income patients (CC -0.442, p = 0.000), racial/ethnic minority patients (CC -0.340, p = 0.003), and patients with less education (CC -0.455, p = 0.000). Radiology departments receiving more funding were ranked lower on the summary weighted measure of hospital inclusivity (CC 0.493, p = 0.000). On measures of community benefit, there were no statistically significant associations between research funding and charity care spending (CC -0.192, p = 0.099), community investment (CC -0.043, p = 0.773), and Medicaid as a share of patient revenue (CC -0.098, p = 0.404).

CONCLUSION

s Radiology departments that received more NIH research dollars were less likely to serve racial/ethnic minority and low-income patients, and patients with lower education levels.

CLINICAL RELEVANCE/APPLICATION

To improve health outcomes of vulnerable populations, efforts should focus on narrowing this research funding gap. Options might include redistributing funds to safety net facilities or fostering collaborations among well-funded institutions with those serving primarily underserved populations.

T5B-SPNPM-3 Patient, Provider, and Practice Characteristics Predicting Use of Imaging in Primary Care

Participants
Sue Yi, PhD,BS, Madison, WI (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate differences in imaging utilization during primary care visits based on patient medical and sociodemographic variables; provider characteristics; and practice setting using nationally representative survey data.

METHODS AND MATERIALS

Retrospective analysis of the National Ambulatory Medical Care Survey (NAMCS) for the years 2013-2018 was conducted. All patient visits coded as primary care were included in the sample. The major outcome variable was the use of diagnostic imaging also further subdivided by modality: MRI, CT, X-ray, ultrasound, mammography, and DXA. Multiple variable logistic regression analyses were performed to evaluate the influence of patient, provider, and practice level characteristics on imaging utilization. Stata survey procedures were used with NAMCS provided sampling weights to account for the complex survey sampling design and provide valid national-level estimates of imaging utilization.

RESULTS

A total of 2,820,381,627 primary care visits were included in the five-year study period. (Data from 2017 is not available). Patient demographics included mean age of 41, 60% female, 64% White, 11% Black, 18% Hispanic, 7% Asian or other race/ethnicity. Overall, 13% of visits resulted in imaging use which did not vary significantly by year (p=0.18). Increased rates of imaging were seen with Black (OR 1.30, 95% CI 1.08-1.56) and Hispanic (OR 1.35, 95% CI 1.12-1.62) patients; female patients (OR 1.87, 95% CI 1.65-2.11); in patients with serious comorbidities such as cancer (OR 1.44, 95% CI 1.17-1.79); and associated with advancing patient age (p<0.001). Imaging use was higher when the provider was not the patient's PCP (OR 1.52, 95% CI 1.27-1.82) but did not vary by MD versus DO credential (p=0.08). Imaging utilization did not vary significantly by region (p=0.95) or rural versus urban location (p=0.79).

CONCLUSION

s Imaging utilization is lower in the primary care setting than what has been reported in the Emergency Department and the disparities in imaging use by patient race seen in that environment are not observed in primary care. This suggests that increasing patient access to primary care may promote health equity. Understanding other factors associated with increased imaging use including patient age, sex, and co-morbidities may help predict health system imaging utilization and guide resource allocation.

CLINICAL RELEVANCE/APPLICATION

Promoting policies to increase patient access to primary care may promote more equitable access to diagnostic imaging.

T5B-SPNR-1 Utility of Vertebral Volumetry in Predicting Early Adjacent Compression Fractures After Kyphoplasty

Participants
Ashwin Deshmukh, MBBS, FRCR, Milford, CT (*Presenter*) Nothing to Disclose

PURPOSE

Several studies have assessed factors associated with development of early adjacent compression fractures (eACF) in patients undergoing kyphoplasty. This first of its kind study explored whether metrics derived from vertebral volume measurements were associated with development of eACF.

METHODS AND MATERIALS

This retrospective study included patients aged 60 and above without spinal metastases who underwent thoracic and/or lumbar kyphoplasty for vertebral compression fractures. Patients who had pre and post procedural cross-sectional imaging, and follow-up imaging at a minimum of 3 months post procedure were included. Vertebral body volumes of the fractured vertebra before and after kyphoplasty were measured. Additionally, volumes of the immediately adjacent vertebrae on pre-procedural scans were also measured. Two metrics derived from vertebral body volume measurements were used to test for statistical significance among those who developed eACF (within three months of kyphoplasty) and those who did not: ratio of post-kyphoplasty volume to pre-kyphoplasty volume of the index vertebra; ratio of post-kyphoplasty volume of the index vertebra to average of volumes of the immediately adjacent vertebrae on pre-procedural imaging.

RESULTS

21 consecutive patients were included. Of these, eight patients developed eACF. The mean age and standard deviation (SD) of eACF and non-eACF groups were 80.5±7.99 years and 76.38±10.99 years, respectively. All but one patients in each group underwent bipedicular kyphoplasty. Four patients (4/8) in eACF group and seven patients (7/13) in non-eACF group had chronic fractures in the thoracolumbar spine on pre-procedural imaging. There was a significant difference among the ratios of post-kyphoplasty volume to pre-kyphoplasty volume of index vertebra in eACF and non-eACF groups, with higher ratios in the eACF group (mean±SD: 1.389±0.353 and 1.077±0.107 respectively; p=0.0072). There was no significant difference among the ratios of post-kyphoplasty volume of the index vertebra to the average of adjacent vertebral body volumes in eACF and non-eACF groups (mean±SD: 0.960±0.139 and 0.907±0.100 respectively; p=0.052).

CONCLUSION

s Results from this pilot study are encouraging, with a significant difference in one of the two assessed metrics. A larger multi-institutional retrospective study assessing these metrics (including assessment of inter-observer variability), and comparison with previously published metrics is currently underway.

CLINICAL RELEVANCE/APPLICATION

If validated and standardized, these ratios could guide operators in injecting optimal volume of cement to avoid development of eACF, and also help inform an active surveillance protocol for those who might be at risk for eACF.

T5B-SPNR-11 Ultrafast Cervical Spine MRI Using Deep Learning-Based Reconstruction: Diagnostic Equivalence to a Conventional Protocol

Participants
Atsushi Nakamoto, MD, PhD, Suita, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the diagnostic equivalency between an ultrafast MRI protocol (2 min 57 s) of the cervical spine using deep learning-based reconstruction (DLR) and a conventional MRI protocol (12 min 54 s).

METHODS AND MATERIALS

This study included 50 patients who underwent cervical spinal MRI of both conventional and ultrafast protocols, including sagittal T1-weighted, T2-weighted, short-TI inversion recovery, and axial T2*-weighted images. Compared with the conventional protocol, the ultrafast protocol shortened the scanning time to about one fourth by using a lower number of excitations, a higher acceleration factor in compressed sensing, and a lower spatial resolution. To compensate for the decreased signal-to-noise ratio caused by shortened scanning time, noise reduction was performed using the Advanced Intelligent Clear-IQ Engine, a recently

commercially available DLR. Three neuroradiologists analysed all images for grading of degenerative changes using a four- or five-point scale and the presence of other spinal abnormalities. For the degenerative changes, inter-protocol intra-reader agreement was assessed by weighted kappa statistics. We also examined interchangeability between the two protocols by calculating the individual equivalence index as the estimated difference between the intra-protocol (conventional) inter-reader and inter-protocol inter-reader agreement. Regarding other abnormalities, the concordance rates of the three readers were calculated.

RESULTS

The kappa values for canal stenosis, disc degeneration, foraminal stenosis, disc hernia, and endplate degeneration, ranged from 0.76 to 0.94, 0.54 to 0.66, 0.54 to 0.87, 0.67 to 0.91, and 0.51 to 0.79, respectively, indicating moderate to almost perfect agreement. Except for endplate degeneration, the 95% confidence interval of the individual equivalence index did not exceed 5%, indicating interchangeability between the two protocols. Six cord lesions and one vertebral lesion were detected as other spinal pathologies. The concordance rates of their detection between the two protocols were 100% in all three readers.

CONCLUSION

s Our proposed ultrafast MRI protocol and the conventional protocol showed approximate diagnostic equivalence.

CLINICAL RELEVANCE/APPLICATION

Our proposed ultrafast spine MRI protocol using DLR showed approximate diagnostic equivalence to a conventional protocol, suggesting its practicality for patients requiring a short examination time.

T5B-SPNR-12 Clinical and Imaging Features of Spinal Extradural Arachnoid Cysts: A Retrospective Study of 50 Cases

Participants
Ahmed Ahmed, MBBS, MSc, (*Presenter*) Nothing to Disclose

PURPOSE

Spinal extradural arachnoid cysts (SEDAC) are rare pockets of CSF or CSF-like fluid that form next to thecal sac in the spine. They are thought to arise from CSF leaking through a dural defect forming an extradural cyst. Prior limited case series have described that they are often found incidentally and rarely cause spinal cord or nerve root compression. This study investigates the demographics and imaging spectrum of SEDACs at our academic institution and compares them with those reported in the literature.

METHODS AND MATERIALS

We reviewed all imaging reports in our institution. Fifty cases with documented MRI diagnosis of SEDAC, Nabors criteria type I meningeal cyst (MC), were identified. We then studied patient demographics, presenting symptoms, cyst characteristics, and management outcomes. We also tested the association between cysts' largest diameter and their location, septation, thecal mass effect, myelopathy, bone remodeling, and extraforaminal extension.

RESULTS

In all 50 subjects, SEDACs were solitary (single) and sporadic (non-familial). The majority were incidental (62%), located posteriorly (92%) and laterally (80%) in the thoracic and thoracolumbar regions (34%, 30%). They were associated with mild thecal mass effect (50%) and bone remodeling (92%). Among symptomatic SEDACs, back pain and radiculopathy were the most reported (68%). Larger cysts were seen caudally in the spinal canal and were associated with greater thecal mass effect, bone remodeling, and septations. All 25 cases (out of 50) that had follow-up MRIs showed stability. 4 out of the six subjects who underwent surgical management had complete or partial remission. One had cyst recurrence.

CONCLUSION

s In this largest series of SEDACs, we found that most were discovered incidentally, stable over time, and most located in the thoracic spine dorsal to the thecal sac. Back pain and radiculopathy constituted most of the presenting symptoms. Treatment with complete surgical excision may yield the best results for symptomatic lesions.

CLINICAL RELEVANCE/APPLICATION

It will help radiologists and clinicians be aware of SEDAC's different clinical presentations, imaging findings, and treatment outcomes.

T5B-SPNR-13 Quiet and Fast MR Imaging of Cervical Spine: A Preliminary Study with AI-assisted Compressed Sensing Quiet Sequences

Participants
Zhang Yukun, (*Presenter*) Nothing to Disclose

PURPOSE

Acoustic noise was one of the major complaints for patients underwent MR examination, which may affect successful scan rates. The purpose of this study was to investigate the clinical feasibility and performance of quiet sequences with AI-assisted compressed sensing (ACS) on cervical spine imaging, compared to quiet sequences with Parallel Imaging (PI) using different acceleration factors (AFs), as well as conventional cervical spine sequences.

METHODS AND MATERIALS

10 participants (6male, mean age: 47.57±17.25 years) were imaged at a 3T scanner (uMR Omega, Imaging Healthcare, Shanghai, China) using four different T1-weighted (T1WI) and T2-weighted (T2WI) sequences: conventional protocol, quiet protocol with PI (AF = 2,3) and quiet protocol with ACS (AF = 4)(Table 1). All of the quiet sequences were acquired with a noise reduction factor of 0.6. Noise sound level and acquisition time were recorded. Image quality was subjectively evaluated by two radiologists, using 4-point scores (Table 2). The mean signal to noise ratio (SNR) and mean contrast to noise ratio (CNR) estimation were performed by ROI analysis of the vertebra and the intervertebral disk (IVD) on T1WI and T2WI sequences(figure 1). The differences of qualitative and quantitative parameters between four protocols (conventional sequences, quiet sequences with PI AF = 2, quiet sequences with PI AF = 3 and quiet sequence with ACS AF = 4) were evaluated by Friedman test. SNR = SI vertebra, IVD /SD muscle, CNR = (SI vertebra, IVD -SI muscle)/SD muscle.

RESULTS

There were no statistical differences in SNR, CNR of vertebra and IVD and subjective evaluation between routine sequences and different quiet sequences with acceleration methods ($p > 0.05$,Tables 3 and 4). Significant acoustic noise and acquisition time reduction was measured for quiet T1WI (36% reduction) and quite T2WI (6% reduction) with ACS compared to conventional sequences(figure 2).

CONCLUSION

s This study demonstrated that both effective acoustic noise reduction and improved acceleration efficiency can be achieved for cervical spine in quiet sequences with ACS (AF = 4), without degrade image quality and quantitative SNR as well as CNR reduction.

CLINICAL RELEVANCE/APPLICATION

Quiet T1WI and T2WI sequences with ACS may be promising methods for cervical spine imaging, which may increase patient comfort and benefit successful scan rates as well as clinical applications.

T5B-SPNR-14 Deep-Learning Image Reconstruction on Low KEV Virtual Monochromatic Image of Dual-Energy CT Improves Image Quality of Adamkiewicz Artery

Participants
Fuminari Tatsugami, MD, Hiroshima, Japan (*Presenter*) Nothing to Disclose

PURPOSE

The detection of the artery of Adamkiewicz (AKA) and the anterior spinal artery (ASA) on CT can be challenging because of their small vascular diameter and the fact that they are surrounded by the spinal canal. Dual-energy CT can increase the iodine contrast by generating low-energy (keV) virtual monochromatic images (VMIs), but the image noise increases as the energy level decrease. Recently introduced deep learning image reconstruction (DLIR) algorithm reduces image noise drastically without degrading image texture compared to iterative reconstruction (IR) algorithms. We investigated whether the use of DLIR on low-keV VMIs can improve the image quality of AKA, using 70 keV VMIs reconstructed with IR algorithms as a reference standard.

METHODS AND MATERIALS

We enrolled 20 patients who underwent CT aortography on a 256-slice CT scanner with dual-energy scan before aortic repair. We prepared the following images; VMI at 70 keV reconstructed with hybrid-IR (HIR), VMI at 40 keV reconstructed with HIR, and VMI at 40 keV reconstructed with DLIR. On axial images, CT attenuation profiles were generated crossing through the center of the ASA lumen, and the maximum value was recorded. The contrast-to-noise ratio (CNR) of ASA was calculated by using the following formula: CNR of ASA= (maximum CT number of the ASA - CT number of the spinal cord) / image noise of the spinal cord. The overall image quality of AKA was visually evaluated by two radiologists using a four-point scale (1 = poor, 4 = excellent). Also, its continuity was visually evaluated using a four-point scale (1 = not visible, 4 = vascular continuity is fully recognized).

RESULTS

The mean image noise in the aorta on 40 keV-DLIR images was slightly lower than on 40 keV-HIR images (43.0 vs. 44.4; $p > 0.05$); they were higher than on 70 keV-HIR images (18.0; $p < 0.01$). CNR of ASA was higher on 40 keV-DLIR images than on 40 keV-HIR and 70 keV-HIR images (11.1, 8.8, and 7.9, respectively; $p < 0.05$). The mean image quality score for 40 keV-DLIR was the highest among the three reconstructions (3.3, 2.7, and 2.3, respectively). The mean score for delineation of AKA on 40 keV-DLIR images was comparable to 40 keV-HIR, but it was higher than on 70 keV-HIR images (3.6, 3.5, and 2.9, respectively).

CONCLUSION

s The use of DLIR on the low keV VMI significantly improves the image quality of AKA compared to conventional methods.

CLINICAL RELEVANCE/APPLICATION

The use of DLIR on the low keV VMI significantly improves the image quality of AKA compared to conventional methods. It can be expected to improve diagnostic performance for the detection of AKA before aortic repair.

T5B-SPNR-15 Blind Spot: Radiologic Reporting of Epidural Metastasis on Body CT in a 12-Year Retrospective Cohort Study

Participants
Lauren M. Kim, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To determine whether imaging features of epidural tumor on CT imaging influenced radiologic reporting.

METHODS AND MATERIALS

293 body CT examinations of 166 patients performed within 30 days of a spine MRI which diagnosed an epidural metastasis were identified. These 293 CT examinations were performed over a 12-year time period at a single institution, with each examination reported by 1 of 17 total radiologists. Majority vote decision among 3 radiologists determined consensus as to whether an epidural metastasis reported on spine MRI was plainly visible on body CT. Epidural metastases deemed plainly visible on body CT were manually segmented by one radiologist for quantitative image analysis. Weighted univariate ?2- and two-tailed t-test analyses were performed to identify statistically significant trends between epidural tumor imaging features and radiologic reporting of epidural metastasis on body CT.

RESULTS

Epidural metastases reported on spine MRI were deemed plainly visible in 80.5% (236/293) of body CTs performed within 30 days, however 65.3% (154/236) of the body CT reports omitted their presence. 432 epidural tumors and which were deemed plainly visible on CT were manually segmented for quantitative image analysis. These epidural tumors were small, on average 1-2 cm3, and low contrast, with average relative contrast (CreI) values less than 1 and average contrast-to-noise (CNR) values between 1-2, representing the lower limit of what the human eye can perceive. The only imaging feature which positively impacted reporting was lesion volume ($p=0.03$) on noncontrast CT, and lesion volume ($p=0.006$) and percentage of spinal canal stenosis ($p=0.001$) on

contrast CT. Mean HUepidural tumor=92 and mean SDHU spinal canal=48, suggesting that the optimal window settings by which to visualized epidural tumor on CT is WL 92/ WW 223.

CONCLUSION

s While body CT is moderately capable of displaying epidural tumor, the majority of these lesions go unreported and therefore likely undetected. Adequate magnification and customized windowing will likely improve the detection of epidural metastasis on CT.

CLINICAL RELEVANCE/APPLICATION

Cognitive bias may preclude a radiologist's search for epidural tumor on body CT; and even when intentionally sought after, this lesion is difficult to see. Directed attention and optimized radiological searching technique may therefore be required, specifically adequate magnification and customized windowing will likely improve the detection of epidural metastasis on CT.

T5B-SPNR-16 Association Between Ligamentous Injuries and Cranio-cervical Junction Malalignment

Participants
David Timaran Montenegro, MD, Houston, TX (*Presenter*) Nothing to Disclose

PURPOSE

To assess the association between cranio-cervical junction (CCJ) ligamentous injuries and atlantooccipital disassociation and/or atlantoaxial dislocation

METHODS AND MATERIALS

Over a 3-year period, an observational, single center study was performed. In total, 443 subjects with CCJ trauma were reviewed. Only patients that were evaluated with cervical spine CT and MRI (171 subjects [39%]) were included in this study. Among them, 107 patients were male (62.5%) with a median age of 36 years (interquartile range [IQR] 24-57 years). Fisher exact test was performed for univariate analysis. Simple logistic regression analysis was used to determine odds ratios (OR) and confidence intervals (95% CI)

RESULTS

In total, 15 patients (8.7%) were diagnosed with either atlantooccipital disassociation (8 patients [53%] or atlantoaxial dislocation (7 patients [47%]). Among patients with either type of CCJ disassociation, 7 (47%) were found to have ligamentous injuries (p=0.006) (OR, 5.06 [95% CI, 1.79-14.71). Injury of the apical ligament was seen in 3 patients (20%) (p=0.01) (OR, 9.5 [95% CI, 2.13-37.78). Additionally, left occipital condyle fracture was observed in 7 patients (47%) (p=0.01) (OR, 4 [95% CI, 1.4-12.59). Among patients with atlantoaxial dislocation only, epidural hematoma was seen in 4 (57%) subjects (p=0.04). Among patients with atlantooccipital disassociation, 3 (37%) had disruption of the alar ligament (p=0.019). Injuries of the other CCJ ligaments failed to demonstrate statistically significant associations with either type of CCJ disassociation

CONCLUSION

s Incidence of atlantooccipital and/or atlantoaxial malalignment reached 8.7%. CCJ ligamentous injuries were found in up to 47% of the cases. Disruption of the apical ligament was seen in 20% of the patients with either type pf CCJ disassociation. Among patients with atlantooccipital disassociation only, 37% had alar ligament injuries. Injury to other CCJ ligaments was not associated with either type of CCJ disassociation

CLINICAL RELEVANCE/APPLICATION

Literature about acute cranio-cervical junction trauma is limited due to the high mortality rate of patients with CCJ trauma at the scene of injury. Our study will help to understand the association of cervical structural injuries with severe cranio-cervical malalignment.

T5B-SPNR-18 Application of synthetic MRI in Quantitative Diagnosis in Cervical Spondylotic Myelopathy

Participants
Xiangyu Tang, Wuhan, China (*Presenter*) Nothing to Disclose

PURPOSE

Cervical spondylotic myelopathy (CSM) is a chronic compressive spinal cord lesion. It is important to identify early symptoms and provide effective treatment. To data, previous studies have shown the feasibility of synthetic MRI (MAGiC) in spinal cord imaging on healthy volunteers. The objective of this work was to investigated the feasibility and diagnostic value of the quantitative PD, T1 and T2 values obtaining by synthetic MRI in addressing the severity of CSM.

METHODS AND MATERIALS

From August 2021 to March 2022, a total of 63 subjects were enrolled including 36 CSM patients and 27 healthy subjects (23 males and 40 females). A 3.0T MR scanner (GE, SIGNATM Architect) was used to perform MAGIC imaging sequence on each subject. Patients and controls were evaluated using the Japanese Orthopaedic Association (JOA) scale, a Visual Analogue Scale (VAS) and Neck Disability Index (NDI). The MAGIC images were post-processed using the GE workstation, and ROIs were manually drawn to measure the axial intervertebral discs and the spinal cord at the C2 vertebral level to generate T1, T2, and PD values. The cervical canal stenosis of subjects were graded according to the method of Kang, Y. After that, LSD-t test was used to compare the differences of each parameter value between each grade and C2 vertebral level, and Spearman correlation analysis was used to test the correlation between C2 vertebral body level and the maximum degree of intervertebral disc herniation and clinical mJOA score, VSA score, NDI score.

RESULTS

The T1 mapping, T2 mapping and PD mapping were generated by MAGiC data (Figure 1). The PD value had a decreasing trend from grade 0 to grade 2. The PD value of C2 is bigger than the value of grade 0, grade1 and grade2, with statistically significant ($P<0.01$), except for the difference between grade3, showing the PD value had a potential for early diagnosis for CSM (Figure 2a). The T1 value had statistically difference between grade3 and the other grade($P<0.05$). (Figure 2b) The T2 value had statistically difference between C2 and the other grade($P<0.05$), showing the CSM patients had the change of T2 values (Figure 2c).

CONCLUSION

s MAGiC was shown to be a reliable and effective method in assessing CSM. The values of PD, T1 and T2 open up a new dimension on quantitative measures in assessing CSM

CLINICAL RELEVANCE/APPLICATION

MAGiC has the potential for clinical diagnosis for CSM

T5B-SPNR-19 Utility and National Trend of Use of Spine MRI in the Setting of Suspected Nonaccidental Trauma (NAT)

Participants
Jeffers Nguyen, MD, Centereach, NY (*Presenter*) Nothing to Disclose

PURPOSE

Abusive head trauma (AHT) is the leading cause of morbidity and mortality in patients below the age of 2 with traumatic brain injury. Given the recently growing awareness of spinal injury in the setting of AHT, the current ACR guidelines now strongly recommend performing MRI of the cervical spine at the time of brain MRI, and that MRI of the total spine be considered. In this study, we aim to examine the MRI spine findings in patients hospitalized for suspected non-accidental trauma (NAT). In addition, we examined the national trend of use of spine MRI in the setting of suspected NAT using the Pediatric Health Information System (PHIS).

METHODS AND MATERIALS

After obtaining approval of the institutional review board, a retrospective study was performed evaluating the spine MRI findings of children aged 0 to 2 years admitted for suspected NAT between January 2017 and December 2021. Using our radiology database (Nuance mPower) and the pediatric child abuse database at our institution, infants and young children aged <24 months who had whole spine MRI for suspected NAT were included. Clinical data, including patient demographics, clinical presentation, interventions, and clinical outcomes, were collected, and analyzed. Additionally, the PHIS database was used to identify hospitalizations for AHT from 1/1/17 to 12/31/21 in children < 2 years of age.

RESULTS

A total of 24 patients with MRI of the spine for suspected NAT were identified. The median age at presentation was 5 months, and approximately two-thirds of patients were male. Although nearly all patients (96%) had findings compatible with AHT on brain MRI, only 9 patients (38%) had positive findings on MRI of the spine. Of those, the vast majority (89%) had thoracolumbar subdural hemorrhage, necessitating surgical evacuation in only one of them. Two patients had evidence of ligamentous injury in the cervical spine, one of which subsequently had a cervical collar placed. The national trend of use of spine MRI for suspected NAT is presented in Figure 1

CONCLUSION

s Thoracolumbar subdural hemorrhage is the most common abnormality seen in patients with suspected NAT who underwent whole spine MRI at our institution. Follow up study with larger samples is needed to validate our data and guide future efforts to improve patient selection and study protocols.

CLINICAL RELEVANCE/APPLICATION

There is increasing use of MRI Spine in patients suspected nonaccidental trauma. Severe spinal injury necessitating clinical intervention remains rare despite increased utilization of MRI of the spine.

T5B-SPNR-2 Dural Branches Supplying the Anterior Fossa Dura Matter From the Anterior Cerebral Artery

Participants
Hiro Kiyosue, MD, (*Presenter*) Research Grant, Koninklijke Philips NV

PURPOSE

It is known that a dural branch to the anterior cranial fossa occasionally originates from the anterior cerebral artery (ACA) which can supply dural hypervascular lesions such as meningioma and anterior fossa dural arteriovenous fistulas. Those dural branches are small but important in interventional procedures because embolic materials injected from the dural branch of the external carotid artery or the ophthalmic artery potentially migrate into the ACA via duro-pial anastomosis. However, no anatomical or angiographical studies regarding dural branches from the ACA have been reported yet. Herein, we evaluate dural branch to the anterior cranial fossa from the proximal portion of the ACA.

METHODS AND MATERIALS

We retrospectively evaluated collateral pathways via the dural arterial anastomoses between the ethmoidal arteries of the ophthalmic artery or the sphenopalatine artery and the anterior cerebral artery in patients with severe stenosis or occlusion of the internal carotid artery. Biplane angiography and 3D angiography images including MPR images in 25 patients (50 sides) were reviewed by two neuroradiologists with a special interest in the origin of the dural branch of ACA.

RESULTS

Duro-pial collaterals via the ethmoidal - ACA dural anastomoses were observed in 18 patients (72%) and 28 sides (56%). Detailed angioarchitecture could be evaluated in 19 sides. In 19 sides, 31 dural branches of the ACA were identified on 3D angiography, which originated from the olfactory artery at the distal portion (n=13) and at the proximal portion (n=7), the orbitofrontal artery (medial frontal artery) (n=2), and directly from ACA(A1 or A2) (n=9).

CONCLUSION

s Dural branches from the proximal portion of the ACA or its branches frequently exists, which often originate at the distal portion of the olfactory artery. Careful attention for the duro-pial anastomosis via the dural branch of the ACA during embolization of the lesion on the anterior cranial fossa

CLINICAL RELEVANCE/APPLICATION

Knowledge of the duro-pial anastomoses between the extracranial dural arteries (e.g. sphenopalatine artery) and the dural branch from the anterior cerebral artery is very important to avoid complications in neurointerventional procedures. This study clarify the frequency and course/origin of the dural branches from the anterior cerebral artery.

T5B-SPNR-20 Clinical Feasibility of Compressed Sensing for Three-dimensional MR Imaging of Cranial Nerves

Participants
HEDAN LUO, DALIAN, China (*Presenter*) Nothing to Disclose

PURPOSE

This study aims to investigate the quality of three-dimensional MR images of cranial nerves based on united compressed sensing (uCS) with different acceleration factors (AFs) and compare with that of images using sensitivity encoding (SENSE),optimized Imaging sequence and choosed the most appropriate acceleration factor.

METHODS AND MATERIALS

We prospectively recruited 14 volunteers (mean age, 40.86±3.60 years) who were scanned using a 3T MRI system (uMR Omega, United Imaging Healthcare, Shanghai, China). The T2-weighted images were acquired using a combination of 3D-MATRIX sequence and uCS with different AFs (3, 4, 5 and 6) and SENSE with AF of 2. Detailed parameters were listed in Table 1. The olfactory nerve(I), optic nerve(II) and trigeminal nerve(V) of cranial nerves were manually located and displayed in Fig.1. Signal to noise ratio (SNR) and contrast to noise ratio (CNR) were calculated from the signal intensity(SI) in cranial nerves. SNR=SII,II,V/SDCSF,CNR=(SICSF-SII,II,V)/SDCSF .SI of the small blood vessels close to the auditory nerve was measured and the corresponding Contrast Ratio (CR) was calculated.CR=(SICSF-SIvessel)/(SICSF+SIvessel)Image quality, including cranial nerve detail visibility, image noise and artifact and diagnostic value, was scored by two observers using a quartet-scale method for oculomotor nerve(III), facial nerve(VII)and glossopharyngeal nerve (IX). Friedman test was conducted to evaluate the differences of SNR, CNR, CR and score under different accelerating settings.

RESULTS

Image quality scores were consistent between two observers (Cohen's kappa coefficient =0.864). There were significant differences in the SNR of cranial nerve II, CR of vascular, and image quality scores of cranial nerves III, VII, and IX under different accelerating settings (all P values < 0.05 for multiple comparisons). For post-hoc analysis, the CR of vascular when using uCS with AF of 5 was significantly larger than that when using SENSE (P value < 0.05). And the scores when using uCS with AF of 6 were significantly lower than those when using SENSE (all P values < 0.05).(Fig.2)

CONCLUSION

s uCS-based MR imaging of cranial nerves could save scanning time without loss of SNR and CNR, compared with conventional MRI using SENSE method. Taking into account both satisfactory image quality and tight clinical time-constraint, we recommended to select AF of 5 for uCS in routine MR scanning.

CLINICAL RELEVANCE/APPLICATION

uCS-based MR imaging of cranial nerves showed high feasibility and clinical applicability: reducing scanning time and meanwhile ensuring image quality.

T5B-SPNR-4 Visualization of Lenticulostriate Artery by Compressed Sensing Imaging

Participants
Huang Fuling, MBChB, (*Presenter*) Nothing to Disclose

PURPOSE

Lenticulostriate artery (LSA) is a vital perforating artery in the brain, and its occlusion often leads to lacunar infarction. At present, digital subtraction angiography (DSA) is mainly used to realize the imaging of lenticulostriate artery in clinic, but the invasiveness of DSA is an important limiting factor. Some studies have shown that TOF (Time-Of-Flight) sequence has been able to obtain better images of lenticulostriate artery under high-field magnetic resonance system (7T). However, the diameter of the LSA is so small (about 0.3 - 0.7 mm) and the blood flow velocity is relatively slow, the imaging of the LSA is still a challenge with 3T MRI scanner. The study aims to visualize the LSA using 3D-TOF sequence and compressed sensing imaging on 3T system.

METHODS AND MATERIALS

Thirty-two patients and twenty-two volunteers underwent brain MRI scanning with routine 3D-TOF sequence and compressed sensing imaging on 3T system. Lenticulostriate artery were reconstructed and visualized by volume rendering (VR) technique, the length and number of lenticulostriate artery were analyzed.

RESULTS

The scanning time of 3D-TOF with and without compressed sensing sequence were 7 minutes and 8 minutes and 44 seconds, respectively, the LSAs were displayed clearly by VR technique on both condition. A total of one hundred and eight hemispheres were analyzed. The total number ($p > 0.05$) and length ($p > 0.05$) of LSAs were non-statistically different between 3D-TOF with and without compressed sensing imaging. There was a significant reduction ($p < 0.05$) in length of visualized LSA in infarction patients compared with the normal people.

CONCLUSION

s We concluded that the compressed sensing technique is of clinical value in the analysis of morphological characteristics of lenticulostriate artery, and it shortens the imaging time to 7 minutes. In summary, using compressed sensing technique to visualize lenticulostriate artery can basically meet the requirements of clinical in scanning time.

CLINICAL RELEVANCE/APPLICATION

Using compressed sensing technique to visualize lenticulostriate artery can basically meet the requirements of clinical in scanning time on 3T system.

T5B-SPNR-5 In Vitro US-Triggered Drug Release from Polymer Film Pocket

Participants
Selin Isguven, Philadelphia, PA (*Presenter*) Nothing to Disclose

PURPOSE

Infection after spinal fusion occurs in up to 16% of cases, with increased hospital stays and healthcare costs. To augment current therapies, we have designed a rupturable antibiotic reservoir that is stable for 3-5 days followed by US-triggered drug delivery (UTDD). We tested rupture as a function of cavitation nuclei, material properties, and acoustics.

METHODS AND MATERIALS

Polylactic acid (PLA) pockets (~3 mL volume; n = 24) comprised of one rupturable (0.5-1.2 g PLA) and one foundational (3 g PLA) film were assembled. Pockets were loaded with methylene blue (MeB) solution as a model drug and cavitation nuclei 1-1.5 mL Sonazoid microbubbles (GE Healthcare) or 2-2.8 mL nanodroplets derived from Definity microbubbles (Lantheus Medical Imaging). Pockets were submerged in water with and irradiated with clinical US or High Intensity Focused US (HIFU). Clinical US used a S50 scanner (SonoScape) with a curvilinear C1-6 probe for 20 min of Power Doppler imaging (2.2 MHz, highest line density, 100% power) followed by 10 min of flash replenishment imaging (3.0 MHz harmonic imaging at 100% power every 4 seconds). HIFU involved 20 min insonation (2.0 MHz at 4V with 50% duty cycle) using an SU-101 probe (Sonic Concepts) run by a 8116A pulse generator (Hewlett Packard) with 50 dB amplification. Three groups were compared using Fisher's exact test (Stata 15; StataCorp): film thickness (0.5 g PLA for rupturable film vs > 0.5 g), type of US (clinical vs HIFU), and cavitation agent (microbubbles vs nanodroplets).

RESULTS

PLA film thickness was 23 ± 5 μm (0.5 g films) and 61 ± 10 μm (1.0 g films). Six out of 24 sealed and insonated pockets ruptured with insonation. Three of 8 pockets containing nanodroplets and three of 16 containing Sonazoid ruptured ($p > 0.35$). 8 pockets were insonated with HIFU and 16 with clinical US; again, three ruptured in each group ($p > 0.35$). The thickness of the rupturable film appeared to not make a difference as four of 16 thin and two of 8 thick films were ruptured.

CONCLUSION

s The feasibility of assembling a drug-loaded pocket using a biodegradable polymer film and achieving UTDD with internal cavitation nuclei was established. Using nanodroplets and applying HIFU were more successful for UTDD, even though the results did not reach statistical significance in this small sample size.

CLINICAL RELEVANCE/APPLICATION

Triggered antibiotic release would increase infection control in spinal surgery. A UTDD system was developed that would be applicable to surgical implant placement and allow targeted, noninvasive, local drug delivery.

T5B-SPNR-6 Standardized Reporting Increases Sensitivity for Brain MRI Findings in Spontaneous Intracranial Hypotension

Participants
Ryan Turner, (*Presenter*) Nothing to Disclose

PURPOSE

MRI findings of spontaneous intracranial hypotension (SIH) can be subtle. This study sought to determine whether implementation of a standardized reporting template for brain MRI performed to evaluate for imaging features of SIH resulted in increased sensitivity for these findings, using a validated probabilistic scoring system as a gold standard.

METHODS AND MATERIALS

A report template which includes a checklist of brain MRI features of SIH (dural enhancement, subdural collections, slumping of the brainstem, decreased mamillo-pontine interval, pituitary/venous engorgement, and hemosiderosis) was introduced at a tertiary academic center for voluntary use by reading neuroradiologists. 3 months of imaging reports were retrospectively reviewed by searching for indications of "SIH", "orthostatic headache", or "CSF leak". A neuroradiologist with subspecialty expertise in SIH blinded to the original reports assessed each exam for features of SIH and assigned a quantitative SIH Bern score corresponding to low, intermediate, or high probability of SIH. The original reports for those exams were scrutinized for whether the original reader utilized the standardized reporting template and whether the report impression accurately reflected the probability of SIH in a given patient compared with the gold standard retrospective review. Secondary analysis assessed which imaging features were most commonly missed by the original reader.

RESULTS

Of 57 reports, 27/57 (47%) of cases utilized the standardized template and 30/57 (53%) of cases did not. In reports where the template was not used, 13 of 30 (43%) were discordant from the gold standard reader, whereas in the group that did use the template, 4 of 27 (15%) were discordant. This difference was statistically significant ($p = .019$). Of discordant cases that did not use the template, the most commonly missed findings were prepontine cistern effacement (77%), suprasellar cistern effacement (69%), engorgement of venous sinus (54%) and reduced mamillo-pontine interval (46%).

CONCLUSION

s Standardized reporting of brain MRIs to evaluate for SIH improves the sensitivity of relevant imaging findings.

CLINICAL RELEVANCE/APPLICATION

SIH is a challenging diagnosis; this work suggests that the use of a standardized reporting template when assessing for SIH imaging features can increase the sensitivity for subtle findings that may otherwise be missed.

T5B-SPNR-8 The Accessory Diagnostic Role of Diffusion-Weighted Imaging in the Assessment of Advanced MRI Spine Evaluation in the Setting of Multiple Myeloma and Metastatic Disease.

Participants
Leen Alkukhun, MD, Syracuse, NY (*Presenter*) Nothing to Disclose

PURPOSE

To assess the utility of diffusion-weighted images (DWI) in patients with history of metastatic disease and/or multiple myeloma to evaluate the degree of response of disease, in comparison to other MRI characteristics such as size and enhancement. Our goal is to illustrate the utility of DWI and the correlating ADC values as a diagnostic tool in differentiating progression of disease versus stable, post-therapy related restricted diffusion.

METHODS AND MATERIALS

A retrospective chart review was conducted in our tertiary care center. A total of 20 patients with a history of metastasis and/or multiple myeloma with multiple spinal magnetic resonance imaging (MRI) with DWI sequences were collected. With additional independent review from a board-certified Neuroradiologist, DWI sequences and the correlating ADC values were obtained on both initial and follow-up spinal MRI post-therapy with an emphasis on the most diffusion restricting spinal lesions. Additional factors such as size and number of lesions and degree of enhancement were used to determine disease stage, this was quantified using a scale of 1 - 3, 1 for improving disease, 2 for disease progression, and 3 for stable disease. These findings were then correlated with the associated ADC values and degree of restricted diffusion.

RESULTS

Of the 20 reviewed patients, three demonstrated disease improvement with the additional factors of degree of enhancement, size, and number of lesions, with corresponding increasing ADC values demonstrating decreasing restricted diffusion. Interestingly, 6 out of 7 patients with stable disease based on additional quantifying factors also demonstrated increasing ADC values suggesting a component of disease response and hypothetical improvement with continued follow-up. Patients that demonstrated deteriorating disease with increasing size or number of lesions also demonstrated decreasing ADC values (increasing restricted diffusion) in 3 of 5 cases. Additionally, two patients with MRI follow-up suggesting disease progression also demonstrated improving ADC values, this is of uncertain significance.

CONCLUSION

s In applying this method in patients with either multiple myeloma or metastatic disease of the spine we believe there is a strong correlation between decreasing degree of restriction in the patient’s spine lesions and a positive therapeutic response, even in the setting of otherwise stable disease.

CLINICAL RELEVANCE/APPLICATION

In DWI, correlating ADC values can be used as a quantitative value of restriction degree. Although limited by our small cohort we believe continued retrospective analysis will further strengthen this correlation and further reinforce the argument for the addition of DWI imaging in routine spinal malignancy surveillance.

T5B-SPNR-9 Characterization of Radiopaque Microspheres with Dual-Energy CT and Interventional X-ray Imaging

Participants
Ethan Nikolau, MS, Madison, WI (*Presenter*) Nothing to Disclose

PURPOSE

To characterize the radiopacity of a novel barium-loaded microsphere and demonstrate visibility of the microspheres in an in vivo porcine splenic embolization model using different interventional imaging techniques.

METHODS AND MATERIALS

Batches of 900-micron radiopaque microspheres were created by precipitation of barium sulfate into microsphere beads using sodium sulfate and barium chloride. Varying barium strengths (x1 to x10) were obtained through repetition of the barium loading steps. Syringes containing microspheres suspended in saline were placed within a 16 cm acrylic phantom. Dual-energy CT (DECT) scans were performed using a clinical CT scanner. Iodine (Water) basis images reconstructed from DECT scans were used to measure equivalent iodine density for each barium loading strength. Conventional CT scans were acquired at 80, 120, and 140 kV to determine CT number for each strength. A porcine study of splenic artery embolization was performed on an interventional x-ray system using the x5 strength microspheres to demonstrate in vivo microsphere visibility in C-arm cone beam CT (CBCT) images and 2D dual-energy (DE) images. 2D DE images with tissue subtraction were formed from successively acquired low and high energy image sequences.

RESULTS

DECT scans demonstrated a close to linear relationship (R2=0.978) between equivalent iodine density and barium loading, ranging from 2.99 mg/mL to 36.5 mg/mL iodine equivalent for x1 to x10 strength microspheres. Conventional CT images of the x10 microspheres had CT numbers of 1767, 1144, and 971 HU at 80, 120 and 140 kV, respectively. Imaging of the x5 microspheres (22.0 mg/mL iodine equivalent) in vivo demonstrated a global distribution with visualization of the microspheres throughout the spleen in a post-embolization CBCT acquired without injected contrast agent. The microspheres were visible in the 2D DE images.

CONCLUSION

s Radiopaque barium-loaded microspheres were prepared with up to 36.5 mg/mL iodine equivalent density. In an in vivo porcine model, the distribution of injected 22.0 mg/mL iodine equivalent microspheres was visualized in 3D CBCT images and tissue-subtracted 2D dual-energy images.

CLINICAL RELEVANCE/APPLICATION

Barium loaded radiopaque microspheres visible on interventional imaging may provide direct intra- and post-procedural monitoring of both on- and off-target microsphere distribution and embolization.

Utility of Vertebral Volumetry in Predicting Early Adjacent Compression Fractures After Kyphoplasty

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Ashwin Deshmukh, MBBS, FRCR, Milford, CT (*Presenter*) Nothing to Disclose

PURPOSE

Several studies have assessed factors associated with development of early adjacent compression fractures (eACF) in patients undergoing kyphoplasty. This first of its kind study explored whether metrics derived from vertebral volume measurements were associated with development of eACF.

METHODS AND MATERIALS

This retrospective study included patients aged 60 and above without spinal metastases who underwent thoracic and/or lumbar kyphoplasty for vertebral compression fractures. Patients who had pre and post procedural cross-sectional imaging, and follow-up imaging at a minimum of 3 months post procedure were included. Vertebral body volumes of the fractured vertebra before and after kyphoplasty were measured. Additionally, volumes of the immediately adjacent vertebrae on pre-procedural scans were also measured. Two metrics derived from vertebral body volume measurements were used to test for statistical significance among those who developed eACF (within three months of kyphoplasty) and those who did not: ratio of post-kyphoplasty volume to pre-kyphoplasty volume of the index vertebra; ratio of post-kyphoplasty volume of the index vertebra to average of volumes of the immediately adjacent vertebrae on pre-procedural imaging.

RESULTS

21 consecutive patients were included. Of these, eight patients developed eACF. The mean age and standard deviation (SD) of eACF and non-eACF groups were 80.5±7.99 years and 76.38±10.99 years, respectively. All but one patients in each group underwent bipedicular kyphoplasty. Four patients (4/8) in eACF group and seven patients (7/13) in non-eACF group had chronic fractures in the thoracolumbar spine on pre-procedural imaging. There was a significant difference among the ratios of post-kyphoplasty volume to pre-kyphoplasty volume of index vertebra in eACF and non-eACF groups, with higher ratios in the eACF group (mean±SD: 1.389±0.353 and 1.077±0.107 respectively; p=0.0072). There was no significant difference among the ratios of post-kyphoplasty volume of the index vertebra to the average of adjacent vertebral body volumes in eACF and non-eACF groups (mean±SD: 0.960±0.139 and 0.907±0.100 respectively; p=0.052).

CONCLUSION

s Results from this pilot study are encouraging, with a significant difference in one of the two assessed metrics. A larger multi-institutional retrospective study assessing these metrics (including assessment of inter-observer variability), and comparison with previously published metrics is currently underway.

CLINICAL RELEVANCE/APPLICATION

If validated and standardized, these ratios could guide operators in injecting optimal volume of cement to avoid development of eACF, and also help inform an active surveillance protocol for those who might be at risk for eACF.

T5B-SPNR-11

Ultrafast Cervical Spine MRI Using Deep Learning-Based Reconstruction: Diagnostic Equivalence to a Conventional Protocol

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Atsushi Nakamoto, MD, PhD, Suita, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the diagnostic equivalency between an ultrafast MRI protocol (2 min 57 s) of the cervical spine using deep learning-based reconstruction (DLR) and a conventional MRI protocol (12 min 54 s).

METHODS AND MATERIALS

This study included 50 patients who underwent cervical spinal MRI of both conventional and ultrafast protocols, including sagittal T1-weighted, T2-weighted, short-TI inversion recovery, and axial T2*-weighted images. Compared with the conventional protocol, the ultrafast protocol shortened the scanning time to about one fourth by using a lower number of excitations, a higher acceleration factor in compressed sensing, and a lower spatial resolution. To compensate for the decreased signal-to-noise ratio caused by shortened scanning time, noise reduction was performed using the Advanced Intelligent Clear-IQ Engine, a recently commercially available DLR. Three neuroradiologists analysed all images for grading of degenerative changes using a four- or five-point scale and the presence of other spinal abnormalities. For the degenerative changes, inter-protocol intra-reader agreement was assessed by weighted kappa statistics. We also examined interchangeability between the two protocols by calculating the individual equivalence index as the estimated difference between the intra-protocol (conventional) inter-reader and inter-protocol inter-reader agreement. Regarding other abnormalities, the concordance rates of the three readers were calculated.

RESULTS

The kappa values for canal stenosis, disc degeneration, foraminal stenosis, disc hernia, and endplate degeneration, ranged from 0.76 to 0.94, 0.54 to 0.66, 0.54 to 0.87, 0.67 to 0.91, and 0.51 to 0.79, respectively, indicating moderate to almost perfect agreement. Except for endplate degeneration, the 95% confidence interval of the individual equivalence index did not exceed 5%, indicating interchangeability between the two protocols. Six cord lesions and one vertebral lesion were detected as other spinal pathologies. The concordance rates of their detection between the two protocols were 100% in all three readers.

CONCLUSION

s Our proposed ultrafast MRI protocol and the conventional protocol showed approximate diagnostic equivalence.

CLINICAL RELEVANCE/APPLICATION

Our proposed ultrafast spine MRI protocol using DLR showed approximate diagnostic equivalence to a conventional protocol, suggesting its practicality for patients requiring a short examination time.

Clinical and Imaging Features of Spinal Extradural Arachnoid Cysts: A Retrospective Study of 50 Cases

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Ahmed Ahmed, MBBS, MSc, (*Presenter*) Nothing to Disclose

PURPOSE

Spinal extradural arachnoid cysts (SEDAC) are rare pockets of CSF or CSF-like fluid that form next to thecal sac in the spine. They are thought to arise from CSF leaking through a dural defect forming an extradural cyst. Prior limited case series have described that they are often found incidentally and rarely cause spinal cord or nerve root compression. This study investigates the demographics and imaging spectrum of SEDACs at our academic institution and compares them with those reported in the literature.

METHODS AND MATERIALS

We reviewed all imaging reports in our institution. Fifty cases with documented MRI diagnosis of SEDAC, Nabors criteria type I meningeal cyst (MC), were identified. We then studied patient demographics, presenting symptoms, cyst characteristics, and management outcomes. We also tested the association between cysts' largest diameter and their location, septation, thecal mass effect, myelopathy, bone remodeling, and extraforaminal extension.

RESULTS

In all 50 subjects, SEDACs were solitary (single) and sporadic (non-familial). The majority were incidental (62%), located posteriorly (92%) and laterally (80%) in the thoracic and thoracolumbar regions (34%, 30%). They were associated with mild thecal mass effect (50%) and bone remodeling (92%). Among symptomatic SEDACs, back pain and radiculopathy were the most reported (68%). Larger cysts were seen caudally in the spinal canal and were associated with greater thecal mass effect, bone remodeling, and septations. All 25 cases (out of 50) that had follow-up MRIs showed stability. 4 out of the six subjects who underwent surgical management had complete or partial remission. One had cyst recurrence.

CONCLUSION

s In this largest series of SEDACs, we found that most were discovered incidentally, stable over time, and most located in the thoracic spine dorsal to the thecal sac. Back pain and radiculopathy constituted most of the presenting symptoms. Treatment with complete surgical excision may yield the best results for symptomatic lesions.

CLINICAL RELEVANCE/APPLICATION

It will help radiologists and clinicians be aware of SEDAC's different clinical presentations, imaging findings, and treatment outcomes.

Quiet and Fast MR Imaging of Cervical Spine: A Preliminary Study with AI-assisted Compressed Sensing Quiet Sequences

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Zhang Yukun, (*Presenter*) Nothing to Disclose

PURPOSE

Acoustic noise was one of the major complaints for patients underwent MR examination, which may affect successful scan rates. The purpose of this study was to investigate the clinical feasibility and performance of quiet sequences with AI-assisted compressed sensing (ACS) on cervical spine imaging, compared to quiet sequences with Parallel Imaging (PI) using different acceleration factors (AFs), as well as conventional cervical spine sequences.

METHODS AND MATERIALS

10 participants (6male, mean age: 47.57±17.25 years) were imaged at a 3T scanner (uMR Omega, Imaging Healthcare, Shanghai, China) using four different T1-weighted (T1WI) and T2-weighted (T2WI) sequences: conventional protocol, quiet protocol with PI (AF = 2,3) and quiet protocol with ACS (AF = 4)(Table 1). All of the quiet sequences were acquired with a noise reduction factor of 0.6. Noise sound level and acquisition time were recorded. Image quality was subjectively evaluated by two radiologists, using 4-point scores (Table 2). The mean signal to noise ratio (SNR) and mean contrast to noise ratio (CNR) estimation were performed by ROI analysis of the vertebra and the intervertebral disk (IVD) on T1WI and T2WI sequences(figure 1). The differences of qualitative and quantitative parameters between four protocols (conventional sequences, quiet sequences with PI AF = 2, quiet sequences with PI AF = 3 and quiet sequence with ACS AF = 4) were evaluated by Friedman test. SNR = SI vertebra, IVD /SD muscle, CNR = (SI vertebra, IVD -SI muscle)/SD muscle.

RESULTS

There were no statistical differences in SNR, CNR of vertebra and IVD and subjective evaluation between routine sequences and different quiet sequences with acceleration methods ($p > 0.05$,Tables 3 and 4). Significant acoustic noise and acquisition time reduction was measured for quiet T1WI (36% reduction) and quite T2WI (6% reduction) with ACS compared to conventional sequences(figure 2).

CONCLUSION

s This study demonstrated that both effective acoustic noise reduction and improved acceleration efficiency can be achieved for cervical spine in quiet sequences with ACS (AF = 4), without degrade image quality and quantitative SNR as well as CNR reduction.

CLINICAL RELEVANCE/APPLICATION

Quiet T1WI and T2WI sequences with ACS may be promising methods for cervical spine imaging, which may increase patient comfort and benefit successful scan rates as well as clinical applications.

Deep-Learning Image Reconstruction on Low KEV Virtual Monochromatic Image of Dual-Energy CT Improves Image Quality of Adamkiewicz Artery

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Fuminari Tatsugami, MD, Hiroshima, Japan (*Presenter*) Nothing to Disclose

PURPOSE

The detection of the artery of Adamkiewicz (AKA) and the anterior spinal artery (ASA) on CT can be challenging because of their small vascular diameter and the fact that they are surrounded by the spinal canal. Dual-energy CT can increase the iodine contrast by generating low-energy (keV) virtual monochromatic images (VMIs), but the image noise increases as the energy level decrease. Recently introduced deep learning image reconstruction (DLIR) algorithm reduces image noise drastically without degrading image texture compared to iterative reconstruction (IR) algorithms. We investigated whether the use of DLIR on low-keV VMIs can improve the image quality of AKA, using 70 keV VMIs reconstructed with IR algorithms as a reference standard.

METHODS AND MATERIALS

We enrolled 20 patients who underwent CT aortography on a 256-slice CT scanner with dual-energy scan before aortic repair. We prepared the following images; VMI at 70 keV reconstructed with hybrid-IR (HIR), VMI at 40 keV reconstructed with HIR, and VMI at 40 keV reconstructed with DLIR. On axial images, CT attenuation profiles were generated crossing through the center of the ASA lumen, and the maximum value was recorded. The contrast-to-noise ratio (CNR) of ASA was calculated by using the following formula: CNR of ASA= (maximum CT number of the ASA - CT number of the spinal cord) / image noise of the spinal cord. The overall image quality of AKA was visually evaluated by two radiologists using a four-point scale (1 = poor, 4 = excellent). Also, its continuity was visually evaluated using a four-point scale (1 = not visible, 4 = vascular continuity is fully recognized).

RESULTS

The mean image noise in the aorta on 40 keV-DLIR images was slightly lower than on 40 keV-HIR images (43.0 vs. 44.4; $p > 0.05$); they were higher than on 70 keV-HIR images (18.0; $p < 0.01$). CNR of ASA was higher on 40 keV-DLIR images than on 40 keV-HIR and 70 keV-HIR images (11.1, 8.8, and 7.9, respectively; $p < 0.05$). The mean image quality score for 40 keV-DLIR was the highest among the three reconstructions (3.3, 2.7, and 2.3, respectively). The mean score for delineation of AKA on 40 keV-DLIR images was comparable to 40 keV-HIR, but it was higher than on 70 keV-HIR images (3.6, 3.5, and 2.9, respectively).

CONCLUSION

s The use of DLIR on the low keV VMI significantly improves the image quality of AKA compared to conventional methods.

CLINICAL RELEVANCE/APPLICATION

The use of DLIR on the low keV VMI significantly improves the image quality of AKA compared to conventional methods. It can be expected to improve diagnostic performance for the detection of AKA before aortic repair.

T5B-SPNR-15

Blind Spot: Radiologic Reporting of Epidural Metastasis on Body CT in a 12-Year Retrospective Cohort Study

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Lauren M. Kim, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To determine whether imaging features of epidural tumor on CT imaging influenced radiologic reporting.

METHODS AND MATERIALS

293 body CT examinations of 166 patients performed within 30 days of a spine MRI which diagnosed an epidural metastasis were identified. These 293 CT examinations were performed over a 12-year time period at a single institution, with each examination reported by 1 of 17 total radiologists. Majority vote decision among 3 radiologists determined consensus as to whether an epidural metastasis reported on spine MRI was plainly visible on body CT. Epidural metastases deemed plainly visible on body CT were manually segmented by one radiologist for quantitative image analysis. Weighted univariate ?2- and two-tailed t-test analyses were performed to identify statistically significant trends between epidural tumor imaging features and radiologic reporting of epidural metastasis on body CT.

RESULTS

Epidural metastases reported on spine MRI were deemed plainly visible in 80.5% (236/293) of body CTs performed within 30 days, however 65.3% (154/236) of the body CT reports omitted their presence. 432 epidural tumors and which were deemed plainly visible on CT were manually segmented for quantitative image analysis. These epidural tumors were small, on average 1-2 cm3, and low contrast, with average relative contrast (Crel) values less than 1 and average contrast-to-noise (CNR) values between 1-2, representing the lower limit of what the human eye can perceive. The only imaging feature which positively impacted reporting was lesion volume (p=0.03) on noncontrast CT, and lesion volume (p=0.006) and percentage of spinal canal stenosis (p=0.001) on contrast CT. Mean HUepidural tumor=92 and mean SDHU spinal canal=48, suggesting that the optimal window settings by which to visualized epidural tumor on CT is WL 92/ WW 223.

CONCLUSION

s While body CT is moderately capable of displaying epidural tumor, the majority of these lesions go unreported and therefore likely undetected. Adequate magnification and customized windowing will likely improve the detection of epidural metastasis on CT.

CLINICAL RELEVANCE/APPLICATION

Cognitive bias may preclude a radiologist’s search for epidural tumor on body CT; and even when intentionally sought after, this lesion is difficult to see. Directed attention and optimized radiological searching technique may therefore be required, specifically adequate magnification and customized windowing will likely improve the detection of epidural metastasis on CT.

T5B-SPNR-16

Association Between Ligamentous Injuries and Cranio-cervical Junction Malalignment

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
David Timaran Montenegro, MD, Houston, TX (*Presenter*) Nothing to Disclose

PURPOSE

To assess the association between cranio-cervical junction (CCJ) ligamentous injuries and atlantooccipital disassociation and/or atlantoaxial dislocation

METHODS AND MATERIALS

Over a 3-year period, an observational, single center study was performed. In total, 443 subjects with CCJ trauma were reviewed. Only patients that were evaluated with cervical spine CT and MRI (171 subjects [39%]) were included in this study. Among them, 107 patients were male (62.5%) with a median age of 36 years (interquartile range [IQR] 24-57 years). Fisher exact test was performed for univariate analysis. Simple logistic regression analysis was used to determine odds ratios (OR) and confidence intervals (95% CI)

RESULTS

In total, 15 patients (8.7%) were diagnosed with either atlantooccipital disassociation (8 patients [53%] or atlantoaxial dislocation (7 patients [47%]). Among patients with either type of CCJ disassociation, 7 (47%) were found to have ligamentous injuries (p=0.006) (OR, 5.06 [95% CI, 1.79-14.71). Injury of the apical ligament was seen in 3 patients (20%) (p=0.01) (OR, 9.5 [95% CI, 2.13-37.78). Additionally, left occipital condyle fracture was observed in 7 patients (47%) (p=0.01) (OR, 4 [95% CI, 1.4-12.59). Among patients with atlantoaxial dislocation only, epidural hematoma was seen in 4 (57%) subjects (p=0.04). Among patients with atlantooccipital disassociation, 3 (37%) had disruption of the alar ligament (p=0.019). Injuries of the other CCJ ligaments failed to demonstrate statistically significant associations with either type of CCJ disassociation

CONCLUSION

s Incidence of atlantooccipital and/or atlantoaxial malalignment reached 8.7%. CCJ ligamentous injuries were found in up to 47% of the cases. Disruption of the apical ligament was seen in 20% of the patients with either type pf CCJ disassociation. Among patients with atlantooccipital disassociation only, 37% had alar ligament injuries. Injury to other CCJ ligaments was not associated with either type of CCJ disassociation

CLINICAL RELEVANCE/APPLICATION

Literature about acute cranio-cervical junction trauma is limited due to the high mortality rate of patients with CCJ trauma at the scene of injury. Our study will help to understand the association of cervical structural injuries with severe cranio-cervical malalignment.

Application of synthetic MRI in Quantitative Diagnosis in Cervical Spondylotic Myelopathy

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Xiangyu Tang, Wuhan, China (*Presenter*) Nothing to Disclose

PURPOSE

Cervical spondylotic myelopathy (CSM) is a chronic compressive spinal cord lesion. It is important to identify early symptoms and provide effective treatment. To data, previous studies have shown the feasibility of synthetic MRI (MAGiC) in spinal cord imaging on healthy volunteers. The objective of this work was to investigated the feasibility and diagnostic value of the quantitative PD, T1 and T2 values obtaining by synthetic MRI in addressing the severity of CSM.

METHODS AND MATERIALS

From August 2021 to March 2022, a total of 63 subjects were enrolled including 36 CSM patients and 27 healthy subjects (23 males and 40 females). A 3.0T MR scanner (GE, SIGNATM Architect) was used to perform MAGIC imaging sequence on each subject. Patients and controls were evaluated using the Japanese Orthopaedic Association (JOA) scale, a Visual Analogue Scale (VAS) and Neck Disability Index (NDI). The MAGIC images were post-processed using the GE workstation, and ROIs were manually drawn to measure the axial intervertebral discs and the spinal cord at the C2 vertebral level to generate T1, T2, and PD values. The cervical canal stenosis of subjects were graded according to the method of Kang, Y. After that, LSD-t test was used to compare the differences of each parameter value between each grade and C2 vertebral level, and Spearman correlation analysis was used to test the correlation between C2 vertebral body level and the maximum degree of intervertebral disc herniation and clinical mJOA score, VSA score, NDI score.

RESULTS

The T1 mapping, T2 mapping and PD mapping were generated by MAGiC data (Figure 1). The PD value had a decreasing trend from grade 0 to grade 2. The PD value of C2 is bigger than the value of grade 0, grade1 and grade2, with statistically significant ($P<0.01$), except for the difference between grade3, showing the PD value had a potential for early diagnosis for CSM (Figure 2a). The T1 value had statistically difference between grade3 and the other grade($P<0.05$). (Figure 2b) The T2 value had statistically difference between C2 and the other grade($P<0.05$), showing the CSM patients had the change of T2 values (Figure 2c).

CONCLUSION

s MAGiC was shown to be a reliable and effective method in assessing CSM. The values of PD, T1 and T2 open up a new dimension on quantitative measures in assessing CSM

CLINICAL RELEVANCE/APPLICATION

MAGiC has the potential for clinical diagnosis for CSM

T5B-SPNR-19

Utility and National Trend of Use of Spine MRI in the Setting of Suspected Nonaccidental Trauma (NAT)

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Jeffers Nguyen, MD, Centereach, NY (*Presenter*) Nothing to Disclose

PURPOSE

Abusive head trauma (AHT) is the leading cause of morbidity and mortality in patients below the age of 2 with traumatic brain injury. Given the recently growing awareness of spinal injury in the setting of AHT, the current ACR guidelines now strongly recommend performing MRI of the cervical spine at the time of brain MRI, and that MRI of the total spine be considered. In this study, we aim to examine the MRI spine findings in patients hospitalized for suspected non-accidental trauma (NAT). In addition, we examined the national trend of use of spine MRI in the setting of suspected NAT using the Pediatric Health Information System (PHIS).

METHODS AND MATERIALS

After obtaining approval of the institutional review board, a retrospective study was performed evaluating the spine MRI findings of children aged 0 to 2 years admitted for suspected NAT between January 2017 and December 2021. Using our radiology database (Nuance mPower) and the pediatric child abuse database at our institution, infants and young children aged <24 months who had whole spine MRI for suspected NAT were included. Clinical data, including patient demographics, clinical presentation, interventions, and clinical outcomes, were collected, and analyzed. Additionally, the PHIS database was used to identify hospitalizations for AHT from 1/1/17 to 12/31/21 in children < 2 years of age.

RESULTS

A total of 24 patients with MRI of the spine for suspected NAT were identified. The median age at presentation was 5 months, and approximately two-thirds of patients were male. Although nearly all patients (96%) had findings compatible with AHT on brain MRI, only 9 patients (38%) had positive findings on MRI of the spine. Of those, the vast majority (89%) had thoracolumbar subdural hemorrhage, necessitating surgical evacuation in only one of them. Two patients had evidence of ligamentous injury in the cervical spine, one of which subsequently had a cervical collar placed. The national trend of use of spine MRI for suspected NAT is presented in Figure 1

CONCLUSION

s Thoracolumbar subdural hemorrhage is the most common abnormality seen in patients with suspected NAT who underwent whole spine MRI at our institution. Follow up study with larger samples is needed to validate our data and guide future efforts to improve patient selection and study protocols.

CLINICAL RELEVANCE/APPLICATION

There is increasing use of MRI Spine in patients suspected nonaccidental trauma. Severe spinal injury necessitating clinical intervention remains rare despite increased utilization of MRI of the spine.

Dural Branches Supplying the Anterior Fossa Dura Matter From the Anterior Cerebral Artery

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Hiro Kiyosue, MD, (*Presenter*) Research Grant, Koninklijke Philips NV

PURPOSE

It is known that a dural branch to the anterior cranial fossa occasionally originates from the anterior cerebral artery (ACA) which can supply dural hypervascular lesions such as meningioma and anterior fossa dural arteriovenous fistulas. Those dural branches are small but important in interventional procedures because embolic materials injected from the dural branch of the external carotid artery or the ophthalmic artery potentially migrate into the ACA via duro-pial anastomosis. However, no anatomical or angiographical studies regarding dural branches from the ACA have been reported yet. Herein, we evaluate dural branch to the anterior cranial fossa from the proximal portion of the ACA.

METHODS AND MATERIALS

We retrospectively evaluated collateral pathways via the dural arterial anastomoses between the ethmoidal arteries of the ophthalmic artery or the sphenopalatine artery and the anterior cerebral artery in patients with severe stenosis or occlusion of the internal carotid artery. Biplane angiography and 3D angiography images including MPR images in 25 patients (50 sides) were reviewed by two neuroradiologists with a special interest in the origin of the dural branch of ACA.

RESULTS

Duro-pial collaterals via the ethmoidal - ACA dural anastomoses were observed in 18 patients (72%) and 28 sides (56%). Detailed angioarchitecture could be evaluated in 19 sides. In 19 sides, 31 dural branches of the ACA were identified on 3D angiography, which originated from the olfactory artery at the distal portion (n=13) and at the proximal portion (n=7), the orbitofrontal artery (medial frontal artery) (n=2), and directly from ACA(A1 or A2) (n=9).

CONCLUSION

s Dural branches from the proximal portion of the ACA or its branches frequently exists, which often originate at the distal portion of the olfactory artery. Careful attention for the duro-pial anastomosis via the dural branch of the ACA during embolization of the lesion on the anterior cranial fossa

CLINICAL RELEVANCE/APPLICATION

Knowledge of the duro-pial anastomoses between the extracranial dural arteries (e.g. sphenopalatine artery) and the dural branch from the anterior cerebral artery is very important to avoid complications in neurointerventional procedures. This study clarify the frequency and course/origin of the dural branches from the anterior cerebral artery.

T5B-SPNR-20

Clinical Feasibility of Compressed Sensing for Three-dimensional MR Imaging of Cranial Nerves

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
HEDAN LUO, DALIAN, China (*Presenter*) Nothing to Disclose

PURPOSE

This study aims to investigate the quality of three-dimensional MR images of cranial nerves based on united compressed sensing (uCS) with different acceleration factors (AFs) and compare with that of images using sensitivity encoding (SENSE),optimized Imaging sequence and choosed the most appropriate acceleration factor.

METHODS AND MATERIALS

We prospectively recruited 14 volunteers (mean age, 40.86±3.60 years) who were scanned using a 3T MRI system (uMR Omega, United Imaging Healthcare, Shanghai, China). The T2-weighted images were acquired using a combination of 3D-MATRIX sequence and uCS with different AFs (3, 4, 5 and 6) and SENSE with AF of 2. Detailed parameters were listed in Table 1. The olfactory nerve(I), optic nerve(II) and trigeminal nerve(V) of cranial nerves were manually located and displayed in Fig.1. Signal to noise ratio (SNR) and contrast to noise ratio (CNR) were calculated from the signal intensity(SI) in cranial nerves. SNR=SII,II,V/SDCSF,CNR=(SICSF-SII,II,V)/SDCSF .SI of the small blood vessels close to the auditory nerve was measured and the corresponding Contrast Ratio (CR) was calculated.CR=(SICSF-SIvessel)/(SICSF+SIvessel)Image quality, including cranial nerve detail visibility, image noise and artifact and diagnostic value, was scored by two observers using a quartet-scale method for oculomotor nerve(III), facial nerve(VII)and glossopharyngeal nerve (IX). Friedman test was conducted to evaluate the differences of SNR, CNR, CR and score under different accelerating settings.

RESULTS

Image quality scores were consistent between two observers (Cohen's kappa coefficient =0.864). There were significant differences in the SNR of cranial nerve II, CR of vascular, and image quality scores of cranial nerves III, VII, and IX under different accelerating settings (all P values < 0.05 for multiple comparisons). For post-hoc analysis, the CR of vascular when using uCS with AF of 5 was significantly larger than that when using SENSE (P value < 0.05). And the scores when using uCS with AF of 6 were significantly lower than those when using SENSE (all P values < 0.05).(Fig.2)

CONCLUSION

s uCS-based MR imaging of cranial nerves could save scanning time without loss of SNR and CNR, compared with conventional MRI using SENSE method. Taking into account both satisfactory image quality and tight clinical time-constraint, we recommended to select AF of 5 for uCS in routine MR scanning.

CLINICAL RELEVANCE/APPLICATION

uCS-based MR imaging of cranial nerves showed high feasibility and clinical applicability: reducing scanning time and meanwhile ensuring image quality.

T5B-SPNR-4

Visualization of Lenticulostriate Artery by Compressed Sensing Imaging

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Huang Fuling, MBChB, (*Presenter*) Nothing to Disclose

PURPOSE

Lenticulostriate artery (LSA) is a vital perforating artery in the brain, and its occlusion often leads to lacunar infarction. At present, digital subtraction angiography (DSA) is mainly used to realize the imaging of lenticulostriate artery in clinic, but the invasiveness of DSA is an important limiting factor. Some studies have shown that TOF (Time-Of-Flight) sequence has been able to obtain better images of lenticulostriate artery under high-field magnetic resonance system (7T). However, the diameter of the LSA is so small (about 0.3 - 0.7 mm) and the blood flow velocity is relatively slow, the imaging of the LSA is still a challenge with 3T MRI scanner. The study aims to visualize the LSA using 3D-TOF sequence and compressed sensing imaging on 3T system.

METHODS AND MATERIALS

Thirty-two patients and twenty-two volunteers underwent brain MRI scanning with routine 3D-TOF sequence and compressed sensing imaging on 3T system. Lenticulostriate artery were reconstructed and visualized by volume rendering (VR) technique, the length and number of lenticulostriate artery were analyzed.

RESULTS

The scanning time of 3D-TOF with and without compressed sensing sequence were 7 minutes and 8 minutes and 44 seconds, respectively, the LSAs were displayed clearly by VR technique on both condition. A total of one hundred and eight hemispheres were analyzed. The total number ($p > 0.05$) and length ($p > 0.05$) of LSAs were non-statistically different between 3D-TOF with and without compressed sensing imaging. There was a significant reduction ($p < 0.05$) in length of visualized LSA in infarction patients compared with the normal people.

CONCLUSION

s We concluded that the compressed sensing technique is of clinical value in the analysis of morphological characteristics of lenticulostriate artery, and it shortens the imaging time to 7 minutes. In summary, using compressed sensing technique to visualize lenticulostriate artery can basically meet the requirements of clinical in scanning time.

CLINICAL RELEVANCE/APPLICATION

Using compressed sensing technique to visualize lenticulostriate artery can basically meet the requirements of clinical in scanning time on 3T system.

T5B-SPNR-5

In Vitro US-Triggered Drug Release from Polymer Film Pocket

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Selin Isguven, Philadelphia, PA (*Presenter*) Nothing to Disclose

PURPOSE

Infection after spinal fusion occurs in up to 16% of cases, with increased hospital stays and healthcare costs. To augment current therapies, we have designed a rupturable antibiotic reservoir that is stable for 3-5 days followed by US-triggered drug delivery (UTDD). We tested rupture as a function of cavitation nuclei, material properties, and acoustics.

METHODS AND MATERIALS

Polylactic acid (PLA) pockets (~3 mL volume; n = 24) comprised of one rupturable (0.5-1.2 g PLA) and one foundational (3 g PLA) film were assembled. Pockets were loaded with methylene blue (MeB) solution as a model drug and cavitation nuclei 1-1.5 mL Sonazoid microbubbles (GE Healthcare) or 2-2.8 mL nanodroplets derived from Definity microbubbles (Lantheus Medical Imaging). Pockets were submerged in water with and irradiated with clinical US or High Intensity Focused US (HIFU). Clinical US used a S50 scanner (SonoScape) with a curvilinear C1-6 probe for 20 min of Power Doppler imaging (2.2 MHz, highest line density, 100% power) followed by 10 min of flash replenishment imaging (3.0 MHz harmonic imaging at 100% power every 4 seconds). HIFU involved 20 min insonation (2.0 MHz at 4V with 50% duty cycle) using an SU-101 probe (Sonic Concepts) run by a 8116A pulse generator (Hewlett Packard) with 50 dB amplification. Three groups were compared using Fisher's exact test (Stata 15; StataCorp): film thickness (0.5 g PLA for rupturable film vs > 0.5 g), type of US (clinical vs HIFU), and cavitation agent (microbubbles vs nanodroplets).

RESULTS

PLA film thickness was 23 ± 5 μm (0.5 g films) and 61 ± 10 μm (1.0 g films). Six out of 24 sealed and insonated pockets ruptured with insonation. Three of 8 pockets containing nanodroplets and three of 16 containing Sonazoid ruptured ($p > 0.35$). 8 pockets were insonated with HIFU and 16 with clinical US; again, three ruptured in each group ($p > 0.35$). The thickness of the rupturable film appeared to not make a difference as four of 16 thin and two of 8 thick films were ruptured.

CONCLUSION

s The feasibility of assembling a drug-loaded pocket using a biodegradable polymer film and achieving UTDD with internal cavitation nuclei was established. Using nanodroplets and applying HIFU were more successful for UTDD, even though the results did not reach statistical significance in this small sample size.

CLINICAL RELEVANCE/APPLICATION

Triggered antibiotic release would increase infection control in spinal surgery. A UTDD system was developed that would be applicable to surgical implant placement and allow targeted, noninvasive, local drug delivery.

Standardized Reporting Increases Sensitivity for Brain MRI Findings in Spontaneous Intracranial Hypotension

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Ryan Turner, (*Presenter*) Nothing to Disclose

PURPOSE

MRI findings of spontaneous intracranial hypotension (SIH) can be subtle. This study sought to determine whether implementation of a standardized reporting template for brain MRI performed to evaluate for imaging features of SIH resulted in increased sensitivity for these findings, using a validated probabilistic scoring system as a gold standard.

METHODS AND MATERIALS

A report template which includes a checklist of brain MRI features of SIH (dural enhancement, subdural collections, slumping of the brainstem, decreased mamillo-pontine interval, pituitary/venous engorgement, and hemosiderosis) was introduced at a tertiary academic center for voluntary use by reading neuroradiologists. 3 months of imaging reports were retrospectively reviewed by searching for indications of “SIH", “orthostatic headache", or "CSF leak”. A neuroradiologist with subspecialty expertise in SIH blinded to the original reports assessed each exam for features of SIH and assigned a quantitative SIH Bern score corresponding to low, intermediate, or high probability of SIH. The original reports for those exams were scrutinized for whether the original reader utilized the standardized reporting template and whether the report impression accurately reflected the probability of SIH in a given patient compared with the gold standard retrospective review. Secondary analysis assessed which imaging features were most commonly missed by the original reader.

RESULTS

Of 57 reports, 27/57 (47%) of cases utilized the standardized template and 30/57 (53%) of cases did not. In reports where the template was not used, 13 of 30 (43%) were discordant from the gold standard reader, whereas in the group that did use the template, 4 of 27 (15%) were discordant. This difference was statistically significant ($p = .019$). Of discordant cases that did not use the template, the most commonly missed findings were prepontine cistern effacement (77%), suprasellar cistern effacement (69%), engorgement of venous sinus (54%) and reduced mamillo-pontine interval (46%).

CONCLUSION

s Standardized reporting of brain MRIs to evaluate for SIH improves the sensitivity of relevant imaging findings.

CLINICAL RELEVANCE/APPLICATION

SIH is a challenging diagnosis; this work suggests that the use of a standardized reporting template when assessing for SIH imaging features can increase the sensitivity for subtle findings that may otherwise be missed.

T5B-SPNR-8

The Accessory Diagnostic Role of Diffusion-Weighted Imaging in the Assessment of Advanced MRI Spine Evaluation in the Setting of Multiple Myeloma and Metastatic Disease.

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Leen Alkukhun, MD, Syracuse, NY (*Presenter*) Nothing to Disclose

PURPOSE

To assess the utility of diffusion-weighted images (DWI) in patients with history of metastatic disease and/or multiple myeloma to evaluate the degree of response of disease, in comparison to other MRI characteristics such as size and enhancement. Our goal is to illustrate the utility of DWI and the correlating ADC values as a diagnostic tool in differentiating progression of disease versus stable, post-therapy related restricted diffusion.

METHODS AND MATERIALS

A retrospective chart review was conducted in our tertiary care center. A total of 20 patients with a history of metastasis and/or multiple myeloma with multiple spinal magnetic resonance imaging (MRI) with DWI sequences were collected. With additional independent review from a board-certified Neuroradiologist, DWI sequences and the correlating ADC values were obtained on both initial and follow-up spinal MRI post-therapy with an emphasis on the most diffusion restricting spinal lesions. Additional factors such as size and number of lesions and degree of enhancement were used to determine disease stage, this was quantified using a scale of 1 - 3, 1 for improving disease, 2 for disease progression, and 3 for stable disease. These findings were then correlated with the associated ADC values and degree of restricted diffusion.

RESULTS

Of the 20 reviewed patients, three demonstrated disease improvement with the additional factors of degree of enhancement, size, and number of lesions, with corresponding increasing ADC values demonstrating decreasing restricted diffusion. Interestingly, 6 out of 7 patients with stable disease based on additional quantifying factors also demonstrated increasing ADC values suggesting a component of disease response and hypothetical improvement with continued follow-up. Patients that demonstrated deteriorating disease with increasing size or number of lesions also demonstrated decreasing ADC values (increasing restricted diffusion) in 3 of 5 cases. Additionally, two patients with MRI follow-up suggesting disease progression also demonstrated improving ADC values, this is of uncertain significance.

CONCLUSION

s In applying this method in patients with either multiple myeloma or metastatic disease of the spine we believe there is a strong correlation between decreasing degree of restriction in the patient’s spine lesions and a positive therapeutic response, even in the setting of otherwise stable disease.

CLINICAL RELEVANCE/APPLICATION

In DWI, correlating ADC values can be used as a quantitative value of restriction degree. Although limited by our small cohort we believe continued retrospective analysis will further strengthen this correlation and further reinforce the argument for the addition of DWI imaging in routine spinal malignancy surveillance.

T5B-SPNR-9

Characterization of Radiopaque Microspheres with Dual-Energy CT and Interventional X-ray Imaging

Tuesday, Nov. 29 12:45PM - 1:15PM Room: Learning Center - NR DPS

Participants
Ethan Nikolau, MS, Madison, WI (*Presenter*) Nothing to Disclose

PURPOSE

To characterize the radiopacity of a novel barium-loaded microsphere and demonstrate visibility of the microspheres in an in vivo porcine splenic embolization model using different interventional imaging techniques.

METHODS AND MATERIALS

Batches of 900-micron radiopaque microspheres were created by precipitation of barium sulfate into microsphere beads using sodium sulfate and barium chloride. Varying barium strengths (x1 to x10) were obtained through repetition of the barium loading steps. Syringes containing microspheres suspended in saline were placed within a 16 cm acrylic phantom. Dual-energy CT (DECT) scans were performed using a clinical CT scanner. Iodine (Water) basis images reconstructed from DECT scans were used to measure equivalent iodine density for each barium loading strength. Conventional CT scans were acquired at 80, 120, and 140 kV to determine CT number for each strength. A porcine study of splenic artery embolization was performed on an interventional x-ray system using the x5 strength microspheres to demonstrate in vivo microsphere visibility in C-arm cone beam CT (CBCT) images and 2D dual-energy (DE) images. 2D DE images with tissue subtraction were formed from successively acquired low and high energy image sequences.

RESULTS

DECT scans demonstrated a close to linear relationship (R2=0.978) between equivalent iodine density and barium loading, ranging from 2.99 mg/mL to 36.5 mg/mL iodine equivalent for x1 to x10 strength microspheres. Conventional CT images of the x10 microspheres had CT numbers of 1767, 1144, and 971 HU at 80, 120 and 140 kV, respectively. Imaging of the x5 microspheres (22.0 mg/mL iodine equivalent) in vivo demonstrated a global distribution with visualization of the microspheres throughout the spleen in a post-embolization CBCT acquired without injected contrast agent. The microspheres were visible in the 2D DE images.

CONCLUSION

s Radiopaque barium-loaded microspheres were prepared with up to 36.5 mg/mL iodine equivalent density. In an in vivo porcine model, the distribution of injected 22.0 mg/mL iodine equivalent microspheres was visualized in 3D CBCT images and tissue-subtracted 2D dual-energy images.

CLINICAL RELEVANCE/APPLICATION

Barium loaded radiopaque microspheres visible on interventional imaging may provide direct intra- and post-procedural monitoring of both on- and off-target microsphere distribution and embolization.

T5B-SPOB-1 Multimodal Deep Learning Models Reach High Prediction Accuracy in the Diagnosis of Ovarian Cancer

Participants
Zimo Wang, MD, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this study is to analyze the diagnostic performance of a deep multimodal representation model based on the integration of tumor ultrasound images, serum tumor markers, and patient menopausal status for the identification of benign and malignant ovarian tumors.

METHODS AND MATERIALS

A total of 1054 patients with ovarian tumors diagnosed from January 2015 to March 2022 by pathology (including 699 patients with benign ovarian tumors and 355 patients with malignant ovarian tumors) were retrospectively analyzed, and 4552 gray-scale and CDFI ultrasound images were collected. (including 2611 ultrasound images of benign ovarian tumors and 1941 ultrasound images of ovarian malignant tumors). In our research, a single-modality CNN model based on ultrasound images, a dual-modality CNN model based on ultrasound images and menopausal status, and a multi-modality CNN model based on ultrasound images, menopausal status, serum CA-125 and serum HE4 were constructed. The performance of these three models in differentiating benign and malignant ovarian tumors was compared.

RESULTS

The diagnostic accuracy and area under the curve (AUC) values for single-modality ultrasound images were 90.95% and 0.957. The dual-modality accuracy and area under the curve (AUC) values after combining menopausal status were 92.38% and 0.968 . With the integration of ultrasound images, serum tumor markers and menopausal status, the diagnostic performance has gradually improved, and the diagnostic accuracy and AUC value of the multimodal model reached 93.80% and 0.983, achieving satisfactory predictive performance.

CONCLUSION

s The multimodal representation learning model constructed by integrating ultrasound images, serum tumor markers and patient menopausal status outperforms the CNN model based on ultrasound images alone and the bimodal CNN model combined with menopausal status. We expect that the deep multimodal representation model can become a more efficient and accurate diagnostic tool, and improve the performance of ultrasound in the identification of benign and malignant ovarian tumors in clinical practice.

CLINICAL RELEVANCE/APPLICATION

The multimodal representation learning model constructed by integrating ultrasound images, serum tumor markers and patients' menopausal status can improve the accuracy of distinguishing benign and malignant ovarian tumors and provide more reliable reference information for clinicians.

T5B-SPOB-2 Diffusion and Perfusion Properties of Placenta in Women with COVID19 Pregnancy Infection: A Preliminary IVIM MRI Study

Participants
Roberta Ninkova, MD, Rome, Italy (*Presenter*) Nothing to Disclose

PURPOSE

The aim of our research was to investigate the potential use of Intravoxel Incoherent Motion (IVIM) MRI in the study of microvascular and microstructural characteristics of the placenta in women with previous COVID-19 infection occurred during gestation.

METHODS AND MATERIALS

15 pregnant women with previous Covid-19 infection occurred during pregnancy were enrolled. Placental MRI was performed on 1.5T scanner, using a Diffusion-Weighted Echo-Planar Imaging sequence with 10 different b values (0,10,30,50,75,100,150,400,700,1000 s/mm2). For each placenta, 6 ROIs were manually placed on different areas of both Fetal and Maternal side. The mean values of fraction of perfusion f, Pseudo-Diffusion Coefficient D* and Diffusion Coefficient D were obtained. Differences between f, D, D* mean values of ex-Covid placentae and those of the uninfected control group (31 placentae) were assessed with Analysis of Variance (ANOVA) test with Bonferroni correction. Pearson test with Bonferroni correction was performed

to investigate the correlation between IVIM parameters and Gestational Age (GA) in both groups.

RESULTS

We found a statistically significant difference in D between the Ex-Covid19 placentae and those of the uninfected control group, in both fetal (p=0,017) and maternal side (p=0,012). No significant differences were found in f, D* between two groups. In Ex-Covid 19 placentae, D has a negative correlation with GA in both maternal (p<0.02) and fetal (p<0.04) ROIs, depicting a decreased diffusivity trend with placental aging. No correlation between D and GA was found in normal placentae.

CONCLUSION

s Placenta is a potential target organ for Covid19 infection via the ACE2 receptor expressed at the maternal-fetal interface, potentially leaving signs of placental injury. The cumulative published data on placenta with COVID-19 infection showed common histological features, with a higher rate of perfusion anomalies. SARS-CoV-2 placental infection is also associated with chronic inflammatory pathologies which include villitis and intervillitis. We think that quantification of the IVIM parameters shows a potential in improving knowledge of the in vivo microstructural changes occurring in these placentae.

CLINICAL RELEVANCE/APPLICATION

In literature there are no MRI studies yet on Covid-19 and Placenta. In our experience, the quantitative detection of subtle microstructural changes in dysfunctional placentae using IVIM model may add useful information about the pathophysiology of pregnancy complications (IUGR, stillbirth...) that could potentially occur in COVID-19 patients.

T5B-SPPD-1 Parkinsonism Syndrome in Primary Mitochondrial Disorders in Children: Imaging and Clinical Findings

Participants
Luis Tierradentro-Garcia, MD, Philadelphia, PA (*Presenter*) Nothing to Disclose

PURPOSE

Movement disorders may be observed in some patients with primary mitochondrial disorders (PMD). However, the frequency of the involvement of associated anatomic structures such as the substantia nigra (SN), the particular associated genetic mutations, and the specific clinical motor symptoms have not been reported. This study aims to analyze MRI abnormalities and follow-up changes of SN involvement in children with Parkinsonian movement disorder, in the context of genetically confirmed PMD to find the possible imaging and clinical correlation.

METHODS AND MATERIALS

In this retrospective analysis, we included patients younger than 18 years old with genetically confirmed PMD and brain MRI. We assessed the presence of various forms of movement disorder symptomatology in the clinical record and reported associated imaging abnormalities. MRI findings that were associated with symptoms of movement disorders or those with significant effect sizes ($p=0.05$-0.1 and Cramer $V > 1.5$) were tested through univariate logistic regression.

RESULTS

One hundred and seven patients with genetically confirmed PMD were included. The SN was involved in 32 (29.9%) patients, and among them, 28 (26.1%) had lesions on the baseline MRI. Follow-up studies were available for 22 subjects, in which four (18.2 %) had improvement of the lesions by MRI. Leigh syndrome (LS) was the most frequent PMD diagnosis in patients with SN involvement ($n=26/32$, 81%). LS was associated with SN involvement both at baseline MRI ($p< 0.001$, $V= 0.5$) and at all time-point pooled MRIs ($p<0.001$, $V=0.53$). Univariate model showed that mutation of genes encoding OXPHOS were strongly predictive (OR= 6.6, CI95% 2.6-17) of SN involvement at baseline (model $Chi2= 16.5$, $p< 0.001$, $R2= 0.21$). SN involvement at baseline was also strongly predictive (OR= 26, CI95% 3.0-223) of Parkinsonism symptoms at baseline (model $Chi2= 42.2$, $p< 0.001$, $R2=0.31$).

CONCLUSION

s SN involvement is a common MRI finding in PMD patients, especially for those with mutations in genes encoding OXPHOS and clinical LS. Early involvement of the SN in the disease course increases the likelihood of exhibiting Parkinsonism symptoms, strongly suggesting SN as the biological substrate of movement disorder symptoms in this population.

CLINICAL RELEVANCE/APPLICATION

Delineation of the prevalent types and anatomic substrate of movement disorders in patients with primary mitochondrial disorders can inform treatment regimens for these patients.

T5B-SPPH-2 Impact of the Automatic Patient Centering Proposed by a 3D Camera on Dose and Image Quality for Chest Abdomen and Pelvis CT Examination

Participants
Joel Greffier, PhD, Nimes, France (*Presenter*) Nothing to Disclose

PURPOSE

To assess the impact of automatic patient centering proposed by a 3D camera on dose and image quality for chest-abdomen and pelvis CT examination

METHODS AND MATERIALS

A CT Torso CTU-41 anthropomorphic phantom (Kyoto Kagaku) with internal anatomical structures including head, thorax, abdomen and pelvis regions was used. All acquisitions were performed on the Incisive CT system (Philips Healthcare Systems) using the same acquisition and reconstruction parameters than those used for chest-abdomen-pelvic (CAP) CT examination in clinical practice. An experienced medical physicist first centered the phantom manually at the CT isocenter and performed 5 repeated acquisitions to assess the reproducibility of the automatic tube-current modulation system (reference values). Then, five experienced technologists manually and consecutively centered the phantom and one acquisition was made for each centering. Last, 5 acquisitions were performed using the automatic centering proposed by the 3D camera (Precise position system). The table height and the mean volume CT dose index (CTDIvol) were recorded. The image noise values were calculated with regions of interest (ROI, 1cm²) placed on lung (chest): 391 slices; liver (abdomen):155 slices; soft tissue (pelvis): 382 slices. The Wilcoxon test for paired samples was used to compare manual and automatic centering acquisitions to reference values

RESULTS

Considering whole scanned CAP area, the reference mean CTDIvol was 4.03 ± 0.02 mGy. The mean offset values from the table height reference position were of 23.0 ± 9.1 mm for manual centering and 8.5 ± 1.5 mm for automatic centering. The mean CTDIvol was similar for the manual centering compared to the reference acquisition (-4.5 ± 2.8%; p>0.05) and also for the automatic centering (4.2 ± 1.6%; p>0.05). For the lung tissue, the difference of mean noise was not significant for the manual centering and the reference acquisition (-2.5 ± 2.1%; p>0.05) and for the automatic centering (3.5%±0.8%; p>0.05). Similar results were observed for liver (-4.5 ± 4.0%; p>0.05 and 5.8 ± 1.9%; p>0.05, respectively) and pelvis soft tissue but with higher differences (9.0 ± 6.1%; p>0.05 and 5.5 ± 1.7%; p>0.05, respectively).

CONCLUSION

s The new automatic patient centering system using a 3D camera allows reducing the table height offset from the isocenter. It increases the reproducibility of the centering compared with manual centering without significantly affecting the radiation dose and the image noise.

CLINICAL RELEVANCE/APPLICATION

The 3D camera allows rapid and reproductible patient positioning at the isocenter during CT examinations. It makes it possible to homogenize and standardize patient centering among technologists to improve practices in terms of dose and image quality.

T5B-SPPH-3 Assessing the Ability of a Deep-Silicon Photon Counting CT to Accurately Image a Realistic Patient-Specific 3-D Printed Lung Phantom

Participants
Dominic Crotty, PhD, (*Presenter*) Employee, General Electric Company

PURPOSE

The objective of this study was to demonstrate the ability of an investigational edge-on silicon photon-counting computed tomography (PCCT) to accurately image a lifelike patient-specific three-dimensional (3-D) lung phantom.

METHODS AND MATERIALS

In this institutional review board-approved retrospective study, a patient with COVID-19 was identified who had undergone a routine thorax CT performed on a conventional CT system (Revolution EVO, GE Healthcare). On the basis of these data, a patient-specific lung phantom was 3-D printed (PixelPrint, University of Pennsylvania) with accurate attenuation profiles and textures. The printed phantom was placed inside a 20 cm bore of a technical phantom (Gammex multi-energy CT phantom, Sun Nuclear

Corporation) to match attenuations profiles of a typical patient (300 × 400 mm2). The setup was imaged using an investigational whole-body PCCT device (GE Healthcare) in axial mode with a 5 cm coverage at 120 kVp and 255 mAs. Reconstruction was performed utilizing a standard reconstruction algorithm with a STD kernel on a 1024x1024 matrix. Measurements of density accuracy and the similarity in the texture of images of the phantom were evaluated for both the PCCT and conventional CT.

RESULTS

Identical regions were chosen for density measurements. Region of interest (ROI) measurements resulted in ROI-1 34.79HU / 32.10, ROI-2 -175.42HU / -169.96, and ROI-3 -854.05HU / -864.86HU for PCCT and conventional CT, respectively. The relative average error of less than 4% is reported when comparing PCCT and conventional CT. Subjective image texture appearances of parenchymal tissue in the phantom are like those in the original CT data set.

CONCLUSION

s The spatial resolution of the edge-on Si-based PCCT system can accurately represent the lung phantom derived from images acquired by a conventional commercial CT system. Further studies will be conducted with PixelPrint phantoms that include high spatial resolution features suitable for ultra-high-resolution PCCT scanners.

CLINICAL RELEVANCE/APPLICATION

In order to evaluate next-generation CT systems, including ultra-high-resolution PCCTs, highly precise and lifelike phantoms are required to ensure a smooth transition into clinical practice.

T5B-SPPH-4 Evaluation of Task-based Automatic keV Selection for Photon Counting Detector CT in Comparison to Automatic kV Selection on Conventional CT

Participants
Kishore Rajendran, PhD, Rochester, MN (*Presenter*) Nothing to Disclose

PURPOSE

A new task-based virtual mono-energy image (VMI) keV selection tool (CARE keV, Siemens) has been introduced for clinical photon-counting detector (PCD) CT. The aim of this study was to assess performance of this auto-keV selection tool and compare with auto-kV selection (CARE kV, Siemens) on energy-integrating detector (EID) CT for different imaging tasks.

METHODS AND MATERIALS

Two phantoms (18 x 24 cm and 25 x 32 cm, CIRS Sun Nuclear) containing iodine (2, 5, 10 mg/cc) and calcium (100 mg/cc) inserts were scanned on a clinical PCD-CT system (NAEOTOM Alpha, Siemens) and an EID-CT system (SOMATOM Force, Siemens). Four tasks were evaluated: non-contrast, bone, soft tissue with contrast, and vascular imaging. Tube current modulation and kV-keV configuration on PCD-CT were auto-set using CARE keV for an image quality level of 180. Similarly, tube current modulation and kV selection on EID-CT was enabled using CARE kV for a quality reference mAs of 180 at reference kV of 120. For all tasks, images were reconstructed using iterative reconstruction algorithm (strength 3), Br40 kernel, and 3 mm slice thickness on both systems. Mean and standard deviation of CT numbers were measured using circular regions-of-interests and contrast-to-noise ratio (CNR) calculated. Percent dose reduction for each task, relative to the non-contrast task were calculated.

RESULTS

The auto-keV selection on PCD-CT enabled a task-based dose reduction (9%, 21%, 38% for bone, soft tissue, and vascular tasks relative to non-contrast task) irrespective of phantom size whereas the auto-kV selection on EID-CT showed size-dependent dose reduction with more dose reduction for smaller size phantom (12-61% on small phantom and 9-50% on large phantom). VMIs at 70, 65, 60 and 55 keV were auto-selected for non-contrast, bone, soft tissue with contrast and vascular tasks irrespective of phantom size on PCD-CT, while EID-CT CARE kV selected 70 to 90 kV for small phantom size and 70 to 100 kV for the large phantom size, for the four tasks. Mean percent changes in image contrast across phantom sizes and tasks were 13% for PCD-CT and 31% for EID-CT.

CONCLUSION

s A new task-dependent auto-keV selection tool on a clinical PCD-CT system provided similar contrast, noise, and CNR compared with an auto-kV selection tool available on a commercial EID-CT system.

CLINICAL RELEVANCE/APPLICATION

Characterization of the auto-keV selection allows appropriate use of this new tool in clinical practice for optimizing image quality and radiation dose. The comparison between auto-keV and auto-kV selections tools can help translation of imaging protocols from one system to the other.

T5B-SPPH-5 Beam Hardening in Multi-Contrast Photon-Counting CT Imaging: A Phantom Study

Participants
Amir Pourmorteza, PhD, Bethesda, MD (*Presenter*) Nothing to Disclose

PURPOSE

Beam hardening artifacts can negatively influence myocardial CT measurements. Dense materials or materials with high effective atomic number cause more beam hardening. Photon-counting detectors (PCD) are inherently more susceptible to beam hardening due to equal weighting of detected photons regardless of their energies. The problem is further confounded by the introduction of new contrast agents such as gadolinium, with a prominent k-edge in the diagnostic CT energy range. The purpose of this study is to quantify the beam hardening effect of different materials in energy-integrating detectors (EID) and PCD at various tube voltage settings.

METHODS AND MATERIALS

Pairs of test tubes were filled with dense contrast agents (iodine, gadolinium, and bismuth) and placed inside water phantom to cause beam hardening. The phantoms were scanned on EID (Somatom Force, Siemens Healthcare) and PCD (Naeotom Alpha, Siemens Healthcare) CT scanners at all available tube voltage settings for the PCD scanner (90, 120, 100 with Sn, and 140 with Sn pre-filtration). Images were reconstructed with standard water beam hardening correction but without any iodine/bone beam

hardening corrections. Virtual monoenergetic images (VMI) were calculated from PCD data.

RESULTS

PCD images showed more beam hardening artifacts in all tube voltages compared to EID. PCD VMI could completely remove iodine beam hardening artifacts. Iodine BH artifacts decreased as we increased the tube voltage. However, gadolinium-based beam hardening artifacts had a different trend due to and increased at 120 kVp.

CONCLUSION

s Energy-integrating detectors had less beam hardening artifacts compared to photon-counting detectors for x-ray tube voltages 120 kVp and higher. The inherent spectral information of PCDs can be used to effectively eliminate beam-hardening artifacts. However, special care is needed to correct beam hardening artifacts when k-edge contrast agents such as gadolinium and bismuth are present.

CLINICAL RELEVANCE/APPLICATION

While PCDs are more susceptible to beam hardening, we could use the spectral information provided by PCDs to correct the beam hardening artifact. It is clear that BH correction algorithms, which are all tuned for iodine, need to be improved to account for the spectral effects of k-edge contrast agents such as gadolinium.

T5B-SPPH-6 A Clinical Prototype CZT-Based Photon-Counting CT Scanner: First Experience in Low-Dose Lung Cancer Screening

Participants
Amir Pourmorteza, PhD, Bethesda, MD (*Presenter*) Nothing to Disclose

PURPOSE

Here we report our initial assessment of the image quality of a whole-body prototype cadmium-zinc-telluride (CZT) photon-counting detector (PCD) CT scanner. The improved tissue contrast and lower radiation noise of PCDs make them suitable for scans such as low-dose lung cancer screening. In this work we focused on the non-spectral image reconstructed from all the detected photons above a low energy threshold set at 25 keV.

METHODS AND MATERIALS

We used the COPDGENE2 phantom to simulate different types of healthy and pathological lung tissues under CT. All scans were performed at 120 kVp and at three different photon fluxes (50, 100, 200 mAs). Images were reconstructed with a filtered backprojection with a soft body kernel (FC13). For comparison, the phantom was also scanned on a state-of-the-art energy-integrating detector (EID) scanner (Aquilion One Genesis, Canon Medical Systems) at similar settings. We investigated CT number stability, contrast, and contrast-to-noise ratio of the two scanners.

RESULTS

The PCD-CT images had CT numbers for all simulated types of lung tissue which were more robust to radiation dose, with maximum deviation of 0.8 vs 2.5 HU for PCD and EID images, respectively. Contrast and CNR of ground-glass opacifications and emphysema was higher for PCD images compared to the clinical EID measurements, indicating better detectability of these lesions with PCD at dose-matched settings.

CONCLUSION

s The preliminary investigation of the new CZT PCD-CT prototype scanner showed improvements in CT number stability and CNR low-dose lung cancer screening tasks. This may lead to better detection and characterization of lung pathologies at reduced radiation doses or with better CNR. Further studies are warranted to assess the clinical performance of the prototype scanner.

CLINICAL RELEVANCE/APPLICATION

Our initial investigation of the new CZT PCD-CT prototype showed improved performance in CT number stability and CNR specifically in low-dose lung CT scans which may lead to better detection and assessment of ground-glass nodules. The improved CNR may be used to lower the radiation dose of screening CT scans which will help include younger patients or patients with less packs per year in lung cancer screening.

T5B-SPPH-7 Diagnostic Value of CT Lymphangiography in Primary Chyluria: A Retrospective Study

Participants
Qi Hao, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the diagnostic value of CT lymphangiography (CTL) in primary chyluria.

METHODS AND MATERIALS

Thirty-seven patients diagnosed as primary chyluria were recruited in this retrospective study. All patients were examined by DLG and CTL. The DLG was performed with a GE Innova 2000-IQ DSA machine, and a combined CT scan of the chest, abdomen and pelvis was performed with Siemens Sensation 16,Philips Brilliance spiral CT or GE revolution CT after 20min~2h.For CTL, the indexs were?Distribution of abnormal lymphatic vessels in the urinary system;?Lymphatic morphology and lymphatic reflux of bilateral iliac lymphatic, lumbar trunk and thoracic duct..The CTL signs of primary chyluria patients were statistically described by composition ratio of classification variables.

RESULTS

CTL showed that lipiodol reflux was seen in 34 patients (91.9%) along the renal vasculature to the renal pelvis and calyces of unilateral or bilateral kidneys, of which 16 cases (43.2%) had lipiodol extending from the calyces into the renal parenchyma; 11 cases (29.7%) had reflux to the renal capsule area outside, 6 cases (16.2%) to the adrenal region, 7 cases (18.9%) to extrafascial and peri-intestinal, 12 cases (32.4%) to the bladder, and 4 cases (10.8%) to the peribladder region.And,CTL showed ipsilateral iliac lymphatic tortuosity and dilatation in 33 cases (89.2%), contralateral iliac lymphatic reflux in 26 cases (70.3%), ipsilateral lumbar

trunk tortuosity,dilatation and reflux in 23 cases (62.2%), contralateral lumbar trunk reflux in 29 cases (78.4%), ipsilateral renal reflux in 19 cases (51.4%), contralateral renal reflux in 24 cases (64.9%), thoracic duct reflux obstruction in 32 cases (86.5%), bronchomediastinal trunk reflux in 14 cases (37.8%), cervical trunk and subclavian trunk reflux in 11 cases (29.7%),14 cases of bronchial mediastinal trunk reflux (37.8%), 11 cases of cervical trunk and subclavian trunk reflux (29.7%).

CONCLUSION

s CTL can show the distribution, extent and severity of abnormal dilated lymphatic vessels in primary chyluria, in particular, it can clearly show the distribution of abnormal lymphatic vessels around the kidney and clarify the relationship with the surrounding tissue structure.

CLINICAL RELEVANCE/APPLICATION

The CTL can provide an important imaging basis for the diagnosis and preoperative evaluation of primary chyluria,it is important for the preoperative evaluation and the development of the surgical plan.

T5B-SPPH-8 On the Optimal Dose Modulation for Coronary Artery Calcium Scoring CT at Standard kVp

Participants
Jimmy Zhou, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

Coronary artery calcium scoring (CACs) CT is performed at 120 kVp in patients with borderline risk. As such, population dose has been a concern. The current dose modulation schemes use general approaches without considering the CACs image quality specifics. We aimed to find the optimal dose modulation based on the SCCT recommended CACs noise thresholds and new experimental data.

METHODS AND MATERIALS

The study consisted of three parts. First, the noise measurements were performed on the images acquired from the Mercury phantom of tapered diameters (16 cm - 36 cm) with a dual-source Siemens Force CT, using gated CASs scans and a simulated ECG of 60 beats/min. The volume dose index (CTDIvol) was manually adjusted from 0.71 -18.7 mGy at 120 kVp. The images were reconstructed to 3 mm thickness. The noise was correlated to the phantom diameter and CTDIvol (n = 264). The SCCT's recommended noise thresholds of 20 HU and 23 HU were used for the medium and large patient sizes, respectively. For the noise thresholds at the other diameters, an exponential function was used to obtain the size dependent thresholds. The corresponding CTDIvol was derived as a function of the phantom diameter. In the second part, the diameter (dp) of the Mercury phantom made of polyethylene was converted to the water equivalent diameter (dw). Lastly, the dw was converted to effective diameter (de) of the chest in the heart region using the retrospectively gathered clinical data (n = 21).

RESULTS

The least-square surface fitting showed that the threshold noise is inversely proportional to the CTDIvol to a power of 0.405, and proportional to an exponential function of de multiplied by a parameter 0.061 (n = 264, R^2= 0.968). The relations of dw, dp, and de were found to be: dw = 0.813de, and dw = 0.953dp.

CONCLUSION

s An optimal dose modulation based on patient-size adjusted noise thresholds was established for coronary artery calcium scans.

CLINICAL RELEVANCE/APPLICATION

Coronary artery calcium scoring CT dose optimization

T5B-SPPH-9 Assessment of COVID-19 Pneumonia Using Darkfield Chest Radiography Compared to CT Imaging

Participants
Henriette Bast, Garching, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Dark-field chest radiography can detect microstructural changes of the lung parenchyma. Here, we compare dark-field chest radiography with CT imaging for the assessment of COVID-19 pneumonia.

METHODS AND MATERIALS

Patients with a COVID-19 infection who underwent a chest CT were included if they had a category of 4, 5 or 6 according to the COVID-19 Reporting and Data System (CO-RADS) assessment scheme. Subjects with a medically indicated chest CT without any pathologic lung changes formed the control group. All participants were imaged at a CT scanner and at a clinical prototype for dark-field chest radiography. Four independent blinded readers rated the dark-field images in random order for the presence of COVID-19 in different lung zones. In the CT images, each of the five lung lobes was rated on a scale from 0 to 5 for the involvement of COVID-19 pneumonia by three independent blinded readers in random order and the sum of CT ratings for each patient was calculated. For quantitative analysis, each subject's COVID-19 CT index was calculated as the percentage of lung tissue above a threshold individually set for each patient. With Spearman's correlation coefficient, this COVID-19 CT index was tested for correlation with a subject's mean dark-field signal per lung volume (dark-field coefficient) and with the sum of CT ratings (total CT score).

RESULTS

A total of 100 patients (59 males, 60 with COVID-19) were included with a mean age of 58 ± 14 years. The dark-field signal of COVID-19 patients is lower and less homogeneous compared to the one of healthy subjects. The dark-field coefficient was negatively correlated with both the CT-based COVID-19 index (r= -.24, p=.02) and the total CT score (r=-.36, p<.001).

CONCLUSION

s The detection and visualization of COVID-19 pneumonia in dark-field images is consistent with the localization in CT images. Hence, dark-field imaging provides capability for the assessment of COVID-19.

CLINICAL RELEVANCE/APPLICATION

COVID-19 pneumonia can be assessed with dark-field chest radiography with less radiation dose than conventional CT imaging.

Impact of the Automatic Patient Centering Proposed by a 3D Camera on Dose and Image Quality for Chest Abdomen and Pelvis CT Examination

Monday, Nov. 28 12:45PM - 1:15PM Room: Learning Center - PH DPS

Participants
Joel Greffier, PhD, Nimes, France (*Presenter*) Nothing to Disclose

PURPOSE

To assess the impact of automatic patient centering proposed by a 3D camera on dose and image quality for chest-abdomen and pelvis CT examination

METHODS AND MATERIALS

A CT Torso CTU-41 anthropomorphic phantom (Kyoto Kagaku) with internal anatomical structures including head, thorax, abdomen and pelvis regions was used. All acquisitions were performed on the Incisive CT system (Philips Healthcare Systems) using the same acquisition and reconstruction parameters than those used for chest-abdomen-pelvic (CAP) CT examination in clinical practice. An experienced medical physicist first centered the phantom manually at the CT isocenter and performed 5 repeated acquisitions to assess the reproducibility of the automatic tube-current modulation system (reference values). Then, five experienced technologists manually and consecutively centered the phantom and one acquisition was made for each centering. Last, 5 acquisitions were performed using the automatic centering proposed by the 3D camera (Precise position system). The table height and the mean volume CT dose index (CTDIvol) were recorded. The image noise values were calculated with regions of interest (ROI, 1cm²) placed on lung (chest): 391 slices; liver (abdomen):155 slices; soft tissue (pelvis): 382 slices. The Wilcoxon test for paired samples was used to compare manual and automatic centering acquisitions to reference values

RESULTS

Considering whole scanned CAP area, the reference mean CTDIvol was 4.03 ± 0.02 mGy. The mean offset values from the table height reference position were of 23.0 ± 9.1 mm for manual centering and 8.5 ± 1.5 mm for automatic centering. The mean CTDIvol was similar for the manual centering compared to the reference acquisition (-4.5 ± 2.8%; p>0.05) and also for the automatic centering (4.2 ± 1.6%; p>0.05). For the lung tissue, the difference of mean noise was not significant for the manual centering and the reference acquisition (-2.5 ± 2.1%; p>0.05) and for the automatic centering (3.5%±0.8%; p>0.05). Similar results were observed for liver (-4.5 ± 4.0%; p>0.05 and 5.8 ± 1.9%; p>0.05, respectively) and pelvis soft tissue but with higher differences (9.0 ± 6.1%; p>0.05 and 5.5 ± 1.7%; p>0.05, respectively).

CONCLUSION

s The new automatic patient centering system using a 3D camera allows reducing the table height offset from the isocenter. It increases the reproducibility of the centering compared with manual centering without significantly affecting the radiation dose and the image noise.

CLINICAL RELEVANCE/APPLICATION

The 3D camera allows rapid and reproductible patient positioning at the isocenter during CT examinations. It makes it possible to homogenize and standardize patient centering among technologists to improve practices in terms of dose and image quality.

T5B-SPPH-3

Assessing the Ability of a Deep-Silicon Photon Counting CT to Accurately Image a Realistic Patient-Specific 3-D Printed Lung Phantom

Monday, Nov. 28 12:45PM - 1:15PM Room: Learning Center - PH DPS

Participants
Dominic Crotty, PhD, (*Presenter*) Employee, General Electric Company

PURPOSE

The objective of this study was to demonstrate the ability of an investigational edge-on silicon photon-counting computed tomography (PCCT) to accurately image a lifelike patient-specific three-dimensional (3-D) lung phantom.

METHODS AND MATERIALS

In this institutional review board-approved retrospective study, a patient with COVID-19 was identified who had undergone a routine thorax CT performed on a conventional CT system (Revolution EVO, GE Healthcare). On the basis of these data, a patient-specific lung phantom was 3-D printed (PixelPrint, University of Pennsylvania) with accurate attenuation profiles and textures. The printed phantom was placed inside a 20 cm bore of a technical phantom (Gammex multi-energy CT phantom, Sun Nuclear Corporation) to match attenuations profiles of a typical patient (300 × 400 mm2). The setup was imaged using an investigational whole-body PCCT device (GE Healthcare) in axial mode with a 5 cm coverage at 120 kVp and 255 mAs. Reconstruction was performed utilizing a standard reconstruction algorithm with a STD kernel on a 1024x1024 matrix. Measurements of density accuracy and the similarity in the texture of images of the phantom were evaluated for both the PCCT and conventional CT.

RESULTS

Identical regions were chosen for density measurements. Region of interest (ROI) measurements resulted in ROI-1 34.79HU / 32.10, ROI-2 -175.42HU / -169.96, and ROI-3 -854.05HU / -864.86HU for PCCT and conventional CT, respectively. The relative average error of less than 4% is reported when comparing PCCT and conventional CT. Subjective image texture appearances of parenchymal tissue in the phantom are like those in the original CT data set.

CONCLUSION

s The spatial resolution of the edge-on Si-based PCCT system can accurately represent the lung phantom derived from images acquired by a conventional commercial CT system. Further studies will be conducted with PixelPrint phantoms that include high spatial resolution features suitable for ultra-high-resolution PCCT scanners.

CLINICAL RELEVANCE/APPLICATION

In order to evaluate next-generation CT systems, including ultra-high-resolution PCCTs, highly precise and lifelike phantoms are required to ensure a smooth transition into clinical practice.

T5B-SPPH-4

Evaluation of Task-based Automatic keV Selection for Photon Counting Detector CT in Comparison to Automatic kV Selection on Conventional CT

Monday, Nov. 28 12:45PM - 1:15PM Room: Learning Center - PH DPS

Participants
Kishore Rajendran, PhD, Rochester, MN (*Presenter*) Nothing to Disclose

PURPOSE

A new task-based virtual mono-energy image (VMI) keV selection tool (CARE keV, Siemens) has been introduced for clinical photon-counting detector (PCD) CT. The aim of this study was to assess performance of this auto-keV selection tool and compare with auto-kV selection (CARE kV, Siemens) on energy-integrating detector (EID) CT for different imaging tasks.

METHODS AND MATERIALS

Two phantoms (18 x 24 cm and 25 x 32 cm, CIRS Sun Nuclear) containing iodine (2, 5, 10 mg/cc) and calcium (100 mg/cc) inserts were scanned on a clinical PCD-CT system (NAEOTOM Alpha, Siemens) and an EID-CT system (SOMATOM Force, Siemens). Four tasks were evaluated: non-contrast, bone, soft tissue with contrast, and vascular imaging. Tube current modulation and kV-keV configuration on PCD-CT were auto-set using CARE keV for an image quality level of 180. Similarly, tube current modulation and kV selection on EID-CT was enabled using CARE kV for a quality reference mAs of 180 at reference kV of 120. For all tasks, images were reconstructed using iterative reconstruction algorithm (strength 3), Br40 kernel, and 3 mm slice thickness on both systems. Mean and standard deviation of CT numbers were measured using circular regions-of-interests and contrast-to-noise ratio (CNR) calculated. Percent dose reduction for each task, relative to the non-contrast task were calculated.

RESULTS

The auto-keV selection on PCD-CT enabled a task-based dose reduction (9%, 21%, 38% for bone, soft tissue, and vascular tasks relative to non-contrast task) irrespective of phantom size whereas the auto-kV selection on EID-CT showed size-dependent dose reduction with more dose reduction for smaller size phantom (12-61% on small phantom and 9-50% on large phantom). VMIs at 70, 65, 60 and 55 keV were auto-selected for non-contrast, bone, soft tissue with contrast and vascular tasks irrespective of phantom size on PCD-CT, while EID-CT CARE kV selected 70 to 90 kV for small phantom size and 70 to 100 kV for the large phantom size, for the four tasks. Mean percent changes in image contrast across phantom sizes and tasks were 13% for PCD-CT and 31% for EID-CT.

CONCLUSION

s A new task-dependent auto-keV selection tool on a clinical PCD-CT system provided similar contrast, noise, and CNR compared with an auto-kV selection tool available on a commercial EID-CT system.

CLINICAL RELEVANCE/APPLICATION

Characterization of the auto-keV selection allows appropriate use of this new tool in clinical practice for optimizing image quality and radiation dose. The comparison between auto-keV and auto-kV selections tools can help translation of imaging protocols from one system to the other.

Beam Hardening in Multi-Contrast Photon-Counting CT Imaging: A Phantom Study

Monday, Nov. 28 12:45PM - 1:15PM Room: Learning Center - PH DPS

Participants
Amir Pourmorteza, PhD, Bethesda, MD (*Presenter*) Nothing to Disclose

PURPOSE

Beam hardening artifacts can negatively influence myocardial CT measurements. Dense materials or materials with high effective atomic number cause more beam hardening. Photon-counting detectors (PCD) are inherently more susceptible to beam hardening due to equal weighting of detected photons regardless of their energies. The problem is further confounded by the introduction of new contrast agents such as gadolinium, with a prominent k-edge in the diagnostic CT energy range. The purpose of this study is to quantify the beam hardening effect of different materials in energy-integrating detectors (EID) and PCD at various tube voltage settings.

METHODS AND MATERIALS

Pairs of test tubes were filled with dense contrast agents (iodine, gadolinium, and bismuth) and placed inside water phantom to cause beam hardening. The phantoms were scanned on EID (Somatom Force, Siemens Healthcare) and PCD (Naeotom Alpha, Siemens Healthcare) CT scanners at all available tube voltage settings for the PCD scanner (90, 120, 100 with Sn, and 140 with Sn pre-filtration). Images were reconstructed with standard water beam hardening correction but without any iodine/bone beam hardening corrections. Virtual monoenergetic images (VMI) were calculated from PCD data.

RESULTS

PCD images showed more beam hardening artifacts in all tube voltages compared to EID. PCD VMI could completely remove iodine beam hardening artifacts. Iodine BH artifacts decreased as we increased the tube voltage. However, gadolinium-based beam hardening artifacts had a different trend due to and increased at 120 kVp.

CONCLUSION

s Energy-integrating detectors had less beam hardening artifacts compared to photon-counting detectors for x-ray tube voltages 120 kVp and higher. The inherent spectral information of PCDs can be used to effectively eliminate beam-hardening artifacts. However, special care is needed to correct beam hardening artifacts when k-edge contrast agents such as gadolinium and bismuth are present.

CLINICAL RELEVANCE/APPLICATION

While PCDs are more susceptible to beam hardening, we could use the spectral information provided by PCDs to correct the beam hardening artifact. It is clear that BH correction algorithms, which are all tuned for iodine, need to be improved to account for the spectral effects of k-edge contrast agents such as gadolinium.

On the Optimal Dose Modulation for Coronary Artery Calcium Scoring CT at Standard kVp

Monday, Nov. 28 12:45PM - 1:15PM Room: Learning Center - PH DPS

Participants
Jimmy Zhou, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

Coronary artery calcium scoring (CACs) CT is performed at 120 kVp in patients with borderline risk. As such, population dose has been a concern. The current dose modulation schemes use general approaches without considering the CACs image quality specifics. We aimed to find the optimal dose modulation based on the SCCT recommended CACs noise thresholds and new experimental data.

METHODS AND MATERIALS

The study consisted of three parts. First, the noise measurements were performed on the images acquired from the Mercury phantom of tapered diameters (16 cm - 36 cm) with a dual-source Siemens Force CT, using gated CASs scans and a simulated ECG of 60 beats/min. The volume dose index (CTDIvol) was manually adjusted from 0.71 -18.7 mGy at 120 kVp. The images were reconstructed to 3 mm thickness. The noise was correlated to the phantom diameter and CTDIvol (n = 264). The SCCT's recommended noise thresholds of 20 HU and 23 HU were used for the medium and large patient sizes, respectively. For the noise thresholds at the other diameters, an exponential function was used to obtain the size dependent thresholds. The corresponding CTDIvol was derived as a function of the phantom diameter. In the second part, the diameter (dp) of the Mercury phantom made of polyethylene was converted to the water equivalent diameter (dw). Lastly, the dw was converted to effective diameter (de) of the chest in the heart region using the retrospectively gathered clinical data (n = 21).

RESULTS

The least-square surface fitting showed that the threshold noise is inversely proportional to the CTDIvol to a power of 0.405, and proportional to an exponential function of de multiplied by a parameter 0.061 (n = 264, R^2= 0.968). The relations of dw, dp, and de were found to be: dw = 0.813de, and dw = 0.953dp.

CONCLUSION

s An optimal dose modulation based on patient-size adjusted noise thresholds was established for coronary artery calcium scans.

CLINICAL RELEVANCE/APPLICATION

Coronary artery calcium scoring CT dose optimization

T5B-SPPH-9

Assessment of COVID-19 Pneumonia Using Darkfield Chest Radiography Compared to CT Imaging

Monday, Nov. 28 12:45PM - 1:15PM Room: Learning Center - PH DPS

Participants
Henriette Bast, Garching, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Dark-field chest radiography can detect microstructural changes of the lung parenchyma. Here, we compare dark-field chest radiography with CT imaging for the assessment of COVID-19 pneumonia.

METHODS AND MATERIALS

Patients with a COVID-19 infection who underwent a chest CT were included if they had a category of 4, 5 or 6 according to the COVID-19 Reporting and Data System (CO-RADS) assessment scheme. Subjects with a medically indicated chest CT without any pathologic lung changes formed the control group. All participants were imaged at a CT scanner and at a clinical prototype for dark-field chest radiography. Four independent blinded readers rated the dark-field images in random order for the presence of COVID-19 in different lung zones. In the CT images, each of the five lung lobes was rated on a scale from 0 to 5 for the involvement of COVID-19 pneumonia by three independent blinded readers in random order and the sum of CT ratings for each patient was calculated. For quantitative analysis, each subject's COVID-19 CT index was calculated as the percentage of lung tissue above a threshold individually set for each patient. With Spearman's correlation coefficient, this COVID-19 CT index was tested for correlation with a subject's mean dark-field signal per lung volume (dark-field coefficient) and with the sum of CT ratings (total CT score).

RESULTS

A total of 100 patients (59 males, 60 with COVID-19) were included with a mean age of 58 ± 14 years. The dark-field signal of COVID-19 patients is lower and less homogeneous compared to the one of healthy subjects. The dark-field coefficient was negatively correlated with both the CT-based COVID-19 index ($r = -.24$, $p = .02$) and the total CT score ($r = -.36$, $p < .001$).

CONCLUSION

s The detection and visualization of COVID-19 pneumonia in dark-field images is consistent with the localization in CT images. Hence, dark-field imaging provides capability for the assessment of COVID-19.

CLINICAL RELEVANCE/APPLICATION

COVID-19 pneumonia can be assessed with dark-field chest radiography with less radiation dose than conventional CT imaging.

W2-SPBR-1 Difference in US Visibility of Tissue Marker in Metastatic Lymph Nodes After Neoadjuvant Chemotherapy in The Breast Cancer Patients

Participants
Ka Eun Kim, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

This study is aimed to investigate the differences in ultrasound (US) visibility for localization of clipped metastatic lymph nodes after neoadjuvant chemotherapy (NAC) according to the type of tissue markers.

METHODS AND MATERIALS

In this single-center retrospective study, 59 consecutive breast cancer patients who underwent tissue marker insertion for histologically proven metastatic axillary lymph node between March 2020 and August 2021 were included. We inserted two different types of breast tissue markers; UltraClip™ (n=29) and UltraCor™ Twirl™ (n=30), within the metastatic axillary lymph node before NAC. After completion of NAC, the patients underwent sentinel lymph node biopsy or axillary dissection with (n=44) or without (n=15) localization of the clipped node. Medical records and imaging findings were retrospectively reviewed. We compared the US visibility and successful excision rate of clipped lymph node between the two types of tissue markers. Fisher's exact test were used for statistical analysis.

RESULTS

The overall US visibility of tissue markers after NAC was better in UltraCor™ Twirl™ than in UltraClip™ (86.7% vs 72,4%), but statistically not significant (p = 0.209). However, UltraCor™ Twirl™ showed significantly better US visibility (83.3%, 15/18) than UltraClip™ (42.9%, 6/14) in the cases with no residual metastatic lymph node on US (n=32) (p = 0.027). Meanwhile, type of tissue markers was not associated with successful excision of clipped lymph node (p = 1.000). The patients who underwent preoperative US-guided localization for clipped lymph node showed higher successful excision rate than the patients without localization (p = 0.010).

CONCLUSION

s UltraCor™ Twirl™ showed better US visibility than UltraClip™ in the metastatic axillary lymph node after NAC, especially when there was no residual suspicious lymph node on US.

CLINICAL RELEVANCE/APPLICATION

The visibility of tissue marker is important for localization. Comparing the US visibility of tissue marker for axillay lymph node would be helpful for succesful targeted axillary dissection.

W2-SPBR-2 Role of Hemastix As A Tool to Determine Pre-test Probability of Abnormal Pathology in Patients with Nipple Discharge

Participants
Ramapriya Ganti, MD, PhD, Charlottesville, VA (*Presenter*) Nothing to Disclose

PURPOSE

Nipple discharge accounts for approximately 5% of breast surgical evaluations and may be associated with malignancy in 2.7%-24.2% of cases. Visually, discharge for evidence of blood, a malignancy indicator, is subjective and can be inaccurate. The association of hemoccult test results with abnormal pathology was analyzed to determine the utility of including hemoccult testing during initial workup for nipple discharge.

METHODS AND MATERIALS

An IRB-approved retrospective cohort study was done of women who underwent breast imaging at our institution for nipple discharge from January 2008 to December 2018. Only patients who had tissue sampling or two years of imaging follow-up were included in the study. The results of all breast imaging and histopathology for workup of nipple discharge were extracted from each patient's medical record. Descriptors of the nipple discharge, including color, number of ducts involved, laterality, spontaneity, and results of hemoccult testing were obtained from the radiology reports. Univariate and multivariate logistic regression analyses were conducted to determine whether hemoccult results, imaging results, and/or discharge descriptors were associated with abnormal pathology, defined as papilloma or malignancy. Sensitivity, specificity, and other performance characteristics were calculated for

hemoccult testing and imaging modalities.

RESULTS

Of a total of 326 women who met inclusion criteria, 247/75.8% had reproducible discharge at time of imaging and 204/62.6% received a hemoccult test. As part of the workup, 307/94.2% had a mammogram, 187/57.4% an ultrasound, 58/17.8% an MRI, and 131/40.4% a galactogram. Tissue sampling revealed non-malignant abnormal pathology in 118/32.6% and malignancy in 19/5.8%. Multivariate analysis showed that abnormal pathology was independently associated with positive hemoccult results (adjusted odds ratio (AOR) 2.68; p=0.026), single-duct (AOR 6.95; p<0.001), spontaneous (AOR 3.84; p=0.013), and suspicious colored discharge (AOR 4.37; p=0.041). Positive hemoccult test was also a predictor of abnormal pathology if all factor characteristics were unknown (OR 5.16; p<0.001). Hemoccult testing showed a sensitivity of 73.7% (95% CI: [63.6%-82.2%]) for abnormal pathology, similar to galactography (87.7%; 95% CI: [77.9%-94.2%]) and MRI (83.3%; 95% CI: [62.6%-95.3%]).

CONCLUSION

s Hemoccult testing is sensitive and independently associated with abnormal histopathology in patients with nipple discharge.

CLINICAL RELEVANCE/APPLICATION

Hemoccult testing may be a useful diagnostic tool in patients with nipple discharge prior to diagnostic imaging to help establish the pre-test probability of abnormal histopathology based on discharge characteristics.

W2-SPBR-3 Contrast-enhanced Spectral Mammography-guided Breast Biopsy: Technique Feasibility and Comparison with MR-guided Vacuum-Assisted Breast Biopsy

Participants
Romy Heriteau, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Contrast-enhanced spectral mammography (CESM) is a recent imaging technique based on the association of spectral mammography and iodinated contrast agent to detect tumor enhancement, linked to neoangenesis. CESM is known to have same sensitivity as MRI with a higher specificity, higher Predictive Positive Value (PPV), and better conditions of accessibility and cost. The purpose of this study is to show the comparison of diagnostic performances of biopsies under CESM compared to biopsies under MRI in terms of availability, procedure duration and failure, side effects and cost

METHODS AND MATERIALS

Retrospective evaluation of our 3 years' experience with CESM procedure and comparison with MR-biopsy procedure in our institution. All consecutive patient referred for an MRI or CESM-guided breast biopsy were included in our study. 25 patients for CESM biopsy and 107 patients for MRI biopsy were included. We analyzed two reliability parameters for each technique, the concordance between radiological BI-RADS classification and histological results of the biopsy. Then, the concordance between histological biopsy results and histological results after surgery. Procedure time, side effects and cost were also collected.

RESULTS

athology results were categorized as benign (38 lesions in MRI and 13 in CESM), high-risk (22/5), or malignant (17/2 ductal carcinoma in situ (DCIS), 21/3 invasive ductal carcinoma, 6/2 invasive lobular carcinoma). Subsequent surgery for high-risk and malignant lesions revealed a 21% discordance rate and 15% underestimation rate for MRI and one discordance and underestimation for CESM (p>0.5). Comparison between BI-RADS classification and pathology results revealed one discordance for MRI and none for CESM (p> 0.5). Duration was significantly shorter for CESM (median duration : 28 minutes) in comparison with MRI (median : 53 minutes) (p<0.05). 15 side effects for MRI versus 2 for CESM have been registered (p = 0.53). Economical study estimated the cost for a biopsy under MR-guided biopsy at 1213€ and a CESM- at 574€

CONCLUSION

s CESM guided-biopsy may be an interesting alternative technique to MR-guided breast biopsy, with time and cost saving, without reducing accuracy.

CLINICAL RELEVANCE/APPLICATION

CESM guided-biopsy is a simpler and more accessible alternative technique to MRI biopsies. This biopsy could be performed in more and more centers in the future.

W2-SPBR-4 Should I Stay, or Should I Go? A Workforce Movement Survey of Breast Radiologists.

Participants
Grayson Baird, PhD, Providence, RI (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate factors associated with whether breast radiologists have left, or are considering leaving, their current job.

METHODS AND MATERIALS

Practicing members of the Society of Breast Imaging were emailed a weblink to an IRB-approved surveys in February 2022. The survey included 32 questions about attitudes towards work and whether they had left their last position within the last two years, were thinking of leaving, or were not thinking of leaving their current position. Exploratory factor analysis (EFA) was used to evaluate construct validity. Internal consistency was evaluated with Cronbach's Alpha. Concurrent validity was examined using discriminant function analysis (DFA). All psychometric analyses were conducted using SAS.

RESULTS

Response rate was 14% (230/1670), with 2 being dropped as they retired over 2 years ago. 82% (182/288) identified as being white, with 77% (173) identifying as female. 5% (11) were 35 years or younger, 33% (75) were between 36-45, 29% (66) were between 46-55, 25% (57) were between 56-65, and 7.5% (17) were 65 or older. The majority (73.6%, 167) reported 76-100% of their practice was focused on breast imaging. Of the 228, 23.3% (53) responded that they had left a practice within the last two

years, 21.9% (50) were thinking of leaving, and 54.8% (125) were not thinking of leaving--45% of respondents were either thinking of leaving or had recently left their practice. Factor analysis identified 5 latent variables (factors) from the 32 questions: 1. "Quality of Life" issues, 2. "Physician Socio-Cultural" issues, 3. "Workplace Condition" issues, 4. "Non-Physician Socio-Cultural" issues, and 5. "Career" issues. Cronbach's Alpha was .89, showing high internal consistency. DFA examined how well the 32 questions classified the groups (Figure 1). Those "staying" (red) clustered positively with the first function (x-axis), while those who "left" (blue) cluster negatively with the first function, and those who were thinking of "leaving" (green) clustered in between but negatively on the first function. Only the first function was significant, $p<.01$, which was highly related with questions concerning Quality of Life.

CONCLUSION

s Quality of life is the factor most associated with workforce movement of breast radiologists. Almost one-half of breast radiologists had recently left or were considering leaving their positions. The survey showed good psychometric properties.

CLINICAL RELEVANCE/APPLICATION

Almost one-half of breast radiologists had left or were considering leaving their positions. It may be important to measure attitudes towards workplace movement to understand why radiologists are staying and leaving.

W2-SPBR-5 A Novel Anthropomorphic Model Observer for Micro-calcification Cluster Detection in Digital Mammography and Digital Breast Tomosynthesis Images for The VICTRE Pipeline

Participants
Katrien Houbrechts, Leuven, Belgium (*Presenter*) Siemens AG

PURPOSE

Develop an anthropomorphic model observer for calcification cluster detection in digital mammography (DM) and digital breast tomosynthesis (DBT) for a clinical range of lesion sizes and dose levels, and illustrate its applicability to predict the impact of blurring.

METHODS AND MATERIALS

Clusters with 5 round calcifications of 100 µm, 150 µm and 200 µm diameter were randomly inserted in heterogeneous VICTRE breast phantoms. DM and DBT images were created using the VICTRE pipeline with a clinical Automatic Exposure Control (AEC) dose, AEC/2 and 2AEC. For both DM and DBT, 20 lesion-present and 120 lesion-absent samples were used for each condition to tune a two-layer Channelized Hoteling Observer (CHO) to four-alternative forced choice reading results of 6 human readers. The CHO performance in the presence of system blurring was investigated for 150 µm clusters. For DM, the focus size and lesion height above the table was changed. For DBT, source motion was varied.

RESULTS

The CHO (localization: 2 Laguerre-Gauss channels; classification: 8 Gabor channels) agreed closely with human results (mean error [-4.12;0.14], linear regression slope [0.98;1.07]) over the studied range of lesion sizes and dose levels for both modalities. CHO readout was more reproducible than human reading, with average standard deviation of 3% compared to 5-6%. The CHO was sensitive to microcalcification blurring. The DM CHO percent correctly detected targets (PC) for clusters located 5 mm above the table was 70±4% and 64±5% for focus sizes of 0.3 mm and 0.5 mm, respectively ($p<0.0001$). When located 40 mm above the table, the PC was 58±4% and 46±5%, respectively ($p<0.0001$). The DBT CHO showed a monotonic decrease in lesion detection performance as source motion blur increased; e.g. for 21 s scan time, the PC was 77±4% and 57±4% for a 90 ms and 150 ms exposure time, respectively ($p<0.0001$).

CONCLUSION

s A two-layer CHO was shown to approximate human observer detection results for microcalcifications in DM and DBT images generated with the VICTRE pipeline and can be used to evaluate the influence of system settings on detection performance for in-silico studies.

CLINICAL RELEVANCE/APPLICATION

The anthropomorphic CHO enables the accurate modelling of microcalcification detection performance for in-silico clinical studies.

Difference in US Visibility of Tissue Marker in Metastatic Lymph Nodes After Neoadjuvant Chemotherapy in The Breast Cancer Patients

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - BR DPS

Participants
Ka Eun Kim, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

This study is aimed to investigate the differences in ultrasound (US) visibility for localization of clipped metastatic lymph nodes after neoadjuvant chemotherapy (NAC) according to the type of tissue markers.

METHODS AND MATERIALS

In this single-center retrospective study, 59 consecutive breast cancer patients who underwent tissue marker insertion for histologically proven metastatic axillary lymph node between March 2020 and August 2021 were included. We inserted two different types of breast tissue markers; UltraClip™ (n=29) and UltraCor™ Twirl™ (n=30), within the metastatic axillary lymph node before NAC. After completion of NAC, the patients underwent sentinel lymph node biopsy or axillary dissection with (n=44) or without (n=15) localization of the clipped node. Medical records and imaging findings were retrospectively reviewed. We compared the US visibility and successful excision rate of clipped lymph node between the two types of tissue markers. Fisher's exact test were used for statistical analysis.

RESULTS

The overall US visibility of tissue markers after NAC was better in UltraCor™ Twirl™ than in UltraClip™ (86.7% vs 72,4%), but statistically not significant (p = 0.209). However, UltraCor™ Twirl™ showed significantly better US visibility (83.3%, 15/18) than UltraClip™ (42.9%, 6/14) in the cases with no residual metastatic lymph node on US (n=32) (p = 0.027). Meanwhile, type of tissue markers was not associated with successful excision of clipped lymph node (p = 1.000). The patients who underwent preoperative US-guided localization for clipped lymph node showed higher successful excision rate than the patients without localization (p = 0.010).

CONCLUSION

s UltraCor™ Twirl™ showed better US visibility than UltraClip™ in the metastatic axillary lymph node after NAC, especially when there was no residual suspicious lymph node on US.

CLINICAL RELEVANCE/APPLICATION

The visibility of tissue marker is important for localization. Comparing the US visibility of tissue marker for axillay lymph node would be helpful for succesful targeted axillary dissection.

Role of Hemastix As A Tool to Determine Pre-test Probability of Abnormal Pathology in Patients with Nipple Discharge

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - BR DPS

Participants
Ramapriya Ganti, MD, PhD, Charlottesville, VA (*Presenter*) Nothing to Disclose

PURPOSE

Nipple discharge accounts for approximately 5% of breast surgical evaluations and may be associated with malignancy in 2.7%-24.2% of cases. Visually, discharge for evidence of blood, a malignancy indicator, is subjective and can be inaccurate. The association of hemoccult test results with abnormal pathology was analyzed to determine the utility of including hemoccult testing during initial workup for nipple discharge.

METHODS AND MATERIALS

An IRB-approved retrospective cohort study was done of women who underwent breast imaging at our institution for nipple discharge from January 2008 to December 2018. Only patients who had tissue sampling or two years of imaging follow-up were included in the study. The results of all breast imaging and histopathology for workup of nipple discharge were extracted from each patient's medical record. Descriptors of the nipple discharge, including color, number of ducts involved, laterality, spontaneity, and results of hemoccult testing were obtained from the radiology reports. Univariate and multivariate logistic regression analyses were conducted to determine whether hemoccult results, imaging results, and/or discharge descriptors were associated with abnormal pathology, defined as papilloma or malignancy. Sensitivity, specificity, and other performance characteristics were calculated for hemoccult testing and imaging modalities.

RESULTS

Of a total of 326 women who met inclusion criteria, 247/75.8% had reproducible discharge at time of imaging and 204/62.6% received a hemoccult test. As part of the workup, 307/94.2% had a mammogram, 187/57.4% an ultrasound, 58/17.8% an MRI, and 131/40.4% a galactogram. Tissue sampling revealed non-malignant abnormal pathology in 118/32.6% and malignancy in 19/5.8%. Multivariate analysis showed that abnormal pathology was independently associated with positive hemoccult results (adjusted odds ratio (AOR) 2.68; p=0.026), single-duct (AOR 6.95; p<0.001), spontaneous (AOR 3.84; p=0.013), and suspicious colored discharge (AOR 4.37; p=0.041). Positive hemoccult test was also a predictor of abnormal pathology if all factor characteristics were unknown (OR 5.16; p<0.001). Hemoccult testing showed a sensitivity of 73.7% (95% CI: [63.6%-82.2%]) for abnormal pathology, similar to galactography (87.7%; 95% CI: [77.9%-94.2%]) and MRI (83.3%; 95% CI: [62.6%-95.3%]).

CONCLUSION

s Hemoccult testing is sensitive and independently associated with abnormal histopathology in patients with nipple discharge.

CLINICAL RELEVANCE/APPLICATION

Hemoccult testing may be a useful diagnostic tool in patients with nipple discharge prior to diagnostic imaging to help establish the pre-test probability of abnormal histopathology based on discharge characteristics.

A Novel Anthropomorphic Model Observer for Micro-calcification Cluster Detection in Digital Mammography and Digital Breast Tomosynthesis Images for The VICTRE Pipeline

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - BR DPS

Participants
Katrien Houbrechts, Leuven, Belgium (*Presenter*) Siemens AG

PURPOSE

Develop an anthropomorphic model observer for calcification cluster detection in digital mammography (DM) and digital breast tomosynthesis (DBT) for a clinical range of lesion sizes and dose levels, and illustrate its applicability to predict the impact of blurring.

METHODS AND MATERIALS

Clusters with 5 round calcifications of 100 µm, 150 µm and 200 µm diameter were randomly inserted in heterogeneous VICTRE breast phantoms. DM and DBT images were created using the VICTRE pipeline with a clinical Automatic Exposure Control (AEC) dose, AEC/2 and 2AEC. For both DM and DBT, 20 lesion-present and 120 lesion-absent samples were used for each condition to tune a two-layer Channelized Hoteling Observer (CHO) to four-alternative forced choice reading results of 6 human readers. The CHO performance in the presence of system blurring was investigated for 150 µm clusters. For DM, the focus size and lesion height above the table was changed. For DBT, source motion was varied.

RESULTS

The CHO (localization: 2 Laguerre-Gauss channels; classification: 8 Gabor channels) agreed closely with human results (mean error [-4.12;0.14], linear regression slope [0.98;1.07]) over the studied range of lesion sizes and dose levels for both modalities. CHO readout was more reproducible than human reading, with average standard deviation of 3% compared to 5-6%. The CHO was sensitive to microcalcification blurring. The DM CHO percent correctly detected targets (PC) for clusters located 5 mm above the table was 70±4% and 64±5% for focus sizes of 0.3 mm and 0.5 mm, respectively ($p<0.0001$). When located 40 mm above the table, the PC was 58±4% and 46±5%, respectively ($p<0.0001$). The DBT CHO showed a monotonic decrease in lesion detection performance as source motion blur increased; e.g. for 21 s scan time, the PC was 77±4% and 57±4% for a 90 ms and 150 ms exposure time, respectively ($p<0.0001$).

CONCLUSION

s A two-layer CHO was shown to approximate human observer detection results for microcalcifications in DM and DBT images generated with the VICTRE pipeline and can be used to evaluate the influence of system settings on detection performance for in-silico studies.

CLINICAL RELEVANCE/APPLICATION

The anthropomorphic CHO enables the accurate modelling of microcalcification detection performance for in-silico clinical studies.

W2-SPCA-1 Myocardial Iron Imaging in Post-reperfusion Injury with Free-breathing, High-dynamic-range Cardiac Quantitative Susceptibility Mapping (HDR-QSM)

Participants
Yuheng Huang, MS, (*Presenter*) Nothing to Disclose

PURPOSE

The detection and quantification of intramyocardial hemorrhage (IMH) have been established as an essential biomarker for managing myocardial infarction (MI) patients. Quantitative susceptibility mapping (QSM) is the standard method for iron imaging in the brain. However, its application in the heart has been challenging because of major technical limitations, such as cardiac and respiratory motion during acquisition, strong B0 inhomogeneity in the heart, and the streaking artifacts caused by the highly concentrated iron in the hemorrhagic lesion. In this study, we developed a free-breathing, motion resolved, whole heart QSM technique with a High Dynamic Range QSM (HDR-QSM) reconstruction to overcome key confounders for iron imaging in hemorrhagic hearts.

METHODS AND MATERIALS

The study was approved by the IACUC at CSMC. Canines with hemorrhagic MIs were created (n=3) by coronary occlusion and reperfusion. Animals were scanned 7 Days post-MI in a clinical 3T scanner using a 3D, non-ECG gated, free-breathing multi-echo GRE sequence. To achieve reliable in-vivo cardiac QSM, a high-dynamic-range reconstruction algorithm was developed (panel A). In brief, phase images of the mGRE sequence were derived with an HDR, SNR optimized algorithm to ensure the fidelity of phase maps. Following, a two-step QSM reconstruction was adopted to minimize streaking artifacts from the extended iron concentration in IMH lesions.

RESULTS

Representative results from an IMH dog are presented in panel B. In the conventional iron-sensitive images (R2*(1/T2*) and standard QSM), strong off-resonance artifacts were observed at the heart-lung interfaces (red boxes) but were eliminated by the HDR-QSM. In addition, HDR-QSM corrected the strong streaking artifacts around the hemorrhagic zone compared to the standard QSM images (green boxes) and provides a more homogeneous susceptibility measure in the lesions. ROC analysis was conducted to compare the diagnosability between R2*(1/T2*) maps, standard QSM and HDR-QSM (panel C). By eliminating the off-resonance artifact at the inferolateral walls, the AUC of HDR-QSM is significantly higher than the other approaches and provides reliable IMH detection (AUC: R2*(1/T2*)=0.72; standard QSM=0.74; HDR-QSM=0.85).

CONCLUSION

s In this study, we developed a free-breathing cardiac QSM technique to quantify iron deposition in IMH. HDR-QSM opens up a reliable way for iron quantification in hearts and can potentially facilitate iron-guided precise patient management.

CLINICAL RELEVANCE/APPLICATION

HDR-QSM enables reliable in-vivo QSM imaging in the heart, it is helpful for various applications, particularly for quantifying IHM and iron concentration in patients with reperfusion injury.

W2-SPCA-2 Global and Regional Strain to Predict Ischemic LGE in Acute and Chronic ST-elevation Myocardial Infarction

Participants
Jennifer Erley, MD, Hamburg, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To monitor left ventricular (LV) myocardial strain in ST-elevation myocardial infarction (STEMI) from acute to chronic stage and determine its ability to predict late gadolinium enhancement (LGE).

METHODS AND MATERIALS

Patients underwent cardiac magnetic resonance imaging (CMR) at a 1.5T scanner (Achieva, Philips) directly (8±5 days) after STEMI at baseline (BL) and at 6 (±1.4)- month follow-up (FU). The imaging protocol included steady-state free precession (SSFP) sequences in long- and short-axis and LGE imaging. Feature-tracking (FT) (Segment, Medviso) analysis was conducted to determine myocardial strain. Myocardial segments were grouped in three categories according to the LGE pattern at BL: negative (LGE-), non-transmural (LGE+) and transmural (LGE++). Data are described using mean (standard deviation) or median (interquartile range). Wilcoxon test, receiver operating characteristic- and binary logistic regression analyses were conducted.

RESULTS

32 patients participated in this prospective study (81% male; age 59±10 years). Global and segmental longitudinal (GLS/SLS), radial (GLS/SRS) and circumferential (GCS/SCS) strain improved from BL to FU: GLS from -14±4% to -16±4%, p<0.001; GCS from -15±4% to -16±4%, p=0.023; GRS from 38±11% to 42±13%, p=0.006. However, regional strain was impaired at baseline and FU in LGE+ and ++ segments (SLS: -15% (-22 to 10) in LGE- vs. -9% (-16 to -5) in LGE+/++ segments at BL and -16% (-23 to -12) vs. -12% (-19 to -6) at FU; SRS: 34% (22 to 48) in LGE- vs. 17% (8 to 29) in LGE +/++ segments at BL and 36% (26 to 48) vs. 22% (11 to 38) at FU; SCS: -16% (-21 to -12) in LGE- vs. -9% (-14 to -3) in LGE+/++ segments at BL and -17% (-21 to -12) vs. -11 %(-16 to -5) at FU; all p<0.001). Especially SCS distinguished LGE- from LGE +/++ segments (SLS: area under the curve (AUC)=0.66 [95% confidence interval (CI) 0.61-0.71], p<0.001; SRS: AUC=0.75 [0.70-0.79], p<0.001; SCS: AUC=0.77 [0.73-0.82], p<0.001). The odds of predicting LGE were not significant for SLS; 0.97 for SRS [0.951-0.981], p<0.001 and 1.1 for SCS [1.077-1.145], p<0.001.

CONCLUSION

s Strain improved from acute to chronic STEMI, but regional strain was persistently impaired in LGE-positive myocardial segments. Circumferential strain was able to predict LGE.

CLINICAL RELEVANCE/APPLICATION

Functional recovery and impairment after STEMI can be reliably determined with global and regional strain. Circumferential strain is able to predict focal LGE following STEMI.

W2-SPCA-3 Regionalized Wall Strain is a Predictor of LV Systolic Function in a Swine Model

Participants
Jacob Ref, (*Presenter*) Nothing to Disclose

PURPOSE

Global longitudinal strain (GLS) is utilized to assess early stage myocardial functional loss. Myocardial strain quantitatively provides regional and global areas of left ventricular (LV) dysfunction using GLS, circumferential (GCS) and radial strain (GRS). GRS and GCS are predictive of late-stage heart failure because these functions are preserved until advanced stages of heart disease. To our knowledge, this is the first analysis of regional cardiac wall strain in a swine model.

METHODS AND MATERIALS

Male Yucatan mini swine underwent left anterior descending (LAD) balloon occlusion/reperfusion to simulate LAD myocardial infarction (MI). Cardiac MRI is performed with a 3T scanner (Skyra, Siemens Healthineers) prior to MI and 1 month post MI. Wall strain analysis was done in short axis (SAX) and long axis (LAX) cines. LV contours were drawn (CVI42, Calgary, Canada) using SAX and LAX images. Global strain values were collected for GLS, GCS and GRS. Median values were calculated to reflect myocardial health in vascular territories - LAD, circumflex (LCX) and right coronary (RCA) arteries.

RESULTS

14 swine were evaluated at both baseline and 1-month post-MI. Average infarct size was 25±4%, GLS increased (P<0.01) from -15±2% to -11±2%. GCS increased (P<0.01) from -16±2% to -12±2%. GRS decreased (P<0.01) from 53±8% to 35±6%.LAD GLS increased (P<0.05) from -15±3% to -10±1%. LAD GCS increased (P<0.01) from -18±3% to -8±2%. LAD GRS decreased (P<0.01) from 52±9% to 27±4%.LCX GLS increased (P<0.05) from -15±3% to -8±2%. LCX GCS increased (P<0.05) from -21±2% to -18±2%. LCX GRS decreased (P<0.01) from 56±9% to 35±5%.RCA GLS increased (P<0.01) from -14±2% to -8±1%. RCA GCS increased from -17±2% to -11±3%. RCA GRS decreased from 55±10% to 43±8%.

CONCLUSION

s Regional analysis of coronary vascular territories provided expected changes in LAD and LCX territories following LAD occlusion. LCX territory showed 8.5% less change than LAD territory. Strain values in RCA territory showed significant change in GLS but no significant change in GCS and GRS. We attribute adverse RCA GLS values to a compensatory phenomenon with RCA territory making up for the lack of involvement from LAD myocardial fibers.

CLINICAL RELEVANCE/APPLICATION

Preclinical measurements of regional myocardial strain can be performed in a swine model as a predictor of heart failure outcomes.

W2-SPCA-4 Myocardial Remodeling and Intracardiac Flow in the Acute Myocardial Infarction: From Coronary Occlusion to Eleven Weeks of Follow-Up in a Swine Model

Participants
Yura Ahn, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

The goal of this study was to describe a chronological change in the left ventricular (LV) myocardium during a reperfused myocardial infarction (MI) using cutting-edge cardiac MRI (CMR) techniques.

METHODS AND MATERIALS

The reperfused MI model was set to two swines, and serial CMR was performed at baseline, 0 day, 3 days, 1-,2-,3-,4-,5-,6-, and 11-week after coronary artery balloon occlusion. A comprehensive CMR protocol included ventricular function, LV strain analysis, T1- and T2-mapping, stress- and rest-perfusion, late gadolinium-enhanced (LGE) images, and intracardiac 4D flow MRI. The LV myocardium was classified as infarcted-, adjacent-, and remote-area, and all CMR parameters were described accordingly.

RESULTS

The %infarct and infarcted wall thickness decreased over time (baseline 30.9%, 11-week 17.4%; baseline 11.7mm, 11 weeks 2.9mm), whether LV volume and myocardial mass increased. Myocardial edema defined by T2 value was highest at 1 week (96.8 msec; baseline). Both global and regional myocardial strains have gradually decreased. Notably, the adjacent area showed the greatest reduction in peak radial strain as compared to the remote and even infarcted area (11-week: adjacent 14.7%, remote 32.9%, infarct 23.8%). Flow stasis, as demonstrated by intracardiac 4D flow MRI, seems to be linked to lower myocardial strain.

CONCLUSION

s In the reperfused MI model, CMR revealed changes in myocardial shape, tissue character, mechanics, and intracardiac flow over time.

CLINICAL RELEVANCE/APPLICATION

CMR helped researchers better understand the natural history and pathophysiology of MI in this animal study, with a focus on LV myocardial remodeling and intracardiac flow.

Myocardial Iron Imaging in Post-reperfusion Injury with Free-breathing, High-dynamic-range Cardiac Quantitative Susceptibility Mapping (HDR-QSM)

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - CA DPS

Participants
Yuheng Huang, MS, (*Presenter*) Nothing to Disclose

PURPOSE

The detection and quantification of intramyocardial hemorrhage (IMH) have been established as an essential biomarker for managing myocardial infarction (MI) patients. Quantitative susceptibility mapping (QSM) is the standard method for iron imaging in the brain. However, its application in the heart has been challenging because of major technical limitations, such as cardiac and respiratory motion during acquisition, strong B0 inhomogeneity in the heart, and the streaking artifacts caused by the highly concentrated iron in the hemorrhagic lesion. In this study, we developed a free-breathing, motion resolved, whole heart QSM technique with a High Dynamic Range QSM (HDR-QSM) reconstruction to overcome key confounders for iron imaging in hemorrhagic hearts.

METHODS AND MATERIALS

The study was approved by the IACUC at CSMC. Canines with hemorrhagic MIs were created (n=3) by coronary occlusion and reperfusion. Animals were scanned 7 Days post-MI in a clinical 3T scanner using a 3D, non-ECG gated, free-breathing multi-echo GRE sequence. To achieve reliable in-vivo cardiac QSM, a high-dynamic-range reconstruction algorithm was developed (panel A). In brief, phase images of the mGRE sequence were derived with an HDR, SNR optimized algorithm to ensure the fidelity of phase maps. Following, a two-step QSM reconstruction was adopted to minimize streaking artifacts from the extended iron concentration in IMH lesions.

RESULTS

Representative results from an IMH dog are presented in panel B. In the conventional iron-sensitive images (R2*(1/T2*) and standard QSM), strong off-resonance artifacts were observed at the heart-lung interfaces (red boxes) but were eliminated by the HDR-QSM. In addition, HDR-QSM corrected the strong streaking artifacts around the hemorrhagic zone compared to the standard QSM images (green boxes) and provides a more homogeneous susceptibility measure in the lesions. ROC analysis was conducted to compare the diagnosability between R2*(1/T2*) maps, standard QSM and HDR-QSM (panel C). By eliminating the off-resonance artifact at the inferolateral walls, the AUC of HDR-QSM is significantly higher than the other approaches and provides reliable IMH detection (AUC: R2*(1/T2*)=0.72; standard QSM=0.74; HDR-QSM=0.85).

CONCLUSION

s In this study, we developed a free-breathing cardiac QSM technique to quantify iron deposition in IMH. HDR-QSM opens up a reliable way for iron quantification in hearts and can potentially facilitate iron-guided precise patient management.

CLINICAL RELEVANCE/APPLICATION

HDR-QSM enables reliable in-vivo QSM imaging in the heart, it is helpful for various applications, particularly for quantifying IHM and iron concentration in patients with reperfusion injury.

W2-SPCH-1 Value-added Opportunistic Screening: Prediction Model of Hypertension Based on Clinical and Thoracic Aorta Imaging Risk Factors

Participants
Jinrong Yang, (*Presenter*) Nothing to Disclose

PURPOSE

This study is to establish and verify a nomogram model based on clinical and thoracic aorta imaging risk factors for predicting the risk of hypertension.

METHODS AND MATERIALS

This is a cross-sectional study. A total of 804 patients were enrolled and the baseline clinical data, biochemical indicators, concomitant diseases and AI data (the diameter, area at 9 levels and volume, length at two adjacent levels of thoracic aorta recommended by AHA Guidelines (2010)) of them were collected. They were randomly divided into the training set of 562 cases (70%) and the validation set of 242 cases (30%). Both two sets, the blood pressure status was monitored and diagnosed according to 2018 ESC/ESH Guidelines for the management of arterial hypertension. In the training set, variance, t-test (for normal distribution) /Mann-Whitney U-test (for non-normal distribution), least absolute shrinkage and selection operator (LASSO) were used for selecting thoracic aorta imaging risk factors to construct AI measurement score and multivariate logistic backward stepwise regression were used to analyze the influencing factors of hypertension. According to the clinical application for different data conditions, five nomogram prediction models were constructed, named AIMeasure model, BasicClinical model, TotalClinical model, AIBasicClinical model, AITotalClinical model. Moreover, receiver operating characteristic (ROC) curve, calibration curve and decision curve analyses (DCA) were used to test the distinction, accuracy and clinical applicability of the model both in training set and validation set.

RESULTS

The results showed age, height, weight, creatinine, hyperlipidemia, atherosclerosis and thoracic aortic dilatation were all related to the occurrence of hypertension. The area under the ROC curve of the above five models was 0.73, 0.77, 0.83, 0.78, 0.84 in the training set and was 0.77, 0.78, 0.81, 0.78, 0.82 in the verification set, respectively. Moreover, the calibration curves and DCAs of the two sets performed well on accuracy and clinical practicality.

CONCLUSION

s The risk prediction nomogram models have good predictive ability and clinical value, which could be used as an effective tool for the risk prediction of hypertension. Furthermore, they would facilitate earlier non-pharmacological intervention to prevent the future development of hypertension.

CLINICAL RELEVANCE/APPLICATION

To construct different hypertension prediction models using clinical and chest CT-based thoracic aorta diameters, which can be used in different clinical scenarios.

W2-SPCH-2 Age and Gender Variations in Normal Bronchial Dimensions on Low-dose Chest CT: Assessment with An Automatic Airway Segmentation and Quantitative Analysis Prototype

Participants
Parisa Kaviani, MD, Boston, MA (*Presenter*) Nothing to Disclose

PURPOSE

We assessed if a machine learning (ML) prototype for airway segmentation and quantitative analysis (AI Rad Companion, Siemens Healthineers) can assess age and gender variations in normal bronchial dimensions on low-dose CT of the chest.

METHODS AND MATERIALS

The retrospective IRB-approved study included 201 adult patients (mean age 46 ± 14 years; male: female 90:111) who underwent low-dose chest CT for lung nodule follow-up. Radiology report and images of all chest CT exams to exclude patients with any airway abnormalities including bronchial wall thickening, dilatation, plugging, nodularity or distortion. We processed thin-section CT images of all 201 patients with the ML prototype for airway segmentation and quantitation to extract following metric parameters: lumen diameter, lumen area, bronchial lumen volume, wall thickness, wall tapering, wall area, and wall area ratio for total lung

volumes and for each lung and lung lobes separately. Mann-Whitney test, Kruskal-Wallis test, and receiver operating characteristics analysis were performed for statistical analysis.

RESULTS

The prototype could not process CT datasets of 7 patients due to issues related to image format. These were excluded from the statistical analysis. In the remaining patients, the prototype demonstrated substantial variations in bronchial dimensions (lumen and wall area ratios) based on patient gender with AUCs of 1.0 for the whole lung and 0.68-0.81 for lobe-based bronchial dimensions. Male had significantly larger 20.95% dimensions than female patients ($p<0.001$). There was a significant difference between different age groups (18-30 years, 31-40 years, 41-50 years, 51-60 years, and 61-70 years) for all parameters based on the whole lung volumes, and each lobe ($p<0.001$). There were variations in generations of segmented bronchial airways based on the lung lobes [LUL (median, M:F 5:4), LLL (M:F 7:5), RUL (M:F 8:6), RML (M:F 7:6), and RLL (M:F7:9)].

CONCLUSION

s Automatic airway segmentation and quantitative analysis prototype demonstrates substantial variations in age- and gender-based bronchial luminal, wall thickness, tapering, and wall area ratios on low-dose chest CT.

CLINICAL RELEVANCE/APPLICATION

Understanding trends and dimensions of normal bronchial airway can help differentiate normal and abnormal airway dimensions in different patient age and gender groups.

W2-SPCH-3 Challenges in Improving Measurement Variability Using Deep Learning-based Kernel Conversion for Airway Quantification on Chest CT

Participants
Jooae Choe, MD, PhD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

This study aimed to assess the feasibility of deep learning-based kernel conversion for normalization of reconstruction kernel effects in airway quantification on chest CT.

METHODS AND MATERIALS

This retrospective study included 30 patients who underwent nonenhanced volumetric chest CT with slice thickness of 1 or 1.25 mm in two centers from June 2021 to July 2021. For each subjects, chest CT reconstructed with five different kernels (soft-very sharp) using one of three vendors (Siemens, n = 10; GE, n = 10; and Toshiba, n = 10). Deep learning-based kernel conversion of chest CT targeted for B30f kernel were performed in chest CT scans with different kernels other than soft kernels of each vendor. Automated quantification for airway was performed before and after normalization. The influence of different kernels and applying image conversion on airway quantification was assessed using ANOVA, paired t-test and concordance correlation coefficient (CCC).

RESULTS

Bronchial wall thickness (Pi10, mean wall thickness, wall area%) and lumen diameter decreased when using a sharper reconstruction kernel (ANOVA, for all, $P <.001$). Applying kernel conversion improved measurement variability between soft and other medium or sharp kernels for all quantitative airway measures (pooled CCC: original vs. converted images, 0.84 vs. 0.93) but significantly increased branch count (paired t-test, $P < .001$). Applying only the segmentation mask from soft kernel (reference standard) on original images with medium to sharp kernels did not improve measurement variability of airway quantification (pooled CCC: original image vs. soft kernel mask over original image, 0.84 vs. 0.85), and the measurement variability was improved when both the soft kernel mask and kernel converted images were used for airway quantification (pooled CCC: original image vs. soft kernel mask converted image, 0.84 vs. 0.95).

CONCLUSION

s While the use of kernel conversion for CT normalization improved the overall measurement variability of airway quantification, the segmentation of airways became less robust and precise. Further improvement in the algorithm regarding airway segmentation in converted images may be needed.

CLINICAL RELEVANCE/APPLICATION

Deep learning-based kernel conversion can be applied for improving measurement variability of airway quantification but further improvement in the algorithm regarding airway segmentation in converted images should be preceded.

W2-SPCH-4 Interstitial Lung Abnormalities in Patients with Locally Advanced Esophageal Cancer: Prevalence- Risk factors and Clinical Implications

Participants
Shu Chi Tseng, MD, Boston, MA (*Presenter*) Nothing to Disclose

PURPOSE

Interstitial lung abnormalities (ILA) represent nondependent abnormalities on chest CT indicating lung parenchymal damages due to inflammation and fibrosis, and are associated with older age and smoking. The prevalence of ILA and its impact on clinical outcome have been studied in lung cancer, but not in other thoracic malignancies. Esophageal cancer is the 8th most common cancer and 6th in mortality worldwide, and is associated with smoking. The purpose of the study was to determine the prevalence of ILA on pre-treatment chest CT in patients with esophageal cancer undergoing chemoradiotherapy, and to identify the association between ILA versus clinical characteristics and overall survival (OS).

METHODS AND MATERIALS

The study included 208 patients with locally advanced esophageal cancer (166 males, 42 females; median age, 65.6 years) who were considered surgical candidates and were treated with chemoradiotherapy as a part of planned tri-modality therapy, who had pre-treatment chest CT prior to the initiation of chemoradiotherapy. ILA was scored on pre-treatment chest CT using a sequential reading method by 3 readers, with a 3-point scale (0=no evidence of ILA, 1=equivocal for ILA, 2=ILA). Clinical characteristics and OS were compared in patients with ILA (score 2) and others.

RESULTS

ILA was present in 14 out of 208 patients (7%) with esophageal cancer on pre-treatment chest CT. Patients with ILA were significantly older (median age: 69 vs. 65; p=0.011), had a higher number of pack-years of smoking (p=0.02), and more commonly had T4 stage disease (p=0.026) than patients with ILA score of 1 or 0. The presence of ILA was associated with a lack of surgery after chemoradiotherapy; surgical resection was not performed in 50% (7/14) of patients with ILA, compared to in 20% (39/194) of patients without ILA on baseline CT (p=0.016). The presence of baseline ILA was not associated with OS (log-rank p=0.75, Cox p=0.613).

CONCLUSION

s ILA was present in 7% of locally advanced esophageal cancer patients, with risk factors including older age, higher number of pack-year of smoking, and T4 disease. ILA on pre-treatment CT was associated with a lack of surgical resection after chemoradiotherapy, indicating an implication of ILA for treatment selection in these patients.

CLINICAL RELEVANCE/APPLICATION

ILA on pre-treatment chest CT was noted in 7% of locally advanced esophageal cancer patients and associated with older age, smoking, and T4 disease. Patients with ILA were significantly less likely to undergo surgical resection after chemoradiotherapy, and thus ILA may have implications for treatment selection in esophageal cancer patients, which can be studied in a larger prospective cohort for validation.

W2-SPCH-5 Interstitial Lung Abnormality (ILA) Progression in the Four-Year Follow-up of Patients with Esophageal Cancer

Participants
Akinori Hata, MD, PhD, Suita, Japan (*Presenter*) Nothing to Disclose

PURPOSE

There is a growing awareness of the clinical significance of interstitial lung abnormality (ILA). Patients with esophageal cancer receive multidisciplinary treatment including surgery, chemotherapy, and radiation therapy. In particular, aspiration pneumonia is frequently experienced after surgery. These therapies and complications may affect the ILA progression. The purpose of our study was to investigate the prevalence of ILA progression in the four-year follow-up of patients with esophageal cancer.

METHODS AND MATERIALS

This retrospective study investigated patients who were diagnosed with esophageal cancer from January 2011 to December 2015 and survived four years or more. The follow-up chest CT four years after diagnosis was evaluated for the prevalence of ILA with a 3-point visual scale (0=non-ILA, 1=indeterminate for ILA, and 2=ILA). In addition, ILA progression was assessed by comparing the follow-up CT at four years with the pretreatment baseline CT with a 5-point visual scale (1=definite regression, 2=probable regression, 3=no change, 4=probable progression, and 5=definite progression). Logistic regression was used to assess factors associated with ILA progression.

RESULTS

Overall, 178 patients (median age, 67 years at diagnosis; interquartile range, 61-67 years; 155 men [87%]) were included. We identified 97 non-ILA patients (score 0, 54%), 55 patients indeterminate for ILA (score 1, 31%), and 26 patients with ILA (score 2, 15%) on the follow-up CTs. Of the 178 patients, 128 showed improvement or no change of ILA (score 1-3, 72%) and 50 showed ILA progression (score 4 or 5, 28%), including indeterminate for ILA. In the univariate logistic regression analysis, age was the significant factor associated with ILA progression (odds ratio 1.07 [95% confidence interval: 1.02, 1.12], P=.004). However, surgery, chemotherapy, radiation therapy, sex, body mass index, smoking history, advanced stage, and pulmonary function test results at baseline (forced expiratory volume in 1 second [FEV1], forced vital capacity [FVC], and FEV1/FVC) were not significant (P>0.05).

CONCLUSION

s ILA progression was seen in 28% of four-year survivors with esophageal cancer. Although age was significantly associated with ILA progression, treatment options were not.

CLINICAL RELEVANCE/APPLICATION

Postoperative esophageal cancer patients often suffer from aspiration, but our results suggest that aspiration due to esophageal cancer surgery may not be related to ILA progression.

W2-SPCH-6 Imaging the Thymus and Anterior Mediastinum with Subtraction Imaging in CT: An Initial Clinical Experience

Participants
Vruti Dattani, MBBS, MA, (*Presenter*) Nothing to Disclose

PURPOSE

Thymic and other anterior mediastinal lesions comprise a range of benign and malignant pathologies but contrast enhanced CT can fail to discriminate between these. Our study explores if iodine concentration obtained from image subtraction CT differs between benign and malignant anterior mediastinal lesions.

METHODS AND MATERIALS

Consecutive adult patients planned for imaging of the anterior mediastinum underwent contrast enhanced CT thorax (120 kV, 40-300 mA) preceded by a low-dose CT thorax (135 kV, 10-20 mA). Scan parameters were slice thickness 3.0 mm, slice interval 2.4 mm, collimation 80 x 0.5 mm, pitch factor 0.814 and tube rotation time 0.5 seconds. Image subtraction software (Canon SURESubtraction) incorporating an elastic registration algorithm was used to generate iodine maps. The mean iodine concentration from 3 regions of interest per lesion was calculated relative to iodine concentration within the IVC. A diagnosis of benign or malignant was obtained from patient records based on a combination of histological, clinical and imaging features. Data was analysed using a machine learning algorithm (C-Support Vector Machine, SVM) using the 'sklearn' Python package. The classifier

was trained both without additional pre-processing and on a Principal Component Analysis (PCA) of the data.

RESULTS

Anterior mediastinal lesions have been assessed in 50 patients (M= 22, F= 28, age range 18-87 years) of which 21 are benign and 29 malignant. Malignant lesions include high risk thymoma, thymic carcinoma and lymphoma. Mean iodine concentration in the benign lesions is 0.956 mg/ml (SD ± 0.628 mg/ml) and in the malignant lesions 0.903 mg/ml (SD ± 0.731 mg/ml). The SVM could classify the iodine concentration data with only 64% accuracy, this was not improved with PCA.

CONCLUSION

s Hence we demonstrate no difference in iodine concentration between benign and malignant anterior mediastinal lesions. However further work is required to explore if iodine concentration from image subtraction CT could contribute to diagnosis when in concert with other imaging features seen on conventional CT imaging.

CLINICAL RELEVANCE/APPLICATION

The addition of subtraction imaging to CT assessment of anterior mediastinal mass is of questionable value as we show iodine concentration cannot discriminate between benign and malignant lesions.

W2-SPCH-7 Performance of Chest MRI for The Detection of Pulmonary Nodules: A Meta-analysis

Participants
Stephan Altmayer, MD, PhD, Framingham, MA (*Presenter*) Nothing to Disclose

PURPOSE

To perform a meta-analysis of the diagnostic performance of chest MRI in the detection of pulmonary nodules.

METHODS AND MATERIALS

MEDLINE, EMBASE, and Cochrane databases were searched through April 2022 for published English language studies. Studies were eligible if they evaluated the diagnostic performance of MRI for the detection of pulmonary nodules in patients with suspected thoracic malignancy (primary or metastatic) or undergoing lung cancer screening, which used chest CT as the reference standard for comparison of performance. Nodules with diameter <4mm, masses (>30 mm), or studies that did not specify the size of the nodules were excluded from the analysis. Other exclusion criteria included studies with less than 10 subjects, pediatric population, and nodules from known infectious or inflammatory etiology. Pooled per-lesion and per-patient sensitivity and specificity, respectively, were calculated with 95% confidence intervals (95% CI) using random-effects model in R.

RESULTS

Eleven studies met the inclusion criteria with a total of 963 patients and 1149 nodules identified. The pooled per-lesion sensitivity of MRI was 88% (95% CI: 80-93%) for the detection of pulmonary nodules of size 4-30 mm. In the subgroup analysis by size, the pooled sensitivity of MRI for nodules <10 mm was 85% (95% CI: 77-91%), while the sensitivity for nodules 10-30 mm was 99% (95% CI: 89-99%). Only 4 studies reported per-patient data with true negatives and false positives for analysis of specificity (total of 90 true negatives). The pooled specificity of MRI in these studies was 94% (95% CI: 84-98%).

CONCLUSION

s The diagnostic performance of MRI for detection of pulmonary nodules =4 mm in the oncology setting is high with detection rates of 99% for nodules =10 mm. Per-patient specificity of MRI was 94%.

CLINICAL RELEVANCE/APPLICATION

Chest MRI can be a reasonable alternative to CT in the detection and follow-up of pulmonary nodules =4 mm in patients with a high radiation burden. This modality also showed limited false-positive cases in a per-patient analysis.

W2-SPCH-1

Value-added Opportunistic Screening: Prediction Model of Hypertension Based on Clinical and Thoracic Aorta Imaging Risk Factors

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - CH DPS

Participants
Jinrong Yang, (*Presenter*) Nothing to Disclose

PURPOSE

This study is to establish and verify a nomogram model based on clinical and thoracic aorta imaging risk factors for predicting the risk of hypertension.

METHODS AND MATERIALS

This is a cross-sectional study. A total of 804 patients were enrolled and the baseline clinical data, biochemical indicators, concomitant diseases and AI data (the diameter, area at 9 levels and volume, length at two adjacent levels of thoracic aorta recommended by AHA Guidelines (2010)) of them were collected. They were randomly divided into the training set of 562 cases (70%) and the validation set of 242 cases (30%). Both two sets, the blood pressure status was monitored and diagnosed according to 2018 ESC/ESH Guidelines for the management of arterial hypertension. In the training set, variance, t-test (for normal distribution) /Mann-Whitney U-test (for non-normal distribution), least absolute shrinkage and selection operator (LASSO) were used for selecting thoracic aorta imaging risk factors to construct AI measurement score and multivariate logistic backward stepwise regression were used to analyze the influencing factors of hypertension. According to the clinical application for different data conditions, five nomogram prediction models were constructed, named AIMeasure model, BasicClinical model, TotalClinical model, AIBasicClinical model, AITotalClinical model. Moreover, receiver operating characteristic (ROC) curve, calibration curve and decision curve analyses (DCA) were used to test the distinction, accuracy and clinical applicability of the model both in training set and validation set.

RESULTS

The results showed age, height, weight, creatinine, hyperlipidemia, atherosclerosis and thoracic aortic dilatation were all related to the occurrence of hypertension. The area under the ROC curve of the above five models was 0.73, 0.77, 0.83, 0.78, 0.84 in the training set and was 0.77, 0.78, 0.81, 0.78, 0.82 in the verification set, respectively. Moreover, the calibration curves and DCAs of the two sets performed well on accuracy and clinical practicality.

CONCLUSION

s The risk prediction nomogram models have good predictive ability and clinical value, which could be used as an effective tool for the risk prediction of hypertension. Furthermore, they would facilitate earlier non-pharmacological intervention to prevent the future development of hypertension.

CLINICAL RELEVANCE/APPLICATION

To construct different hypertension prediction models using clinical and chest CT-based thoracic aorta diameters, which can be used in different clinical scenarios.

Age and Gender Variations in Normal Bronchial Dimensions on Low-dose Chest CT: Assessment with An Automatic Airway Segmentation and Quantitative Analysis Prototype

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - CH DPS

Participants
Parisa Kaviani, MD, Boston, MA (*Presenter*) Nothing to Disclose

PURPOSE

We assessed if a machine learning (ML) prototype for airway segmentation and quantitative analysis (AI Rad Companion, Siemens Healthineers) can assess age and gender variations in normal bronchial dimensions on low-dose CT of the chest.

METHODS AND MATERIALS

The retrospective IRB-approved study included 201 adult patients (mean age 46 ± 14 years; male: female 90:111) who underwent low-dose chest CT for lung nodule follow-up. Radiology report and images of all chest CT exams to exclude patients with any airway abnormalities including bronchial wall thickening, dilatation, plugging, nodularity or distortion. We processed thin-section CT images of all 201 patients with the ML prototype for airway segmentation and quantitation to extract following metric parameters: lumen diameter, lumen area, bronchial lumen volume, wall thickness, wall tapering, wall area, and wall area ratio for total lung volumes and for each lung and lung lobes separately. Mann-Whitney test, Kruskal-Wallis test, and receiver operating characteristics analysis were performed for statistical analysis.

RESULTS

The prototype could not process CT datasets of 7 patients due to issues related to image format. These were excluded from the statistical analysis. In the remaining patients, the prototype demonstrated substantial variations in bronchial dimensions (lumen and wall area ratios) based on patient gender with AUCs of 1.0 for the whole lung and 0.68-0.81 for lobe-based bronchial dimensions. Male had significantly larger 20.95% dimensions than female patients ($p<0.001$). There was a significant difference between different age groups (18-30 years, 31-40 years, 41-50 years, 51-60 years, and 61-70 years) for all parameters based on the whole lung volumes, and each lobe ($p<0.001$). There were variations in generations of segmented bronchial airways based on the lung lobes [LUL (median, M:F 5:4), LLL (M:F 7:5), RUL (M:F 8:6), RML (M:F 7:6), and RLL (M:F7:9)].

CONCLUSION

s Automatic airway segmentation and quantitative analysis prototype demonstrates substantial variations in age- and gender-based bronchial luminal, wall thickness, tapering, and wall area ratios on low-dose chest CT.

CLINICAL RELEVANCE/APPLICATION

Understanding trends and dimensions of normal bronchial airway can help differentiate normal and abnormal airway dimensions in different patient age and gender groups.

W2-SPCH-3

Challenges in Improving Measurement Variability Using Deep Learning-based Kernel Conversion for Airway Quantification on Chest CT

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - CH DPS

Participants
Jooae Choe, MD, PhD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

This study aimed to assess the feasibility of deep learning-based kernel conversion for normalization of reconstruction kernel effects in airway quantification on chest CT.

METHODS AND MATERIALS

This retrospective study included 30 patients who underwent nonenhanced volumetric chest CT with slice thickness of 1 or 1.25 mm in two centers from June 2021 to July 2021. For each subjects, chest CT reconstructed with five different kernels (soft-very sharp) using one of three vendors (Siemens, n = 10; GE, n = 10; and Toshiba, n = 10). Deep learning-based kernel conversion of chest CT targeted for B30f kernel were performed in chest CT scans with different kernels other than soft kernels of each vendor. Automated quantification for airway was performed before and after normalization. The influence of different kernels and applying image conversion on airway quantification was assessed using ANOVA, paired t-test and concordance correlation coefficient (CCC).

RESULTS

Bronchial wall thickness (Pi10, mean wall thickness, wall area%) and lumen diameter decreased when using a sharper reconstruction kernel (ANOVA, for all, P <.001). Applying kernel conversion improved measurement variability between soft and other medium or sharp kernels for all quantitative airway measures (pooled CCC: original vs. converted images, 0.84 vs. 0.93) but significantly increased branch count (paired t-test, P < .001). Applying only the segmentation mask from soft kernel (reference standard) on original images with medium to sharp kernels did not improve measurement variability of airway quantification (pooled CCC: original image vs. soft kernel mask over original image, 0.84 vs. 0.85), and the measurement variability was improved when both the soft kernel mask and kernel converted images were used for airway quantification (pooled CCC: original image vs. soft kernel mask converted image, 0.84 vs. 0.95).

CONCLUSION

s While the use of kernel conversion for CT normalization improved the overall measurement variability of airway quantification, the segmentation of airways became less robust and precise. Further improvement in the algorithm regarding airway segmentation in converted images may be needed.

CLINICAL RELEVANCE/APPLICATION

Deep learning-based kernel conversion can be applied for improving measurement variability of airway quantification but further improvement in the algorithm regarding airway segmentation in converted images should be preceded.

W2-SPCH-4

Interstitial Lung Abnormalities in Patients with Locally Advanced Esophageal Cancer: Prevalence- Risk factors and Clinical Implications

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - CH DPS

Participants
Shu Chi Tseng, MD, Boston, MA (*Presenter*) Nothing to Disclose

PURPOSE

Interstitial lung abnormalities (ILA) represent nondependent abnormalities on chest CT indicating lung parenchymal damages due to inflammation and fibrosis, and are associated with older age and smoking. The prevalence of ILA and its impact on clinical outcome have been studied in lung cancer, but not in other thoracic malignancies. Esophageal cancer is the 8th most common cancer and 6th in mortality worldwide, and is associated with smoking. The purpose of the study was to determine the prevalence of ILA on pre-treatment chest CT in patients with esophageal cancer undergoing chemoradiotherapy, and to identify the association between ILA versus clinical characteristics and overall survival (OS).

METHODS AND MATERIALS

The study included 208 patients with locally advanced esophageal cancer (166 males, 42 females; median age, 65.6 years) who were considered surgical candidates and were treated with chemoradiotherapy as a part of planned tri-modality therapy, who had pre-treatment chest CT prior to the initiation of chemoradiotherapy. ILA was scored on pre-treatment chest CT using a sequential reading method by 3 readers, with a 3-point scale (0=no evidence of ILA, 1=equivocal for ILA, 2=ILA). Clinical characteristics and OS were compared in patients with ILA (score 2) and others.

RESULTS

ILA was present in 14 out of 208 patients (7%) with esophageal cancer on pre-treatment chest CT. Patients with ILA were significantly older (median age: 69 vs. 65; p=0.011), had a higher number of pack-years of smoking (p=0.02), and more commonly had T4 stage disease (p=0.026) than patients with ILA score of 1 or 0. The presence of ILA was associated with a lack of surgery after chemoradiotherapy; surgical resection was not performed in 50% (7/14) of patients with ILA, compared to in 20% (39/194) of patients without ILA on baseline CT (p=0.016). The presence of baseline ILA was not associated with OS (log-rank p=0.75, Cox p=0.613).

CONCLUSION

s ILA was present in 7% of locally advanced esophageal cancer patients, with risk factors including older age, higher number of pack-year of smoking, and T4 disease. ILA on pre-treatment CT was associated with a lack of surgical resection after chemoradiotherapy, indicating an implication of ILA for treatment selection in these patients.

CLINICAL RELEVANCE/APPLICATION

ILA on pre-treatment chest CT was noted in 7% of locally advanced esophageal cancer patients and associated with older age, smoking, and T4 disease. Patients with ILA were significantly less likely to undergo surgical resection after chemoradiotherapy, and thus ILA may have implications for treatment selection in esophageal cancer patients, which can be studied in a larger prospective cohort for validation.

W2-SPCH-5

Interstitial Lung Abnormality (ILA) Progression in the Four-Year Follow-up of Patients with Esophageal Cancer

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - CH DPS

Participants
Akinori Hata, MD, PhD, Suita, Japan (*Presenter*) Nothing to Disclose

PURPOSE

There is a growing awareness of the clinical significance of interstitial lung abnormality (ILA). Patients with esophageal cancer receive multidisciplinary treatment including surgery, chemotherapy, and radiation therapy. In particular, aspiration pneumonia is frequently experienced after surgery. These therapies and complications may affect the ILA progression. The purpose of our study was to investigate the prevalence of ILA progression in the four-year follow-up of patients with esophageal cancer.

METHODS AND MATERIALS

This retrospective study investigated patients who were diagnosed with esophageal cancer from January 2011 to December 2015 and survived four years or more. The follow-up chest CT four years after diagnosis was evaluated for the prevalence of ILA with a 3-point visual scale (0=non-ILA, 1=indeterminate for ILA, and 2=ILA). In addition, ILA progression was assessed by comparing the follow-up CT at four years with the pretreatment baseline CT with a 5-point visual scale (1=definite regression, 2=probable regression, 3=no change, 4=probable progression, and 5=definite progression). Logistic regression was used to assess factors associated with ILA progression.

RESULTS

Overall, 178 patients (median age, 67 years at diagnosis; interquartile range, 61-67 years; 155 men [87%]) were included. We identified 97 non-ILA patients (score 0, 54%), 55 patients indeterminate for ILA (score 1, 31%), and 26 patients with ILA (score 2, 15%) on the follow-up CTs. Of the 178 patients, 128 showed improvement or no change of ILA (score 1-3, 72%) and 50 showed ILA progression (score 4 or 5, 28%), including indeterminate for ILA. In the univariate logistic regression analysis, age was the significant factor associated with ILA progression (odds ratio 1.07 [95% confidence interval: 1.02, 1.12], P=.004). However, surgery, chemotherapy, radiation therapy, sex, body mass index, smoking history, advanced stage, and pulmonary function test results at baseline (forced expiratory volume in 1 second [FEV1], forced vital capacity [FVC], and FEV1/FVC) were not significant (P>0.05).

CONCLUSION

s ILA progression was seen in 28% of four-year survivors with esophageal cancer. Although age was significantly associated with ILA progression, treatment options were not.

CLINICAL RELEVANCE/APPLICATION

Postoperative esophageal cancer patients often suffer from aspiration, but our results suggest that aspiration due to esophageal cancer surgery may not be related to ILA progression.

Imaging the Thymus and Anterior Mediastinum with Subtraction Imaging in CT: An Initial Clinical Experience

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - CH DPS

Participants
Vruti Dattani, MBBS, MA, (*Presenter*) Nothing to Disclose

PURPOSE

Thymic and other anterior mediastinal lesions comprise a range of benign and malignant pathologies but contrast enhanced CT can fail to discriminate between these. Our study explores if iodine concentration obtained from image subtraction CT differs between benign and malignant anterior mediastinal lesions.

METHODS AND MATERIALS

Consecutive adult patients planned for imaging of the anterior mediastinum underwent contrast enhanced CT thorax (120 kV, 40-300 mA) preceded by a low-dose CT thorax (135 kV, 10-20 mA). Scan parameters were slice thickness 3.0 mm, slice interval 2.4 mm, collimation 80 x 0.5 mm, pitch factor 0.814 and tube rotation time 0.5 seconds. Image subtraction software (Canon SURESubtraction) incorporating an elastic registration algorithm was used to generate iodine maps. The mean iodine concentration from 3 regions of interest per lesion was calculated relative to iodine concentration within the IVC. A diagnosis of benign or malignant was obtained from patient records based on a combination of histological, clinical and imaging features. Data was analysed using a machine learning algorithm (C-Support Vector Machine, SVM) using the 'sklearn' Python package. The classifier was trained both without additional pre-processing and on a Principal Component Analysis (PCA) of the data.

RESULTS

Anterior mediastinal lesions have been assessed in 50 patients (M= 22, F= 28, age range 18-87 years) of which 21 are benign and 29 malignant. Malignant lesions include high risk thymoma, thymic carcinoma and lymphoma. Mean iodine concentration in the benign lesions is 0.956 mg/ml (SD ± 0.628 mg/ml) and in the malignant lesions 0.903 mg/ml (SD ± 0.731 mg/ml). The SVM could classify the iodine concentration data with only 64% accuracy, this was not improved with PCA.

CONCLUSION

s Hence we demonstrate no difference in iodine concentration between benign and malignant anterior mediastinal lesions. However further work is required to explore if iodine concentration from image subtraction CT could contribute to diagnosis when in concert with other imaging features seen on conventional CT imaging.

CLINICAL RELEVANCE/APPLICATION

The addition of subtraction imaging to CT assessment of anterior mediastinal mass is of questionable value as we show iodine concentration cannot discriminate between benign and malignant lesions.

W2-SPCH-7

Performance of Chest MRI for The Detection of Pulmonary Nodules: A Meta-analysis

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - CH DPS

Participants
Stephan Altmayer, MD, PhD, Framingham, MA (*Presenter*) Nothing to Disclose

PURPOSE

To perform a meta-analysis of the diagnostic performance of chest MRI in the detection of pulmonary nodules.

METHODS AND MATERIALS

MEDLINE, EMBASE, and Cochrane databases were searched through April 2022 for published English language studies. Studies were eligible if they evaluated the diagnostic performance of MRI for the detection of pulmonary nodules in patients with suspected thoracic malignancy (primary or metastatic) or undergoing lung cancer screening, which used chest CT as the reference standard for comparison of performance. Nodules with diameter <4mm, masses (>30 mm), or studies that did not specify the size of the nodules were excluded from the analysis. Other exclusion criteria included studies with less than 10 subjects, pediatric population, and nodules from known infectious or inflammatory etiology. Pooled per-lesion and per-patient sensitivity and specificity, respectively, were calculated with 95% confidence intervals (95% CI) using random-effects model in R.

RESULTS

Eleven studies met the inclusion criteria with a total of 963 patients and 1149 nodules identified. The pooled per-lesion sensitivity of MRI was 88% (95% CI: 80-93%) for the detection of pulmonary nodules of size 4-30 mm. In the subgroup analysis by size, the pooled sensitivity of MRI for nodules <10 mm was 85% (95% CI: 77-91%), while the sensitivity for nodules 10-30 mm was 99% (95% CI: 89-99%). Only 4 studies reported per-patient data with true negatives and false positives for analysis of specificity (total of 90 true negatives). The pooled specificity of MRI in these studies was 94% (95% CI: 84-98%).

CONCLUSION

s The diagnostic performance of MRI for detection of pulmonary nodules =4 mm in the oncology setting is high with detection rates of 99% for nodules =10 mm. Per-patient specificity of MRI was 94%.

CLINICAL RELEVANCE/APPLICATION

Chest MRI can be a reasonable alternative to CT in the detection and follow-up of pulmonary nodules =4 mm in patients with a high radiation burden. This modality also showed limited false-positive cases in a per-patient analysis.

Sub-Events

W2-SPER-1 The Impact of Clinical Decision Support System on the Yield of Pulmonary Emboli on CT Pulmonary Angiography

Participants
Abdullah Khan, MD, Sacramento, CA (*Presenter*) Nothing to Disclose

PURPOSE

CT pulmonary angiography (CTPA) is generally considered to be overutilized and has low diagnostic yield for suspected acute pulmonary embolism (PE), prompting CMS to require consultation of Clinical Decision Support (CDS) at the time of order entry for suspected PE. We assess the effect of CDS on CTPA diagnostic yield by measuring test positivity pre and post implementation.

METHODS AND MATERIALS

CDS data and final radiology report impressions for all CTPA orders from the Emergency Department of our quaternary care hospital between July 2016 and April 2022 were obtained prior to and following our CDS go-live date in December 2019. Primary outcome was the percentage of reports positive for PE, determined by manual classification. Secondary outcomes were stratified by CDS appropriateness score and data elements captured at order entry: degree of clinical suspicion for PE, D-dimer status, and signs or symptoms of DVT. Pearson's Chi-squared test and logistic regression statistical tests were applied.

RESULTS

976 of 6953 CTPA exams were positive for PE (14.1%), including 546 of 3824 pre-CDS (14.3%) and 430 of 3129 post-CDS (13.7%; p=0.545). 292 of 2036 exams deemed 'Appropriate' by CDS were positive (14.4%), while 40 of 382 'Inappropriate' exams were positive (10.5%; p=0.053). 102 of the remaining 711 exams were positive (14.3%) - these had 'Moderate' appropriateness (n=4), an indication that was out of scope for CDS (n=125), or the score was not readily available for technical reasons (n=582). Availability of stratified data elements was limited due to variable input by ordering providers when interfacing with the CDS. Stratification demonstrated no statistically significant differences in positivity rate between the High (16.8%), Moderate (10.5%), and Low (14.7%) clinical suspicion groups, between positive (6.3%) or negative (11.9%) signs/symptoms of DVT, or between elevated (12.2%) and normal (0%, n=8) D-dimer stratifications.

CONCLUSION

s There was no significant change in diagnostic yield following implementation of CDS for CTPA orders from the Emergency Department at a quaternary care hospital. Exams with 'High' clinical suspicion for PE had slightly higher and those with 'Inappropriate' CDS determinations slightly lower positivity rates, but none of the detected differences was statistically significant.

CLINICAL RELEVANCE/APPLICATION

CDS tools require tremendous effort and cost to design, implement, use, and maintain, and may not improve utilization. We found no difference in CTPA PE positivity pre and post CDS implementation.

W2-SPER-1

The Impact of Clinical Decision Support System on the Yield of Pulmonary Emboli on CT Pulmonary Angiography

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - ER DPS

Participants
Abdullah Khan, MD, Sacramento, CA (*Presenter*) Nothing to Disclose

PURPOSE

CT pulmonary angiography (CTPA) is generally considered to be overutilized and has low diagnostic yield for suspected acute pulmonary embolism (PE), prompting CMS to require consultation of Clinical Decision Support (CDS) at the time of order entry for suspected PE. We assess the effect of CDS on CTPA diagnostic yield by measuring test positivity pre and post implementation.

METHODS AND MATERIALS

CDS data and final radiology report impressions for all CTPA orders from the Emergency Department of our quaternary care hospital between July 2016 and April 2022 were obtained prior to and following our CDS go-live date in December 2019. Primary outcome was the percentage of reports positive for PE, determined by manual classification. Secondary outcomes were stratified by CDS appropriateness score and data elements captured at order entry: degree of clinical suspicion for PE, D-dimer status, and signs or symptoms of DVT. Pearson's Chi-squared test and logistic regression statistical tests were applied.

RESULTS

976 of 6953 CTPA exams were positive for PE (14.1%), including 546 of 3824 pre-CDS (14.3%) and 430 of 3129 post-CDS (13.7%; p=0.545). 292 of 2036 exams deemed 'Appropriate' by CDS were positive (14.4%), while 40 of 382 'Inappropriate' exams were positive (10.5%; p=0.053). 102 of the remaining 711 exams were positive (14.3%) - these had 'Moderate' appropriateness (n=4), an indication that was out of scope for CDS (n=125), or the score was not readily available for technical reasons (n=582). Availability of stratified data elements was limited due to variable input by ordering providers when interfacing with the CDS. Stratification demonstrated no statistically significant differences in positivity rate between the High (16.8%), Moderate (10.5%), and Low (14.7%) clinical suspicion groups, between positive (6.3%) or negative (11.9%) signs/symptoms of DVT, or between elevated (12.2%) and normal (0%, n=8) D-dimer stratifications.

CONCLUSION

s There was no significant change in diagnostic yield following implementation of CDS for CTPA orders from the Emergency Department at a quaternary care hospital. Exams with 'High' clinical suspicion for PE had slightly higher and those with 'Inappropriate' CDS determinations slightly lower positivity rates, but none of the detected differences was statistically significant.

CLINICAL RELEVANCE/APPLICATION

CDS tools require tremendous effort and cost to design, implement, use, and maintain, and may not improve utilization. We found no difference in CTPA PE positivity pre and post CDS implementation.

W2-SPGI-10 Accelerated liver diffusion-weighted imaging with a deep learning-based reconstruction: Evaluation of image quality and performance for focal lesion detection in comparison with conventional diffusion-weighted imaging

Participants
Bohyun Kim, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To assess image quality and performance for focal liver lesion (FLL) detection of an accelerated liver diffusion-weighted image with deep learning-based image reconstruction (DL-DWI) compared with conventional DWI (C-DWI) at 3T.

METHODS AND MATERIALS

This retrospective study assessed 102 patients who underwent respiratory-triggered DL-DWI and C-DWI using matched b-values (100, 800, 1000 s/mm2) and resolution (2.7 x 2.7 x 5 mm3) at 3T (MAGNETOM Vida; Siemens Healthcare). DL-DWI used the number of average of 1/1/1 for each b-value and a parallel imaging factor of 4, while those for C-DWI were 1/2/2 and 3, respectively. Two radiologists scored image qualities and measured apparent diffusion coefficient (ADC) values, signal intensity (SI), and signal-to-noise ratio (SI/SD) of two DWI (b = 1000 s/mm2) sets. For FLLs, conspicuity and margin sharpness scores, numbers, SI, and lesion-to-liver contrast [(SIlesion-SIliver)/(SIlesion+SIliver)] were assessed. Wilcoxon signed-rank test, Student t-test, and ? statistics evaluated differences and agreements.

RESULTS

DL-DWI reduced median acquisition time by 20% to C-DWI (391 s vs. 482 s; $p < 0.001$). DL-DWI received significantly higher scores for image noise and respiratory motion artifact (ps < 0.001), comparable scores for overall image quality, but lower scores for cardiac motion artifact ($p < 0.001$) in both readers (?, 0.35-0.63). ADC values were more homogeneous in DL-DWI, indicated by lesser variance in measurements and smaller SD across liver segments ($p < 0.021$). DL-DWI showed significantly higher SI (110.1 vs. 80.6; $p < 0.001$) and SNR (15.07 vs. 9.21; $p < 0.001$). FLLs were more conspicuous on DL-DWI ($p < 0.019$), with significantly higher SI (245 vs. 193.7; $p < 0.001$) and comparable lesion-to-liver contrast (0.41 vs. 0.39; $p = 0.137$). Lesser number of FLLs was detected in DL-DWI (130 vs. 148 and 138 vs. 147), though both readers identified a similar number of malignant FLLs (74/86 vs. 80/86 and 76/86 vs. 82/86, ps < 0.099). The mean size of the FLL missed or invisible on DL-DWI was 0.6 cm (range, 0.3-2.3) and frequently located near the capsule (9/15; 60%), with the largest lesion at S2.

CONCLUSION

s DL-DWI provided lower image noise, reduced motion artifact, homogeneous ADC values, and higher liver parenchymal SI within a significantly shorter time. Despite superior conspicuity and higher SI for FLL with DL-DWI, small lesions near the capsule or S2 tended to be missed/invisible, underlined by the lower score for cardiac motion artifact. This might attribute to protocol setting and suggests a corresponding refinement as future work.

CLINICAL RELEVANCE/APPLICATION

DL-DWI showed reduced image noise, better FLL conspicuity, and substantially higher liver parenchymal SI acquired within a 20% shorter scan time than C-DWI.

W2-SPGI-2 Diagnostic performance of two kinds of abbreviated gadoxetic acid-enhanced MR protocols for the detection of colorectal liver metastases

Participants
Kumi Ozaki, MD, PhD, Fukui, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To compare the diagnostic performance of two kinds of abbreviated enhanced magnetic resonance imaging (Ab-MRI) protocols with the standard MRI protocol for the detection of colorectal liver metastases.

METHODS AND MATERIALS

The study participants were 87 patients (51 males, 36 females; mean age, 67.2 ± 10.8 years) who had undergone gadoxetic acid-enhanced MRI during the initial work-up for colorectal cancer from 2010 to 2021. All exams were independently reviewed by two readers in three reading sessions: (1) only single-shot fast spin echo (FSE) T2-weighted or fat-suppressed-FSE-T2-weighted,

diffusion-weighted, and hepatobiliary phase images (Ab-MRI protocol 1 or 2), and (2) all acquired MRI sequences (standard protocol). The diagnostic performance was then statistically analyzed.

RESULTS

A total of 380 lesions, including 195 metastases (51.4%), were analyzed. The results of the two Ab-MRI protocols were similar. The sensitivity, specificity, and positive and negative predictive values of Ab-MRI were non-inferior to those of standard MRI ($p > 0.05$), while those of the combination of Ab-MRI protocol and CE-CT were higher than those of Ab-MRI alone, although not significantly different ($p > 0.05$), and were quite similar to those of standard MRI ($p > 0.05$).

CONCLUSION

s The diagnostic performance of both two kinds of Ab-MRI protocols was non-inferior to that of the standard protocol.

CLINICAL RELEVANCE/APPLICATION

The diagnostic performance of both two kinds of abbreviated MRI protocols was non-inferior to that of the standard protocol for the detection of colorectal liver metastases.

W2-SPGI-3 Study on biological activity of hepatic alveolar echinococcus by multimodal MR imaging combined with serum circulating free DNA .

Participants
Hai Hua Bao, Xining, China (*Presenter*) Nothing to Disclose

PURPOSE

Hepatic alveolar echinococcosis (HAE) grows aggressively in the liver, and its growth characteristics are important for diagnosis and treatment. In this study, the biological activity of hepatic alveolar echinococcosis was studied by multi-mode MR imaging combined with circulating free DNA(cfDNA) in serum.

METHODS AND MATERIALS

Seventy-two patients with HAE diagnosed clinically from August 2018 to January 2019 were included in the study. Serum cfDNA was detected before MRI. The examination equipment is a 3.0 T MRI scanner. The scanning sequence includes MRI plain scan and dynamic contrast examination, DWI and MRCP water imaging sequence; MRI evaluation first defines the location, size and imaging type of the lesion; The evaluation indexes of activity include the range of high signal band of DWI images(marginal band), microbubbles and enhancement characteristics.The marginal zone, microbubbles and ADC values were measured by T2WI, MRCP and DWI sequences (b = 800 mm/s) to further evaluate the biological activity of the lesions. The correlation between the size, imaging type of lesions and serum cfDNA was analyzed.

RESULTS

1. Lesions characteristics: there were 92 lesions in 72 patients with HAE, including 16 lesions < 5 cm, 36 lesions >5-10 cm and 40 lesions >10cm. Imaging types of lesions: solid type 51 cases, liquefied type 7 cases, multiple nodular type 4 cases, mixed type 4 cases and calcified type 6 cases. 2. Evaluation of lesion activity: 49 lesions (53.3%) showed mild annular enhancement in portal vein phase after dynamic contrast-enhanced scanning; On DWI images, 87 lesions had high signal intensity (marginal zone) with limited diffusion, while 5 calcified lesions had no obvious marginal zone. The width of the band is between (0.28 ~ 0.98) cm; The average ADC value is about (1.10±0.17) × $10^{-3}mm^2/s$ measured at 0.5cm in the marginal zone. Average ADC value of microbubbles is about (0.79±0.16) × $10^{-3}mm^2/s$; Compared with ADC, the difference was statistically significant ($P < 0.05$). 3. Correlation between the size and classification of lesions and cfDNA: The cfDNA range of lesions with HAE=10cm is (98 ~ 11770) ng/ml, which is higher than that of small lesions (0 ~ 98 ng/ml), and the correlation between them is statistically different ($r=0.482$, $P = 0.000$); cfDNA was found in all types, with calcified DNA being the lowest (0 ~ 2 ng/ml) and solid's DNA being the highest (0 ~ 11770 ng/ml).

CONCLUSION

s cfDNA is related to the size, imaging type and activity of HAE lesions, and MRI combined with cfDNA can better evaluate the biological activity of HAE lesions.

CLINICAL RELEVANCE/APPLICATION

MRI combined with cfDNA can better evaluate the biological activity of HAE lesions.

W2-SPGI-4 Detection of Lymph Node Metastases in Intrehepatic Cholangiocarcinoma - an Ongoing Challenge

Participants
Johannes Kolck, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Objectives of the present study were to investigate the predictive value of the short lymph node (LN) axis, a widely recognised discriminator for lymph node metastases (LNM) in tumor imaging, and to develop a predictive model for LNM in iCC based on multiple CT imaging features.

METHODS AND MATERIALS

Retrospectively enrolled were 102 patients with pathologically proven mass-forming iCC, who underwent multiphase CT imaging prior to and standardised lymph node dissection during resection from 2005 to 2021. Two blinded radiologists assessed various quantitative and qualitative imaging characteristics. These were implemented to develop a prediction model for lymph node metastasis.

RESULTS

Lymph node dissection (LND) was performed in all patients. In 3 cases pathology reports on LN status were missing or inconclusive. Survival estimates were almost significantly diminished ($p = 0.07$) for LN positive patients and the prevalence of LNM was high at 42.4 %. Even after adjusting the short axis threshold to 5 mm, resulting in high sensitivity but low specificity for LNM, the LN

diameter proved to be a relevant but not reliable predictor. The detailed analysis of CT exams revealed four statistically significant imaging features: Presence of intrahepatic metastasis (CI 1.206 - 9.368; p = 0.020), hilar infiltration (CI 1.507 - 14.650; p = 0.008) and tumour outgrowth along the liver capsule (CI 1.665 - 27.984; p = 0.008). Of which the latter two might indicate direct tumor involvement with lymphatic liver structures. These four were integrated into a prediction model, which substantially outperformed the sole consideration of LN axis in ROC analysis (AUC 0.8 vs 0.657).

CONCLUSION

s LNM rates among patients suffering from iCC are high and worsen their prognosis. Predicting tumor positive LN in presurgical imaging remains a challenge, as evaluation of LN short axis alone appears insufficient. Based on four imaging features, we build a prediction model that proved enhanced discriminatory ability in LNM detection.

CLINICAL RELEVANCE/APPLICATION

LN short axis alone is an unreliable imaging marker for LNM in iCC. Our data emphasise the need for standardized LND, in patients with LN diameters greater than 5 mm.

W2-SPGI-5 Improving survival prediction with volumetric functional MRI and modified Fudan prognostic grading system for unresectable intrahepatic cholangiocarcinoma treated with systemic chemotherapy.

Participants
Alireza Mohseni, MD, Baltimore, MD (*Presenter*) Nothing to Disclose

PURPOSE

This study aimed to compare the incremental value of volumetric functional MRI-derived parameters to the Fudan clinical prognostic scoring system in patients with intrahepatic cholangiocarcinoma (ICCA) treated with systemic chemotherapy.

METHODS AND MATERIALS

This retrospective study included 114 patients with unresectable ICCA (age, 65±11 yrs; 53 men [47%]). Following baseline MRI, all patients received systemic chemotherapy. The single largest tumor was evaluated for anatomic (total tumor volume and maximum axial tumor diameter) and functional parameters (viable tumor volume, percentage viable tumor volume [100 × viable tumor volume/whole tumor volume], viable tumor burden [100 × viable tumor volume/whole liver volume], and apparent diffusion coefficient (ADC)). Based on previous research for the threshold of the venous enhancement parameter value, 40 was set as the lower limit of viability. For ADC, we used the cohort-derived median values as the threshold (1350 x 10-6 mm2/sec). The strongest functional predictor of overall survival (OS) was identified using Cox regression. Fudan Score (using serum alkaline phosphatase, carbohydrate antigen 19-9, tumor margin type, tumor size, and the number of intrahepatic tumors) and a modified Fudan Score (with functional MRI parameters replacing subjective tumor characteristics) were used to calculate prognostic scores for each patient. The performance of both scores was measured and compared by the C-index and Kaplan-Meier survival estimates in different risk groups.

RESULTS

Tumor ADC had the strongest association with OS among the volumetric functional MRI parameters. Both Fudan and modified Fudan scores (replacing tumor margin and diameter with ADC and percentage viable tumor volume) provided prognostic prediction, with differences in OS between low, intermediate, high, and very high-risk groups (Fudan, P=.041; modified Fudan, P=0.007). The modified Fudan score had a c-index of 0.75 (95% CI, 0.65-0.84) for predicting survival, which was higher than the C-index of the original Fudan score (0.63 [95% CI, 0.52-0.73]).

CONCLUSION

s The Fudan model was supplemented with ADC and percentage viable tumor volume to provide a more accurate prognosis for ICCA patients undergoing systemic chemotherapy, improving survival prediction performance by 12%.

CLINICAL RELEVANCE/APPLICATION

Results of this study suggest the prognostic role of functional MRI in assessing outcome of patients with ICCA. Supplementing Fudan score with ADC and percentage viable tumor volume could better predict survival of ICCA patients.

W2-SPGI-7 Demystifying the misty mesentery: when should we follow up?

Participants
Madusha Chandratilleke, MBBS, (*Presenter*) Nothing to Disclose

PURPOSE

"Misty mesentery" is a common incidental radiological finding. The benign spectrum of mesenteric panniculitis is well described, but currently no guidelines exist to guide the radiological management or follow up. The purpose of this retrospective study, was to ascertain which features, if any, are concerning about this common incidental finding and if/when this should be followed up with further imaging.

METHODS AND MATERIALS

Retrospective analysis was performed on 52 patients (derived from 500) who had findings of misty mesentery incidentally detected on a contrast enhanced CT scan. Any cases of mesenteric misting which had a clear cause such as trauma, infection or known malignancy were excluded. The incident study of each patient was read by two specialist abdominal Radiologists, who reached a consensus on each case and documented their findings according to an imaging checklist provided to them.

RESULTS

Of the 52 cases, 41 were reported as benign, 8 reported as indeterminate and 3 reported as concerning. The 41 benign cases and 8 indeterminate cases either resolved, improved, remained stable or progressively calcified over an average time period of 5 years.2 of the 'concerning' cases were later diagnosed as biopsy proven low grade follicular lymphoma, with an average time of disease progression being 2 years. The third 'concerning' case was biopsy proven sclerosing mesenteritis and had a unique radiological feature - calcification.Common features identified in both lymphoma cases: Mesenteric nodes 20 mm or larger, peritoneal nodes or mesenteric nodes outside the root of mesentery 20 mm or larger, retroperitoneal lymphadenopathy 10mm to gt 20 mm, obliteration

of ‘fat ring sign’.Follow up recommendations in the original reports were varied included ‘no follow up’, ‘a few months’, ‘3 months’, ‘3-6 months’, ‘6 months’, ‘6-9 months’, and ‘6-12 months’.

CONCLUSION

s If a contrast enhanced CT abdomen is reported by an abdominal imaging specialist, the sensitivity of detecting concerning ‘misty mesentery’ should be close to 100%. Features of benignity are established in the literature, however based on this particular study, we can now confidently state that in the absence of concerning imaging features, follow up of incidental ‘misty mesentery’ is not recommended. Conversely, if some or all of the radiographic features of concern are present, appearances may reflect low grade lymphoma, in which case a follow up scan could be performed in 12 months, or biopsy may be considered.

CLINICAL RELEVANCE/APPLICATION

These outcomes may alleviate patient and doctor anxiety regarding follow up recommendations and disease progression of mesenteric panniculitis and obviate unnecessary follow up imaging.

W2-SPGI-8 Towards structured reporting of universally detected and labeled lesions in CT volumes

Participants
Tejas Sudharshan Mathai, PhD, MS, (*Presenter*) Nothing to Disclose

PURPOSE

To use an automated deep learning-based model to universally detect and label lesions in CT volumes, and create a structured “Lesions” subsection for entry into the ‘Findings’ section of radiology reports.

METHODS AND MATERIALS

The publicly available DeepLesion dataset containing 32,735 lesions identified on 32,120 CT slices was used. An annotated 30% subset of this dataset (9816 lesions from 9624 slices) consisting of lesion bounding box coordinates and anatomical labels (e.g. liver, pelvis etc.) were used in this study. Subsequently, a deep learning model (VFNet) trained on this data yielded the bounding box coordinates, confidence scores, and anatomical labels of predicted lesions. Following this, a structured “Lesions” subsection was created for inclusion in the “Findings” section of a radiology report, and contained the following: 1) Lesion location coordinates (denoted by a hyperlink, which when clicked on, displayed the lesion coordinates on a CT slice), 2) anatomical label, 3) prediction confidence, 4) study and series names, and 5) slice index of volume.

RESULTS

The deep learning model detected and classified lesions with a sensitivities of 73.2%, 80%, and 83.3% at 2, 4, and 6 false positives (FP) per slice respectively. The model showed a recall (at 4 FP per slice) of 80% with the following class-wise breakdown: lung nodule (89%), mediastinal LN (85%), liver mass (81%), kidney (80%), soft tissue (77%), pelvic mass (76%), abdomen (70%), and bone (56%). As seen in Figs. 1A and 1B, classes with fewer samples (e.g. `Bone`) fared poorly compared with over-represented classes (e.g. `Lung`). When lesions were divided by their size (= 1cm, clinically suspicious), the sensitivity at 4FP improved for classes with large data quantities (abdomen, mediastinum, liver). Qualitative evaluation revealed that many FP detections were true positives that were not labeled in the dataset, which reduced the overall sensitivity. A structured “Lesions” subsection was created for entry into the “Findings” section of a radiology report (see Fig. 1C-E).

CONCLUSION

s The presented approach universally detected and labeled lesions with 80% sensitivity at 4FP, while identifying important missed lesions in the original DeepLesion dataset. A structured “Lesion” subsection was created for entry into the “Findings” section of a radiology report.

CLINICAL RELEVANCE/APPLICATION

Radiologists assessing cancer burden and managing patient therapy will benefit from a “second reader” AI model that reports a structured list of suspicious lesions in the “Findings” section.

W2-SPGI-9 Diffusion tensor imaging and diffusion kurtosis imaging of the pancreas at 3 Tesla MRI - reproducibility and normal findings

Participants
Carlos Bilreiro, MD, Lisbon, Portugal (*Presenter*) Nothing to Disclose

PURPOSE

To assess the reproducibility of diffusion tensor imaging (DTI) and diffusion kurtosis imaging (DKI) of the pancreas at 3T MRI, and to describe the normal findings in a healthy population.

METHODS AND MATERIALS

In this Institutional Review Board-approved prospective pilot study, healthy volunteers underwent two repeated sessions of abdominal MRI in a clinical 3T scanner, performing both DTI and DKI of the pancreas in each session. In each imaging session, a single acquisition of spin-echo echo-planar imaging (EPI) was performed, with 6 slices encompassing the entire pancreas, using 16 evenly distributed diffusion directions for b values of 0, 200, 1000 and 1700 s/mm2. The acquired data were pre-processed with denoising (Marchenko-Pastur principal component analysis) and Gibbs unringing algorithms. DTI analysis was performed for producing fractional anisotropy (FA) maps. DKI using the mean signal from all directions was used to calculate mean diffusivity (MD) and mean kurtosis (MK) maps. Standard apparent diffusion coefficient (ADC) maps were also produced. Two dedicated abdominal radiologists delineated the entire pancreas in each image, and the values measured for the pancreatic parenchyma were registered and compared.

RESULTS

Ten volunteers (aged 30-60 years, 6 females and 4 males) underwent both imaging sessions. For all volunteers, the measurements performed on the pancreatic parenchyma revealed: median MK = 1.01 (IQR: 0.52); median MD = 2.44x10-3 (IQR: 1.61x10-3) mm2/s; median FA = 0.21 (IQR: 0.11); median ADC = 1.12x10-3 (IQR: 0.27x10-3) mm2/s. There was no significant variability in FA, MD, MK and ADC measurements within different sessions for each volunteer, determining intra-patient reproducibility. Values

obtained between different volunteers were also not significantly different, suggesting inter-patient reproducibility. Regarding inter-reader reliability, there was good agreement between both radiologists.

CONCLUSION

s DTI and DKI of the pancreas can be performed reliably with a single acquisition at clinical 3T MRI scanners, with adequate intra-patient and inter-patient reproducibility.

CLINICAL RELEVANCE/APPLICATION

This study describes the findings in healthy subjects when performing DTI and DKI of the pancreas and determines their reproducibility, both critical steps for its implementation in clinical practice

Accelerated liver diffusion-weighted imaging with a deep learning-based reconstruction: Evaluation of image quality and performance for focal lesion detection in comparison with conventional diffusion-weighted imaging

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - GI DPS

Participants
Bohyun Kim, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To assess image quality and performance for focal liver lesion (FLL) detection of an accelerated liver diffusion-weighted image with deep learning-based image reconstruction (DL-DWI) compared with conventional DWI (C-DWI) at 3T.

METHODS AND MATERIALS

This retrospective study assessed 102 patients who underwent respiratory-triggered DL-DWI and C-DWI using matched b-values (100, 800, 1000 s/mm2) and resolution (2.7 x 2.7 x 5 mm3) at 3T (MAGNETOM Vida; Siemens Healthcare). DL-DWI used the number of average of 1/1/1 for each b-value and a parallel imaging factor of 4, while those for C-DWI were 1/2/2 and 3, respectively. Two radiologists scored image qualities and measured apparent diffusion coefficient (ADC) values, signal intensity (SI), and signal-to-noise ratio (SI/SD) of two DWI (b = 1000 s/mm2) sets. For FLLs, conspicuity and margin sharpness scores, numbers, SI, and lesion-to-liver contrast [(SIlesion-SIliver)/(SIlesion+SIliver)] were assessed. Wilcoxon signed-rank test, Student t-test, and ? statistics evaluated differences and agreements.

RESULTS

DL-DWI reduced median acquisition time by 20% to C-DWI (391 s vs. 482 s; $p < 0.001$). DL-DWI received significantly higher scores for image noise and respiratory motion artifact (ps < 0.001), comparable scores for overall image quality, but lower scores for cardiac motion artifact ($p < 0.001$) in both readers (?, 0.35-0.63). ADC values were more homogeneous in DL-DWI, indicated by lesser variance in measurements and smaller SD across liver segments ($p < 0.021$). DL-DWI showed significantly higher SI (110.1 vs. 80.6; $p < 0.001$) and SNR (15.07 vs. 9.21; $p < 0.001$). FLLs were more conspicuous on DL-DWI ($p < 0.019$), with significantly higher SI (245 vs. 193.7; $p < 0.001$) and comparable lesion-to-liver contrast (0.41 vs. 0.39; $p = 0.137$). Lesser number of FLLs was detected in DL-DWI (130 vs. 148 and 138 vs. 147), though both readers identified a similar number of malignant FLLs (74/86 vs. 80/86 and 76/86 vs. 82/86, ps < 0.099). The mean size of the FLL missed or invisible on DL-DWI was 0.6 cm (range, 0.3-2.3) and frequently located near the capsule (9/15; 60%), with the largest lesion at S2.

CONCLUSION

s DL-DWI provided lower image noise, reduced motion artifact, homogeneous ADC values, and higher liver parenchymal SI within a significantly shorter time. Despite superior conspicuity and higher SI for FLL with DL-DWI, small lesions near the capsule or S2 tended to be missed/invisible, underlined by the lower score for cardiac motion artifact. This might attribute to protocol setting and suggests a corresponding refinement as future work.

CLINICAL RELEVANCE/APPLICATION

DL-DWI showed reduced image noise, better FLL conspicuity, and substantially higher liver parenchymal SI acquired within a 20% shorter scan time than C-DWI.

W2-SPGI-2

Diagnostic performance of two kinds of abbreviated gadoxetic acid-enhanced MR protocols for the detection of colorectal liver metastases

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - GI DPS

Participants
Kumi Ozaki, MD, PhD, Fukui, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To compare the diagnostic performance of two kinds of abbreviated enhanced magnetic resonance imaging (Ab-MRI) protocols with the standard MRI protocol for the detection of colorectal liver metastases.

METHODS AND MATERIALS

The study participants were 87 patients (51 males, 36 females; mean age, 67.2 ± 10.8 years) who had undergone gadoxetic acid-enhanced MRI during the initial work-up for colorectal cancer from 2010 to 2021. All exams were independently reviewed by two readers in three reading sessions: (1) only single-shot fast spin echo (FSE) T2-weighted or fat-suppressed-FSE-T2-weighted, diffusion-weighted, and hepatobiliary phase images (Ab-MRI protocol 1 or 2), and (2) all acquired MRI sequences (standard protocol). The diagnostic performance was then statistically analyzed.

RESULTS

A total of 380 lesions, including 195 metastases (51.4%), were analyzed. The results of the two Ab-MRI protocols were similar. The sensitivity, specificity, and positive and negative predictive values of Ab-MRI were non-inferior to those of standard MRI ($p > 0.05$), while those of the combination of Ab-MRI protocol and CE-CT were higher than those of Ab-MRI alone, although not significantly different ($p > 0.05$), and were quite similar to those of standard MRI ($p > 0.05$).

CONCLUSION

s The diagnostic performance of both two kinds of Ab-MRI protocols was non-inferior to that of the standard protocol.

CLINICAL RELEVANCE/APPLICATION

The diagnostic performance of both two kinds of abbreviated MRI protocols was non-inferior to that of the standard protocol for the detection of colorectal liver metastases.

Study on biological activity of hepatic alveolar echinococcus by multimodal MR imaging combined with serum circulating free DNA .

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - GI DPS

Participants
Hai Hua Bao, Xining, China (*Presenter*) Nothing to Disclose

PURPOSE

Hepatic alveolar echinococcosis (HAE) grows aggressively in the liver, and its growth characteristics are important for diagnosis and treatment. In this study, the biological activity of hepatic alveolar echinococcosis was studied by multi-mode MR imaging combined with circulating free DNA(cfDNA) in serum.

METHODS AND MATERIALS

Seventy-two patients with HAE diagnosed clinically from August 2018 to January 2019 were included in the study. Serum cfDNA was detected before MRI. The examination equipment is a 3.0 T MRI scanner. The scanning sequence includes MRI plain scan and dynamic contrast examination, DWI and MRCP water imaging sequence; MRI evaluation first defines the location, size and imaging type of the lesion; The evaluation indexes of activity include the range of high signal band of DWI images(marginal band), microbubbles and enhancement characteristics.The marginal zone, microbubbles and ADC values were measured by T2WI, MRCP and DWI sequences (b = 800 mm/s) to further evaluate the biological activity of the lesions. The correlation between the size, imaging type of lesions and serum cfDNA was analyzed.

RESULTS

1. Lesions characteristics: there were 92 lesions in 72 patients with HAE, including 16 lesions < 5 cm, 36 lesions >5-10 cm and 40 lesions >10cm. Imaging types of lesions: solid type 51 cases, liquefied type 7 cases, multiple nodular type 4 cases, mixed type 4 cases and calcified type 6 cases. 2. Evaluation of lesion activity: 49 lesions (53.3%) showed mild annular enhancement in portal vein phase after dynamic contrast-enhanced scanning; On DWI images, 87 lesions had high signal intensity (marginal zone) with limited diffusion, while 5 calcified lesions had no obvious marginal zone. The width of the band is between (0.28 ~ 0.98) cm; The average ADC value is about (1.10±0.17) × $10^{-3}mm^2/s$ measured at 0.5cm in the marginal zone. Average ADC value of microbubbles is about (0.79±0.16) × $10^{-3}mm^2/s$; Compared with ADC, the difference was statistically significant ($P < 0.05$). 3. Correlation between the size and classification of lesions and cfDNA: The cfDNA range of lesions with HAE=10cm is (98 ~ 11770) ng/ml, which is higher than that of small lesions (0 ~ 98 ng/ml), and the correlation between them is statistically different ($r=0.482$, $P = 0.000$); cfDNA was found in all types, with calcified DNA being the lowest (0 ~ 2 ng/ml) and solid's DNA being the highest (0 ~ 11770 ng/ml).

CONCLUSION

s cfDNA is related to the size, imaging type and activity of HAE lesions, and MRI combined with cfDNA can better evaluate the biological activity of HAE lesions.

CLINICAL RELEVANCE/APPLICATION

MRI combined with cfDNA can better evaluate the biological activity of HAE lesions.

Detection of Lymph Node Metastases in Intrehepatic Cholangiocarcinoma - an Ongoing Challenge

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - GI DPS

Participants
Johannes Kolck, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Objectives of the present study were to investigate the predictive value of the short lymph node (LN) axis, a widely recognised discriminator for lymph node metastases (LNM) in tumor imaging, and to develop a predictive model for LNM in iCC based on multiple CT imaging features.

METHODS AND MATERIALS

Retrospectively enrolled were 102 patients with pathologically proven mass-forming iCC, who underwent multiphase CT imaging prior to and standardised lymph node dissection during resection from 2005 to 2021. Two blinded radiologists assessed various quantitative and qualitative imaging characteristics. These were implemented to develop a prediction model for lymph node metastasis.

RESULTS

Lymph node dissection (LND) was performed in all patients. In 3 cases pathology reports on LN status were missing or inconclusive. Survival estimates were almost significantly diminished ($p = 0.07$) for LN positive patients and the prevalence of LNM was high at 42.4 %. Even after adjusting the short axis threshold to 5 mm, resulting in high sensitivity but low specificity for LNM, the LN diameter proved to be a relevant but not reliable predictor. The detailed analysis of CT exams revealed four statistically significant imaging features: Presence of intrahepatic metastasis (CI 1.206 - 9.368; $p = 0.020$), hilar infiltration (CI 1.507 - 14.650; $p = 0.008$) and tumour outgrowth along the liver capsule (CI 1.665 - 27.984; $p = 0.008$). Of which the latter two might indicate direct tumor involvement with lymphatic liver structures. These four were integrated into a prediction model, which substantially outperformed the sole consideration of LN axis in ROC analysis (AUC 0.8 vs 0.657).

CONCLUSION

s LNM rates among patients suffering from iCC are high and worsen their prognosis. Predicting tumor positive LN in presurgical imaging remains a challenge, as evaluation of LN short axis alone appears insufficient. Based on four imaging features, we build a prediction model that proved enhanced discriminatory ability in LNM detection.

CLINICAL RELEVANCE/APPLICATION

LN short axis alone is an unreliable imaging marker for LNM in iCC. Our data emphasise the need for standardized LND, in patients with LN diameters greater than 5 mm.

W2-SPGI-5

Improving survival prediction with volumetric functional MRI and modified Fudan prognostic grading system for unresectable intrahepatic cholangiocarcinoma treated with systemic chemotherapy.

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - GI DPS

Participants
Alireza Mohseni, MD, Baltimore, MD (*Presenter*) Nothing to Disclose

PURPOSE

This study aimed to compare the incremental value of volumetric functional MRI-derived parameters to the Fudan clinical prognostic scoring system in patients with intrahepatic cholangiocarcinoma (ICCA) treated with systemic chemotherapy.

METHODS AND MATERIALS

This retrospective study included 114 patients with unresectable ICCA (age, 65±11 yrs; 53 men [47%]). Following baseline MRI, all patients received systemic chemotherapy. The single largest tumor was evaluated for anatomic (total tumor volume and maximum axial tumor diameter) and functional parameters (viable tumor volume, percentage viable tumor volume [100 × viable tumor volume/whole tumor volume], viable tumor burden [100 × viable tumor volume/whole liver volume], and apparent diffusion coefficient (ADC)). Based on previous research for the threshold of the venous enhancement parameter value, 40 was set as the lower limit of viability. For ADC, we used the cohort-derived median values as the threshold (1350 x 10-6 mm2/sec). The strongest functional predictor of overall survival (OS) was identified using Cox regression. Fudan Score (using serum alkaline phosphatase, carbohydrate antigen 19-9, tumor margin type, tumor size, and the number of intrahepatic tumors) and a modified Fudan Score (with functional MRI parameters replacing subjective tumor characteristics) were used to calculate prognostic scores for each patient. The performance of both scores was measured and compared by the C-index and Kaplan-Meier survival estimates in different risk groups.

RESULTS

Tumor ADC had the strongest association with OS among the volumetric functional MRI parameters. Both Fudan and modified Fudan scores (replacing tumor margin and diameter with ADC and percentage viable tumor volume) provided prognostic prediction, with differences in OS between low, intermediate, high, and very high-risk groups (Fudan, P=.041; modified Fudan, P=0.007). The modified Fudan score had a c-index of 0.75 (95% CI, 0.65-0.84) for predicting survival, which was higher than the C-index of the original Fudan score (0.63 [95% CI, 0.52-0.73]).

CONCLUSION

s The Fudan model was supplemented with ADC and percentage viable tumor volume to provide a more accurate prognosis for ICCA patients undergoing systemic chemotherapy, improving survival prediction performance by 12%.

CLINICAL RELEVANCE/APPLICATION

Results of this study suggest the prognostic role of functional MRI in assessing outcome of patients with ICCA. Supplementing Fudan score with ADC and percentage viable tumor volume could better predict survival of ICCA patients.

W2-SPGI-7

Demystifying the misty mesentery: when should we follow up?

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - GI DPS

Participants
Madusha Chandratilleke, MBBS, (*Presenter*) Nothing to Disclose

PURPOSE

"Misty mesentery" is a common incidental radiological finding. The benign spectrum of mesenteric panniculitis is well described, but currently no guidelines exist to guide the radiological management or follow up. The purpose of this retrospective study, was to ascertain which features, if any, are concerning about this common incidental finding and if/when this should be followed up with further imaging.

METHODS AND MATERIALS

Retrospective analysis was performed on 52 patients (derived from 500) who had findings of misty mesentery incidentally detected on a contrast enhanced CT scan. Any cases of mesenteric misting which had a clear cause such as trauma, infection or known malignancy were excluded. The incident study of each patient was read by two specialist abdominal Radiologists, who reached a consensus on each case and documented their findings according to an imaging checklist provided to them.

RESULTS

Of the 52 cases, 41 were reported as benign, 8 reported as indeterminate and 3 reported as concerning. The 41 benign cases and 8 indeterminate cases either resolved, improved, remained stable or progressively calcified over an average time period of 5 years.2 of the 'concerning' cases were later diagnosed as biopsy proven low grade follicular lymphoma, with an average time of disease progression being 2 years. The third 'concerning' case was biopsy proven sclerosing mesenteritis and had a unique radiological feature - calcification.Common features identified in both lymphoma cases: Mesenteric nodes 20 mm or larger, peritoneal nodes or mesenteric nodes outside the root of mesentery 20 mm or larger, retroperitoneal lymphadenopathy 10mm to gt 20 mm, obliteration of 'fat ring sign'.Follow up recommendations in the original reports were varied included 'no follow up', 'a few months', '3 months', '3-6 months', '6 months', '6-9 months', and '6-12 months'.

CONCLUSION

s If a contrast enhanced CT abdomen is reported by an abdominal imaging specialist, the sensitivity of detecting concerning 'misty mesentery' should be close to 100%. Features of benignity are established in the literature, however based on this particular study, we can now confidently state that in the absence of concerning imaging features, follow up of incidental 'misty mesentery' is not recommended. Conversely, if some or all of the radiographic features of concern are present, appearances may reflect low grade lymphoma, in which case a follow up scan could be performed in 12 months, or biopsy may be considered.

CLINICAL RELEVANCE/APPLICATION

These outcomes may alleviate patient and doctor anxiety regarding follow up recommendations and disease progression of mesenteric panniculitis and obviate unnecessary follow up imaging.

W2-SPGI-8

Towards structured reporting of universally detected and labeled lesions in CT volumes

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - GI DPS

Participants
Tejas Sudharshan Mathai, PhD, MS, (*Presenter*) Nothing to Disclose

PURPOSE

To use an automated deep learning-based model to universally detect and label lesions in CT volumes, and create a structured "Lesions" subsection for entry into the 'Findings' section of radiology reports.

METHODS AND MATERIALS

The publicly available DeepLesion dataset containing 32,735 lesions identified on 32,120 CT slices was used. An annotated 30% subset of this dataset (9816 lesions from 9624 slices) consisting of lesion bounding box coordinates and anatomical labels (e.g. liver, pelvis etc.) were used in this study. Subsequently, a deep learning model (VFNet) trained on this data yielded the bounding box coordinates, confidence scores, and anatomical labels of predicted lesions. Following this, a structured "Lesions" subsection was created for inclusion in the "Findings" section of a radiology report, and contained the following: 1) Lesion location coordinates (denoted by a hyperlink, which when clicked on, displayed the lesion coordinates on a CT slice), 2) anatomical label, 3) prediction confidence, 4) study and series names, and 5) slice index of volume.

RESULTS

The deep learning model detected and classified lesions with a sensitivities of 73.2%, 80%, and 83.3% at 2, 4, and 6 false positives (FP) per slice respectively. The model showed a recall (at 4 FP per slice) of 80% with the following class-wise breakdown: lung nodule (89%), mediastinal LN (85%), liver mass (81%), kidney (80%), soft tissue (77%), pelvic mass (76%), abdomen (70%), and bone (56%). As seen in Figs. 1A and 1B, classes with fewer samples (e.g. `Bone`) fared poorly compared with over-represented classes (e.g. `Lung`). When lesions were divided by their size (= 1cm, clinically suspicious), the sensitivity at 4FP improved for classes with large data quantities (abdomen, mediastinum, liver). Qualitative evaluation revealed that many FP detections were true positives that were not labeled in the dataset, which reduced the overall sensitivity. A structured "Lesions" subsection was created for entry into the "Findings" section of a radiology report (see Fig. 1C-E).

CONCLUSION

s The presented approach universally detected and labeled lesions with 80% sensitivity at 4FP, while identifying important missed lesions in the original DeepLesion dataset. A structured "Lesion" subsection was created for entry into the "Findings" section of a radiology report.

CLINICAL RELEVANCE/APPLICATION

Radiologists assessing cancer burden and managing patient therapy will benefit from a "second reader" AI model that reports a structured list of suspicious lesions in the "Findings" section.

W2-SPGI-9

Diffusion tensor imaging and diffusion kurtosis imaging of the pancreas at 3 Tesla MRI - reproducibility and normal findings

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - GI DPS

Participants
Carlos Bilreiro, MD, Lisbon, Portugal (*Presenter*) Nothing to Disclose

PURPOSE

To assess the reproducibility of diffusion tensor imaging (DTI) and diffusion kurtosis imaging (DKI) of the pancreas at 3T MRI, and to describe the normal findings in a healthy population.

METHODS AND MATERIALS

In this Institutional Review Board-approved prospective pilot study, healthy volunteers underwent two repeated sessions of abdominal MRI in a clinical 3T scanner, performing both DTI and DKI of the pancreas in each session. In each imaging session, a single acquisition of spin-echo echo-planar imaging (EPI) was performed, with 6 slices encompassing the entire pancreas, using 16 evenly distributed diffusion directions for b values of 0, 200, 1000 and 1700 s/mm2. The acquired data were pre-processed with denoising (Marchenko-Pastur principal component analysis) and Gibbs unringing algorithms. DTI analysis was performed for producing fractional anisotropy (FA) maps. DKI using the mean signal from all directions was used to calculate mean diffusivity (MD) and mean kurtosis (MK) maps. Standard apparent diffusion coefficient (ADC) maps were also produced. Two dedicated abdominal radiologists delineated the entire pancreas in each image, and the values measured for the pancreatic parenchyma were registered and compared.

RESULTS

Ten volunteers (aged 30-60 years, 6 females and 4 males) underwent both imaging sessions. For all volunteers, the measurements performed on the pancreatic parenchyma revealed: median MK = 1.01 (IQR: 0.52); median MD = 2.44x10-3 (IQR: 1.61x10-3) mm2/s; median FA = 0.21 (IQR: 0.11); median ADC = 1.12x10-3 (IQR: 0.27x10-3) mm2/s. There was no significant variability in FA, MD, MK and ADC measurements within different sessions for each volunteer, determining intra-patient reproducibility. Values obtained between different volunteers were also not significantly different, suggesting inter-patient reproducibility. Regarding inter-reader reliability, there was good agreement between both radiologists.

CONCLUSION

s DTI and DKI of the pancreas can be performed reliably with a single acquisition at clinical 3T MRI scanners, with adequate intra-patient and inter-patient reproducibility.

CLINICAL RELEVANCE/APPLICATION

This study describes the findings in healthy subjects when performing DTI and DKI of the pancreas and determines their reproducibility, both critical steps for its implementation in clinical practice

Genitourinary Wednesday Poster Discussions

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - GU DPS

Sub-Events

W2-SPGU-1 The Role of Magnetic Resonance Imaging in Prostate Cancer Screening: Does it Perform Better than the Prostate-specific Antigen Test?

Participants
Taekmin Kim, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To compare the performance of biparametric prostate magnetic resonance imaging (bpMRI) and prostate-specific antigen (PSA) testing as screening tests in a large paired-cohort study.

METHODS AND MATERIALS

We retrospectively reviewed 1,793 men who underwent both bpMRI and PSA testing for prostate cancer screening from January 2018 to June 2021. If PSA level was =3 ng/mL, or prostate cancer was suspected based on bpMRI, urology consultation was requested. We compared the proportion of men with positive MRI (PI-RADS 3-5 or 4-5) or PSA tests (=3 ng/mL). The cancer detection rates, false positive rates, and positive predictive values (calculated from all screening-positive cases [PPV1] or biopsied cases [PPV2]) were compared between two screening tests.

RESULTS

The proportion of the positive PSA test (150/1793, 8.4%; 95% CI 7.1-9.8%) was significantly higher than that of positive MRI results (PI-RADS 3-5, 62/1793, 3.5%; 2.7-4.5% and PI-RADS 4-5, 41/1793, 2.3%; 1.7-3.2%, P<0.001). The cancer detection rates were similar between two tests (1.1% in PI-RADS 3-5, PI-RADS 4-5, and PSA). The false positive rate was significantly higher in PSA test (7.4%) than those of PI-RADS 3-5 and 4-5 (2.4% and 1.2%, respectively, P<0.05). The positive predictive values (PPVs) were significantly lower in PSA test (PPV1, 12.7%; PPV2, 36.5%) than that in PI-RADS 3-5 (PPV1 32.3%, PPV2 58.8%) or PI-RADS 4-5 (PPV1, 46.3%; PPV2, 87.5%, P<0.001 for all).

CONCLUSION

s MRI-based screening may reduce the number of patients recommended for biopsy without increasing the risk of underdiagnosis than PSA-base screening.

CLINICAL RELEVANCE/APPLICATION

PSA-based screening has been used for prostate cancer screening, but the evidence of the benefits and harms is still controversial. MRI-based screening showed lower proportions of screening-positive cases, lower false positive rates, and higher PPVs than those of PSA-based screening.

W2-SPGU-2 Differentiation Clear Cell Renal Cell Carcinoma from Other Common Malignant and Benign Renal Masses on Multiphasic MRI: A Likert Based Multireader Analysis

Participants
Ali Bassir, MD, Los Angeles, CA (*Presenter*) Nothing to Disclose

PURPOSE

To determine the diagnostic performance and the interreader agreement of the Kidney MR score (KMRS) in differentiating benign and malignant lesions and clear cell renal cell carcinoma (ccRCC) from other common lesions on multiphasic magnetic resonance imaging (MRI).

METHODS AND MATERIALS

With IRB approval and HIPAA compliance, the study cohort comprised 178 patients with 191 pathologically proven and 11 stable, fatty renal masses (142 malignant, 54 benign, and 6 uncertain malignant potential). After training on 5 non study cases, four abdominal radiologists and four abdominal radiology fellows independently interpreted the study cohort and assigned a KMRS to each lesion on a 5-point scale to indicate the probability of benignity, malignancy, and ccRCC, blinded to clinical data. The MRS included both quantitative and qualitative features and ancillary findings to adjust the final score.

RESULTS

In distinguishing malignant from benign lesions, a KMRS = 4 had a median sensitivity, specificity, and AUC of 87.5% (83.8-94.6%), 69.5% (64.8-77.8%), and 0.79 (0.77-0.89), respectively. The median sensitivity and specificity of the KMRS = 2 in diagnosing benignity were 33.4% (31.5-40.7%) and 95.6% (93.9-99.3%), respectively. A KMRS of 5 had a median sensitivity, specificity, and AUC of 72.3% (65.4-78.3%), 87.0% (84.9-91.6%) and 0.82 (0.77-0.88), respectively for diagnosing ccRCC. The interreader

agreement (kappa (?) score) was 0.59-0.82.

CONCLUSION

s The KMRS had relatively high performance for diagnosing malignant from benign T1 lesions and ccRCC from all other T1 lesions with good to excellent interreader agreement.

CLINICAL RELEVANCE/APPLICATION

With further validation and refinement, it may become useful in routine clinical practice especially if augmented by artificial intelligence techniques to confidently diagnose renal lesions, with judicious use of alternative imaging techniques and renal mass biopsy to accurately triage patients to no further intervention, active surveillance, ablation, radiation or surgery.

W2-SPGU-3 Artifact severity due to total hip replacement in 1.5T and 3T MRI of the prostate

Participants
Matthias Boschheidgen, Dusseldorf, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate image quality and diagnostic value of multiparametric MRI (mpMRI) of the prostate in patients with total hip replacement (THR) at 1.5 and 3 Tesla.

METHODS AND MATERIALS

In this retrospective multicenter cohort study patients with uni- or bilateral THR and 1.5T or 3T mpMRI were included. Seventy consecutive, standard-of-care examinations per field strength were evaluated regarding their diagnostic value. The overall diagnostic value and prostate imaging quality score (PI-Qual) were assessed. Artifact severity in the localizer and mpMRI sequences (T2w, DWI, DCE) was scored on a 3-point-scale. Correlation between diagnostic value and artifacts was analysed. Moreover, a subgroup analysis focussed on image quality at different 3T scanner generations.

RESULTS

140 consecutive patients (mean age 72, median PSA value 8.3 ng/ml) were included. When comparing 1.5T to 3T examinations, no significant differences were observed regarding the artifact severity of DWI and the localizer and the overall diagnostic value of the images. There was a strong correlation between the diagnostic value, PI-Qual score, and artifact severity in the localizer and DWI ($t > 0.85$). T2 und DCE sequences showed overall low artifacts. Significant improvement in image quality for 3T at the latest scanner generation was observed, especially for DWI ($p < 0.03$).

CONCLUSION

s MpMRI of patients with THR can be conducted at both field strengths without significant differences in artifacts. The localizer is useful as an early forecasting feature for diagnostic value and particularly might be useful for contrast medium application decision. Patients with THR benefited from latest scanner generation and new DWI sequences.

CLINICAL RELEVANCE/APPLICATION

Patients with hip replacements showed similar artifact severity at 1,5T and 3T scanners for prostate MRI examinations. Technicians can predict the extent of artifacts in the localizer already allowing an adjustment of the MRI parameters to receive the highest quality level achievable and DCE sequences should not be omitted in any cases with expected artifacts. For 3T latest scanner generations and newest DWI sequences showed reduced artifacts related to total hip replacement.

Sub-Events

W2-SPHN-2 Is Qualitative Ultrasound Elastography Useful for Predicting Tumor Resectability in Locally Advanced Head and Neck Cancer?

Participants
Paul B. DiDomenico, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Assessment of tumor involvement of the carotid sheath is important for surgical planning in head and neck cancer. Invasion of the carotid artery is a contraindication to surgery while invasion of other components of the carotid sheath is not. We investigated whether ultrasound elastography of the tumor and peri-tumoral tissues provides useful information for staging and prediction of tumor resectability.

METHODS AND MATERIALS

We conducted an IRB-approved prospective study of 27 patients with head and neck cancers to determine if tumor resectability could be accurately predicted by qualitative Ultrasound elastography of the tumor and through visualization of a separating fat plane between the tumor and structures within carotid sheath, in particular the carotid artery. Patients' elastogram images were independently interpreted by two board-certified Radiologists. We evaluated the images using a risk-stratification scoring system that combined evaluation of the qualitative elastogram with measured distance between the tumor and carotid artery. Inter-observer agreement was evaluated using the weighted Kappa statistic. Imaging findings were compared to either surgical or clinical staging information using Receiver Operating Characteristic (ROC)-Area Under the Curve (AUC) analysis.

RESULTS

The weighted Kappa statistic for the combined qualitative and ordinal distance stratification scores was 0.49. The highest agreement of 0.68 was found for evaluation of the qualitative elastography images. Fifteen of 27 patients had neck dissection surgery which provided information on local tumor invasion, and the remaining 12 patients were staged through a combination of clinical and other imaging information such as neck CT. One of two readers attained a statistically significant AUC of 0.77 (95% CI 0.59-0.95, p=0.04) for the elastogram only. The best-performing model combined the elastogram findings with the binary observation of a fat plane separating the tumor from the carotid artery (AUC of 0.84, 95% CI 0.69-0.99, p=0.006), which was equal or superior to visualization of a fat plane alone for both readers.

CONCLUSION

s We evaluated the utility of ultrasound elastography for determining carotid artery invasion in head and neck cancer. There was good agreement between two Radiologists with general ultrasound skills, and one attained a statistically significant result with ROC-AUC analysis indicating good accuracy. Ultrasound elastography may serve as a useful adjunct for tumor staging and pre-surgical planning in head and neck cancer.

CLINICAL RELEVANCE/APPLICATION

Qualitative Ultrasound elastography may be a useful for pre-surgical planning in head and neck cancer, as an adjunct to clinical and other imaging findings.

W2-SPHN-3 Assessment of Tumor Burden and Response by RECIST vs Volume Change in HPV+ Oropharyngeal Cancer: An Exploratory Analysis of Prospective Trials

Participants
Muzamil Arshad, MD, PhD, Romeoville, IL (*Presenter*) Nothing to Disclose

PURPOSE

Using HPV+ oropharyngeal carcinoma as a tumor model, we report a comparison of RECIST and volumetric measurements from 2 consecutive prospective trials of response-adaptive de-escalation of therapy.

METHODS AND MATERIALS

Patients enrolled on 2 prospective phase II response adapted de-escalation trials for HPV+ oropharynx cancer were included in the analysis. Target lesions were initially assessed using RECIST 1.1 at baseline and post-induction therapy; patients with > 50% response by RECIST received de-escalated treatment. Primary tumors and nodes were retrospectively delineated on diagnostic scans before and after induction therapy to ascertain volumetric tumor burden and response. Mean differences in RECIST and volume were evaluated with paired t-tests. Linear regression and chi-squared analysis were used to evaluate the correlation between percent change in tumor burden as well as de-escalation-concordance. Analysis was thus done to identify proportion that responded 50% by volume.

RESULTS

104 patients were evaluable. The mean post-induction therapy reduction in RECIST and volumetry was 3.13 cm and 25.18 cm3 respectively. Primary tumor response to induction was greater than nodal response for both RECIST and volumetry. The mean percent difference in size post induction was 27.3% and 14.8% for RECIST and volumetry. Percent change in RECIST was correlated with volume change, r = 0.687 ($p<0.001$). An increased proportion ($p=0.008$) of patients would be eligible for de-escalation based on response assessment (72% de-escalated by RECIST vs 89% by volumetry), and 4% (N=4) of patients who were de-escalated by RECIST would not meet criteria for de-escalation by volumetry. 2 of these 4 patients developed a local failure.

CONCLUSION

s While volumetry was correlated with RECIST, a large proportion of variance in volume-based measurements was not accounted for by RECIST. Patients that responded by RECIST but not volume had higher rates of local failure. A higher proportion of patients met response criteria by volume and could have been considered for de-escalation.

CLINICAL RELEVANCE/APPLICATION

A volume based approach was found to have less variance and greater sensitivity to identify responders as compared with traditional RECIST response measurements

Sub-Events

W2-SPIN-2 Segmentation of Post-Treatment Glioblastoma Tissue Types and Resection Cavities

Participants
Saif Baig, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Adjuvant radiation therapy is critical to the management of glioblastoma, yet contouring post-surgical residual tumor and resection cavities is a laborious and time-intensive manual process. Fully automated segmentation of glioma volumes could reduce inter-rater variability and increase workflow efficiency for both radiation planning and routine longitudinal radiographic assessment. We sought to evaluate whether a 3D neural network would be comparable to expert manual contouring of post-operative glioblastoma tissue types and resection cavities.

METHODS AND MATERIALS

A retrospective cohort of 251 MRIs of patients with glioblastoma (average 56.8 years, 56% female) from several publicly available datasets at The Cancer Imaging Archive (TCIA), were randomly selected into training (176) and testing (75) samples. All patients had undergone surgery with a median 237 days from surgery (range 0-1368) and most had undergone adjuvant chemoradiation. T1, T1-post contrast, T2 and FLAIR images were registered, skull stripped and interpolated to 1x1x1. Four post-treatment tissue classes, consisting of edema/infiltrative tissue (ED), enhancing tissue (ET), necrotic core (NCR) and resection cavities (RC) were manually segmented by an expert neuroradiologist. The nnU-Net, a state-of-the-art 3D U-Net convolutional neural network was trained to predict the multiclass predictions using the four modalities as multichannel input.

RESULTS

Segmentation performance in the test set for the ED, ET and RC classes were at the level of inter-rater expert human reliability, as measured by Dice scores, which ranged from from 0.79 to 0.89; volume similarities that ranged from 0.90 to 0.95; and Hausdorff distance metrics, which ranged from 4 to 6 mm. There was a near perfect correlation between manually segmented total lesion volumes (Pearson r = 0.99).

CONCLUSION

s 3D convolutional neural networks were able to segment and quantify post treatment glioma tissue volumes, consisting of edema/infiltrative tissue, enhancing tissue, necrotic core, and resection cavities, with high accuracy.

CLINICAL RELEVANCE/APPLICATION

The results of this study support the potential clinical value of artificial-intelligence-based automated volumetric quantification of post-treatment diffuse glioma tissue volumes.

W2-SPIN-3 Measuring FEV1 from Preoperative Chest Computed Tomography Scans using Deep Learning

Participants
Ji-eun Oh, PhD, Goyang-si, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the feasibility of generating deep learning-based FEV1 measurements from preoperative chest computed tomography (CT) scans.

METHODS AND MATERIALS

We collected 565 preoperative chest CT scans and FEV1 values performed on subjects undergoing lung cancer surgery between 2009 and 2015. FEV1 values were between 0.81 and 4.86 with mean 2.52 and standard deviation 0.63. All scans were resized to the median voxel size of our entire dataset (2.5x0.668x0.668 mm) and all axial slices were padded to 672x672 pixels with the lowest pixel intensity of each slice. Each scan was them windowed twice and saved separately, with the first scaled between 0 and 1000 Hounsfield units and the second between -1000 and -250 HU. All axial slices were then resized to 224x224 pixels. We generate predictions using a feature extractor and a recurrent neural network (RNN). The feature extractor is a ResNet50 model pretrained on ImageNet with global average pooling and outputs embeddings with length 2048. Each pair of windowed axial slices is used as input for the ResNet model and the outputted embeddings are concatenated to make arrays with length 4096. The embeddings for each study was padded with arrays of zeros with length 4096 to create uniform 220x4096 inputs for the regressor. The RNN architecture comprised of the following layers: two successive gated recurrent units layers with hyperbolic tangent activation and sigmoid recurrent activation with 32 and 16 units respectively, dropout with rate 0.25, three successive blocks of dense layers, ReLU activation, and dropout with rate 0.25, followed by an output layer with one unit. The dense layers had had 256, 64, 32 units each. The regressor was trained with an Adam optimizer using default hyperparameters and mean absolute error loss for 1000

epochs.

RESULTS

The model generated FEV1 predictions with mean absolute error of 0.301 L, root mean squared error of 0.381 L, mean absolute percentage error of 13.298 %. The Pearson correlation coefficient between the predicted and observed values was 0.816 ($p<0.001$).

CONCLUSION

s A recurrent neural network trained on embeddings from two different Hounsfield unit windows can measure FEV1 values from preoperative chest CT scans.

CLINICAL RELEVANCE/APPLICATION

Chest CT scans may be sufficient in determining pulmonary function without spirometry. This system can enable repeatable FEV1 measurements.

W2-SPIN-4 In Vivo Measurement of Abdominal Muscle Mass on CT using a Machine Learning Tool.

Participants
Chantal Chahine, MD, Philadelphia, PA (*Presenter*) Nothing to Disclose

PURPOSE

Muscle mass is a chief determinant of health and disease, playing a key role in bone health, as well as whole-body protein metabolism, which has been implicated in various illnesses. There continues to be an unmet need for a reference standard for assessing muscle mass. The purpose of this study was to determine the distribution of lean abdominal muscle mass of different muscle groups and establish an association between sex, age and lean muscle mass using a machine learning tool applied to computed tomography (CT) images.

METHODS AND MATERIALS

This retrospective study was conducted using a medical biobank (MBB), a single-institutional IRB-approved research protocol that recruits adult participants during outpatient visits, including 34,150 patients for whom 186,721 CTs and years of detailed electronic health record, genomic, and laboratory data were collected. Using a convenience cohort of 313 patients with abdominal CTs, we deployed a deep residual U-Net (ResUNet) to segment 12 abdominal muscle groups and determine lean muscle volume from non-contrast CTs. Inferencing was performed using software (Python 3.9.5 and Tensorflow) equipped with an Nvidia GTX 970 GPU. Associations between sex, age and lean muscle mass were determined using linear regression in R (R Foundation, Vienna). Descriptive statistics were reported as mean±std. Statistical significance was assessed using $p<0.05$. Volumes of individual muscle groups were plotted to distribution curves.

RESULTS

Abdominal muscle mass and distribution for each muscle group was obtained. We found abdominal muscle mass of the L Psoas: 146.1±55.4 g, R Psoas: 142.0±52.8 g, L Quad. Lumb.: 55.6±21.8 g, R Quad. Lumb.: 52.4±20.7 g, L. Erec. Spinae: 409.5±125.8 g, R. Erec. Spinae: 407.9±121.2 g, L. Glut. Med.: 51.7±38.1 g, R. Glut. Med.: 51.3±38.9 g, L. Rect. Abd.: 124.8±51.3 g, R. Rect. Abd.: 123.7±55.9 g, L. Lat. Abd.: 464.8±182.7 g, R. Lat. Abd.: 468.8±186.9 g. There was strong negative correlation between abdominal muscle mass and age (beta = -1.12, $p<0.001$) after adjusting by sex (beta [male sex] = 73.1, $p<0.001$).

CONCLUSION

s We were able to generate normative data about masses of different muscle groups and demonstrate a statistically significant negative association between muscle mass and age. Unlike prior efforts, these results are based on direct in-vivo measurement of abdominal muscle mass. We will apply this technique to a larger cohort to generate normative data of muscle mass distribution and lifetime variation in MBB patients grouped by illness, adjusting for age and sex.

CLINICAL RELEVANCE/APPLICATION

This work will allow researchers to better include muscle mass data as a measurable variable in future investigations, elucidating its clinical and public health implications.

W2-SPIN-5 Automatic Lesion Changes Detection and Classification by Bipartite Graph Lesions Matching

Participants
Leo Joskowicz, PhD, Jerusalem, Israel (*Presenter*) Officer, HighRAD Ltd

PURPOSE

To evaluate the performance of a novel method that automatically identifies and classifies lesion changes in longitudinal CT scans based on individual lesion segmentations.

METHODS AND MATERIALS

We have developed a method for the automatic detection and classification of lesion changes in longitudinal CT studies. The method is based on the analysis of pairs of consecutive pairs (prior and current) scans. It inputs the lesion segmentations in each scan (performed manually or obtained automatically) and outputs the lesion matching and the lesion changes in the same region of the evaluated organ. The method performs automatic prior and current scan deformable registration and matches the corresponding lesions in the scans based on their spatial location and their relative proximity. The matching is performed with a model-based bipartite graph technique in which lesions are represented by graph nodes and lesion matchings are represented by edges between the corresponding nodes. Once the matching is computed, three types of lesion changes are identified: existing lesions (appear in both scans), new lesions (appear in the current scan only), and disappeared lesions (appear in the prior scan only). We evaluated our method on two datasets: lung metastases in chest CT and liver metastases in CECT longitudinal studies. The lungs metastases dataset consists of 30 pairs of scans from 14 patients with a total of 266 lesions (mean of 7.79±6.34 lesions per scan). The liver metastases dataset consists of 199 pairs of scans from 49 patients with a total of 4,046 lesions (mean of 10.16±8.64 lesions per scan). Lesion segmentations were obtained by manual delineation of an expert radiologist, as well as ground truth lesion matching and lesion changes classification. The quality of the lesions pairing and the lesion changes classification was evaluated by

comparing the ground truth and computed lesions bipartite graphs.

RESULTS

The lungs metastases matching and classification is perfect: all lesion pairings and lesion changes are correct. The liver metastases matching Precision is 0.96±0.04 and the Recall is 0.97±0.03. The lesion classification specificity is 0.97±0.07, the precision is 0.95±0.03, and the recall is 0.96±0.03. Most of the errors were due to a few liver lesion clusters (conglomerates) and slight liver deformable registration inaccuracies.

CONCLUSION

s Automatic lesion pairings and lesion changes analysis achieves high performance on consecutive pairs of liver and lung metastases on retrospective clinical studies.

CLINICAL RELEVANCE/APPLICATION

Computer-aided lesion matching and lesion changes analysis may improve quantitative follow-up and evaluation of disease status, assessment of treatment efficacy and response to therapy.

W2-SPIN-6 Reproducibility Crisis in Medical Image Radiomic Studies: Contribution of Dynamic Histogram Binning

Participants
Timothy L. Kline, PhD, Rochester, MN (*Presenter*) Nothing to Disclose

PURPOSE

In the field of computer vision, extraction of image texture features is a fundamental process facilitating the development of AI algorithms to perform a wide range of tasks - from object detection and segmentation to region-of-interest classification. The purpose of this abstract is to educate the radiology AI/ML community regarding a foundational component of the radiomic feature pipeline involving dynamic histogram binning (DHB) which likely has contributed to poor generalization of machine learning models.

METHODS AND MATERIALS

Screening mammograms were queried from our institution’s imaging archive ranging from January 2009 to December 2019. Lesions were annotated as bounding boxes highlighting areas that had been subsequently biopsied. Images and masks were resampled to the median pixel dimensions and normalized. Radiomic features were extracted from the preprocessed images in Python using either PyRadiomics (where DHB is performed in accordance with the IBSI standard), or a modified code where static histogram binning (SHB) is performed. To investigate feature robustness, the original bounding boxes were eroded or dilated until the percent change in area exceeded either 10% or 20% (to simulate inter-observer variability). Simulation experiments and investigation of the underlying mathematical formulation of the features were used to explain the hyper-sensitivity of DHB to even modest changes in ROI definition.

RESULTS

Use of DHB (i.e. binning based on ROI voxel intensities) caused a subset of radiomic features to be hyper-sensitive to ROI definition compared with SHB (i.e. binning based on standardized whole image voxel intensities). Comparing feature values pre and post morphological operations highlights artifactual variation attributable to DHB that is remedied by SHB. This DHB- induced feature hyper-sensitivity was observed in real-world data, and explainable by both simulation and the mathematical formulations of the individual features.

CONCLUSION

s Here we show that a foundational component of the feature extraction procedure is flawed, relatively unknown to users and may have unintended downstream consequences on model performance. The de facto standard of dynamic histogram binning leads to an elevated sensitivity to even minor changes in the annotated regions. This finding may widely impact the majority of radiomic studies published in recent years and may contribute to well-known issues regarding poor reproducibility of developed machine learning models utilizing radiomics data.

CLINICAL RELEVANCE/APPLICATION

Whole image binning and/or study specific ranges for calibrated images (as recommended in IBSI standard) should become standard practice for models built on top of image texture/radiomics features.

Measuring FEV1 from Preoperative Chest Computed Tomography Scans using Deep Learning

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - IN DPS

Participants
Ji-eun Oh, PhD, Goyang-si, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the feasibility of generating deep learning-based FEV1 measurements from preoperative chest computed tomography (CT) scans.

METHODS AND MATERIALS

We collected 565 preoperative chest CT scans and FEV1 values performed on subjects undergoing lung cancer surgery between 2009 and 2015. FEV1 values were between 0.81 and 4.86 with mean 2.52 and standard deviation 0.63. All scans were resized to the median voxel size of our entire dataset (2.5x0.668x0.668 mm) and all axial slices were padded to 672x672 pixels with the lowest pixel intensity of each slice. Each scan was them windowed twice and saved separately, with the first scaled between 0 and 1000 Hounsfield units and the second between -1000 and -250 HU. All axial slices were then resized to 224x224 pixels. We generate predictions using a feature extractor and a recurrent neural network (RNN). The feature extractor is a ResNet50 model pretrained on ImageNet with global average pooling and outputs embeddings with length 2048. Each pair of windowed axial slices is used as input for the ResNet model and the outputted embeddings are concatenated to make arrays with length 4096. The embeddings for each study was padded with arrays of zeros with length 4096 to create uniform 220x4096 inputs for the regressor. The RNN architecture comprised of the following layers: two successive gated recurrent units layers with hyperbolic tangent activation and sigmoid recurrent activation with 32 and 16 units respectively, dropout with rate 0.25, three successive blocks of dense layers, ReLU activation, and dropout with rate 0.25, followed by an output layer with one unit. The dense layers had had 256, 64, 32 units each. The regressor was trained with an Adam optimizer using default hyperparameters and mean absolute error loss for 1000 epochs.

RESULTS

The model generated FEV1 predictions with mean absolute error of 0.301 L, root mean squared error of 0.381 L, mean absolute percentage error of 13.298 %. The Pearson correlation coefficient between the predicted and observed values was 0.816 ($p<0.001$).

CONCLUSION

s A recurrent neural network trained on embeddings from two different Hounsfield unit windows can measure FEV1 values from preoperative chest CT scans.

CLINICAL RELEVANCE/APPLICATION

Chest CT scans may be sufficient in determining pulmonary function without spirometry. This system can enable repeatable FEV1 measurements.

In Vivo Measurement of Abdominal Muscle Mass on CT using a Machine Learning Tool.

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - IN DPS

Participants
Chantal Chahine, MD, Philadelphia, PA (*Presenter*) Nothing to Disclose

PURPOSE

Muscle mass is a chief determinant of health and disease, playing a key role in bone health, as well as whole-body protein metabolism, which has been implicated in various illnesses. There continues to be an unmet need for a reference standard for assessing muscle mass. The purpose of this study was to determine the distribution of lean abdominal muscle mass of different muscle groups and establish an association between sex, age and lean muscle mass using a machine learning tool applied to computed tomography (CT) images.

METHODS AND MATERIALS

This retrospective study was conducted using a medical biobank (MBB), a single-institutional IRB-approved research protocol that recruits adult participants during outpatient visits, including 34,150 patients for whom 186,721 CTs and years of detailed electronic health record, genomic, and laboratory data were collected. Using a convenience cohort of 313 patients with abdominal CTs, we deployed a deep residual U-Net (ResUNet) to segment 12 abdominal muscle groups and determine lean muscle volume from non-contrast CTs. Inferencing was performed using software (Python 3.9.5 and Tensorflow) equipped with an Nvidia GTX 970 GPU. Associations between sex, age and lean muscle mass were determined using linear regression in R (R Foundation, Vienna). Descriptive statistics were reported as mean±std. Statistical significance was assessed using $p<0.05$. Volumes of individual muscle groups were plotted to distribution curves.

RESULTS

Abdominal muscle mass and distribution for each muscle group was obtained. We found abdominal muscle mass of the L Psoas: 146.1±55.4 g, R Psoas: 142.0±52.8 g, L Quad. Lumb.: 55.6±21.8 g, R Quad. Lumb.: 52.4±20.7 g, L. Erec. Spinae: 409.5±125.8 g, R. Erec. Spinae: 407.9±121.2 g, L. Glut. Med.: 51.7±38.1 g, R. Glut. Med.: 51.3±38.9 g, L. Rect. Abd.: 124.8±51.3 g, R. Rect. Abd.: 123.7±55.9 g, L. Lat. Abd.: 464.8±182.7 g, R. Lat. Abd.: 468.8±186.9 g. There was strong negative correlation between abdominal muscle mass and age (beta = -1.12, $p<0.001$) after adjusting by sex (beta [male sex] = 73.1, $p<0.001$).

CONCLUSION

s We were able to generate normative data about masses of different muscle groups and demonstrate a statistically significant negative association between muscle mass and age. Unlike prior efforts, these results are based on direct in-vivo measurement of abdominal muscle mass. We will apply this technique to a larger cohort to generate normative data of muscle mass distribution and lifetime variation in MBB patients grouped by illness, adjusting for age and sex.

CLINICAL RELEVANCE/APPLICATION

This work will allow researchers to better include muscle mass data as a measurable variable in future investigations, elucidating its clinical and public health implications.

W2-SPIN-5

Automatic Lesion Changes Detection and Classification by Bipartite Graph Lesions Matching

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - IN DPS

Participants
Leo Joskowicz, PhD, Jerusalem, Israel (*Presenter*) Officer, HighRAD Ltd

PURPOSE

To evaluate the performance of a novel method that automatically identifies and classifies lesion changes in longitudinal CT scans based on individual lesion segmentations.

METHODS AND MATERIALS

We have developed a method for the automatic detection and classification of lesion changes in longitudinal CT studies. The method is based on the analysis of pairs of consecutive pairs (prior and current) scans. It inputs the lesion segmentations in each scan (performed manually or obtained automatically) and outputs the lesion matching and the lesion changes in the same region of the evaluated organ. The method performs automatic prior and current scan deformable registration and matches the corresponding lesions in the scans based on their spatial location and their relative proximity. The matching is performed with a model-based bipartite graph technique in which lesions are represented by graph nodes and lesion matchings are represented by edges between the corresponding nodes. Once the matching is computed, three types of lesion changes are identified: existing lesions (appear in both scans), new lesions (appear in the current scan only), and disappeared lesions (appear in the prior scan only). We evaluated our method on two datasets: lung metastases in chest CT and liver metastases in CECT longitudinal studies. The lungs metastases dataset consists of 30 pairs of scans from 14 patients with a total of 266 lesions (mean of 7.79±6.34 lesions per scan). The liver metastases dataset consists of 199 pairs of scans from 49 patients with a total of 4,046 lesions (mean of 10.16±8.64 lesions per scan). Lesion segmentations were obtained by manual delineation of an expert radiologist, as well as ground truth lesion matching and lesion changes classification. The quality of the lesions pairing and the lesion changes classification was evaluated by comparing the ground truth and computed lesions bipartite graphs.

RESULTS

The lungs metastases matching and classification is perfect: all lesion pairings and lesion changes are correct. The liver metastases matching Precision is 0.96±0.04 and the Recall is 0.97±0.03. The lesion classification specificity is 0.97±0.07, the precision is 0.95±0.03, and the recall is 0.96±0.03. Most of the errors were due to a few liver lesion clusters (conglomerates) and slight liver deformable registration inaccuracies.

CONCLUSION

s Automatic lesion pairings and lesion changes analysis achieves high performance on consecutive pairs of liver and lung metastases on retrospective clinical studies.

CLINICAL RELEVANCE/APPLICATION

Computer-aided lesion matching and lesion changes analysis may improve quantitative follow-up and evaluation of disease status, assessment of treatment efficacy and response to therapy.

W2-SPIN-6

Reproducibility Crisis in Medical Image Radiomic Studies: Contribution of Dynamic Histogram Binning

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - IN DPS

Participants
Timothy L. Kline, PhD, Rochester, MN (*Presenter*) Nothing to Disclose

PURPOSE

In the field of computer vision, extraction of image texture features is a fundamental process facilitating the development of AI algorithms to perform a wide range of tasks - from object detection and segmentation to region-of-interest classification. The purpose of this abstract is to educate the radiology AI/ML community regarding a foundational component of the radiomic feature pipeline involving dynamic histogram binning (DHB) which likely has contributed to poor generalization of machine learning models.

METHODS AND MATERIALS

Screening mammograms were queried from our institution's imaging archive ranging from January 2009 to December 2019. Lesions were annotated as bounding boxes highlighting areas that had been subsequently biopsied. Images and masks were resampled to the median pixel dimensions and normalized. Radiomic features were extracted from the preprocessed images in Python using either PyRadiomics (where DHB is performed in accordance with the IBSI standard), or a modified code where static histogram binning (SHB) is performed. To investigate feature robustness, the original bounding boxes were eroded or dilated until the percent change in area exceeded either 10% or 20% (to simulate inter-observer variability). Simulation experiments and investigation of the underlying mathematical formulation of the features were used to explain the hyper-sensitivity of DHB to even modest changes in ROI definition.

RESULTS

Use of DHB (i.e. binning based on ROI voxel intensities) caused a subset of radiomic features to be hyper-sensitive to ROI definition compared with SHB (i.e. binning based on standardized whole image voxel intensities). Comparing feature values pre and post morphological operations highlights artifactual variation attributable to DHB that is remedied by SHB. This DHB- induced feature hyper-sensitivity was observed in real-world data, and explainable by both simulation and the mathematical formulations of the individual features.

CONCLUSION

s Here we show that a foundational component of the feature extraction procedure is flawed, relatively unknown to users and may have unintended downstream consequences on model performance. The de facto standard of dynamic histogram binning leads to an elevated sensitivity to even minor changes in the annotated regions. This finding may widely impact the majority of radiomic studies published in recent years and may contribute to well-known issues regarding poor reproducibility of developed machine learning models utilizing radiomics data.

CLINICAL RELEVANCE/APPLICATION

Whole image binning and/or study specific ranges for calibrated images (as recommended in IBSI standard) should become standard practice for models built on top of image texture/radiomics features.

W2-SPIR-1 Radiogenomic Biomarkers for Microvascular Invasion predict the Clinical Outcome in Patients with Hepatocellular Carcinoma after Locoregional Therapies

Participants
Robin Schmidt, (*Presenter*) Nothing to Disclose

PURPOSE

Microvascular invasion (MVI) in hepatocellular carcinoma (HCC) represents an independent risk factor for early recurrence and poor survival outcome. MVI can only be determined invasively after operative treatments by histopathology. However, its clinical utility for minimally invasive locoregional therapies (LRT) as guideline-approved standard of care for many unresectable HCC patients remains limited. Radiogenomic venous invasion (RVI) and two-trait predictor of MVI (TTPVI) are two imaging biomarkers derived from linking imaging features to HCC-specific gene profile analyses to predict the presence of MVI. This study aims to compare their predictive value for the outcome of patients with HCC receiving LRT.

METHODS AND MATERIALS

This study included 95 HCC patients, who received either CT-guided brachytherapy alone (n=48) or combined with transarterial chemoembolization (TACE, n=47) between 01/2016-12/2017. Patients were stratified according to RVI and TTPVI being assessed on baseline contrast-enhanced MRI using decision-tree-models: Presence of internal vessels in arterial (TTPVI) or portalvenous phase (RVI), followed by absence of an hypointense halo (TTPVI/RVI) and a sharp tumor-liver-transition in portalvenous phase (RVI). Primary endpoints were overall survival (OS), progression-free survival (PFS), time to progression (TTP). Statistics included Fisher's exact test and Kaplan-Meier analysis.

RESULTS

Median OS (26.7 vs 23.7 months), median PFS (9.3 vs 7.3 months) and median TTP (9.8 vs 9.3 months) did not sigificantly differ between patients receiving brachytherapy and TACE/brachytherapy, respectively (Figure 1). While TTPVI was frequently observed in TACE/brachytherapy treated patients (60.9% vs 40.4%, p=0.063) than after brachytherapy alone, the presence of RVI occurred equally in both groups (32.6% vs 29.8%, p=0.825). As for brachytherapy, TTPVI achieved significant separation of OS (p=<0.001) and PFS (p=0.029) but not TTP (p=0.142), while RVI was predictive of TTP (p=0.032), PFS (p=0.004) but not OS (p=0.078). Both biomarkers revealed poorer outcome after brachytherapy for positively scored patients at baseline. On the contrary, they did not achieve significant separation for any endpoint in patients following TACE/brachytherapy (Figure 2).

CONCLUSION

s The findings underscore the potential of TTPVI/RVI to predict early recurrence and poor survival in HCC patients receiving brachytherapy. Those patients could potentially benefit from a prior TACE.

CLINICAL RELEVANCE/APPLICATION

RVI/TTPVI represent non-invasive prognostic biomarkers, that could be implemented into treatment allocation and monitoring strategies for unresectable HCC.

W2-SPIR-2 Ultrasound-guided Radiofrequency Ablation Treatment in Early Stage Breast Cancer: Efficacy of Ablation with Vacuum Assisted Biopsy and Magnetic Resonance

Participants
Jaime Jimenez, MD, Barcelona, Spain (*Presenter*) Nothing to Disclose

PURPOSE

To clinically validate the efficacy and safety of the cool-tip ablation method in breast tumors smaller than 2 cm.

METHODS AND MATERIALS

Eleven patients aged more than 70 years-old with luminal infiltrating ductal carcinoma of the breast were treated with ultrasonography (US)-guided percutaneous RFA between 2020-2022. Tumors measured less than 2 cm and were located more than 1 cm from the chest wall and skin. Effectiveness of the treatment was assessed with breast MRI and vacuum assisted biopsy (BAB) one month after RFA. Tumor viability was assessed with Nicotinamide adenine dinucleotide (NADH)-diaphorase.

RESULTS

MRI evaluation demonstrated round ablation area without tumor enhancement in all cases. Ten cases showed no evidence of viable tumor after BAB. One tumor with inconclusive pathological changes after BAB was surgically removed, nevertheless final analysis

showed no residual viable tumor. No recurrences have occurred after MRI follow-up for less than 6 months (5 cases), 6 months (1 case) and one year (3 cases). Breast cosmesis is excellent in all patients.

CONCLUSION

s Preliminary results show that, in early stage tumors smaller than 2cm, cool-tip RFA ablation achieves complete tumor ablation with so far no signs of tumor recurrence in the patients included.

CLINICAL RELEVANCE/APPLICATION

Preliminary studies on treatment of breast tumors with radiofrequency ablation (RFA) followed by surgical resection have demonstrated its feasibility, effectiveness, and safety in tumors smaller than 2 cm, with percentage of complete tumor ablation between 76-100%.

W2-SPIR-4 Evaluation of Chemotherapy-free Interval Overall Survival and Progression-free Survival of Patients Undergoing Ablation of Pulmonary Sarcoma Metastases

Participants
Jose Maluf, MD, MD, Sao Paulo, Brazil (*Presenter*) Nothing to Disclose

PURPOSE

To assess the chemotherapy-free interval, overall survival and progression-free survival of patients undergoing ablation of pulmonary sarcoma metastasis.

METHODS AND MATERIALS

Retrospective study, carried out from the analysis of data from electronic medical record. Patients submitted to radiofrequency ablation of sarcoma pulmonary metastasis between 2013 and 2020 were included. Were excluded patients: with other primary tumors than sarcoma; with extrapulmonary metastases; who discontinued chemotherapy after ablation of lung metastases; as well as those who lost follow-up to the institution after ablative treatment. The data obtained were entered into Excel and later exported to the IBM SPSS version 20.0 program for statistical analysis. The Kaplan Meier curve was used to estimate the mean and median of overall survival and disease-free survival. It was considered a significance level of 5%.

RESULTS

A total of 30 patients were included, with the majority (56.7%) being under 50 years old at the first ablation. The absolute majority (93.3%) of the tumors had high histological grade. Synovial sarcoma and fibrosarcoma were the most frequent histological subtypes (prevalences of 23.3% and 13.3%). Most patients (63.3%) had undergone previous chemotherapy treatment, while only 30% underwent previous surgical resection of lung metastases. Almost all underwent single lung ablations, with only 20% undergoing more than one metastasis ablation session. The median of treated nodules was 2 nodules per patient and only 6 patients died by the end of the study. The mean chemotherapy-free interval after lung metastases ablation treatment in the study population was 23.2 months, with a mean overall survival time of 69.3 months (95% confidence interval: 51.1 - 87.6 months) and median progression-free survival of 13 months (95% confidence interval: 9.2 to 16.8 months).

CONCLUSION

s The results of this study show a significant chemotherapy-free interval in patients undergoing ablation of pulmonary sarcoma metastases, with relevant results for overall survival and progression-free survival.

CLINICAL RELEVANCE/APPLICATION

Strategies that can promote a chemotherapy-free interval for patients with metastatic sarcomas are increasingly valued, aiming to reduce side effects and increase quality of life during cancer follow-up. The ablation of pulmonary metastases, used in other scenarios as curative therapy, emerged as a possible candidate for palliative measures, aiming to stop the natural course of the disease and promote a period without from chemotherapy to the patient.

W2-SPIR-5 Percutaneous Cryoablation vs Microwave Ablation of Renal Cell Carcinoma: A Comparative Study of Effectiveness and Safety

Participants
Lilit Aslanyan, DO, MS, Atlanta, GA (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate differences in efficacy and safety between percutaneous cryoablation (CRA) and microwave ablation (MWA) of renal cell carcinoma (RCC).

METHODS AND MATERIALS

From 2013-2017, consecutive RCC patients treated with CRA and MWA were retrospectively included. Baseline characteristics (age, gender, race, BMI, tumor size, RENAL-nephrometry score) were evaluated. Peri- and post-procedural variables (number of probes utilized, total CT dose, procedural time, incidence of hematoma and creatinine adverse-event (AE) grade =1, critical structure involvement, post-op hospitalization, Clavien-Dindo Class =1, complete response) were also evaluated. Overall-survival from initial treatment was calculated using Kaplan-Meier estimation and compared using log-rank analysis. Differences in variables were assessed with chi-square and student's t-test using JMP statistical software.

RESULTS

176 patients were evaluated (130 CRA; 46 MWA). Overall mean age and gender was 68 years and 56% male. No significant differences in baseline characteristics (age, gender, race, BMI, tumor size, RENAL-nephrometry score) were noted. Compared to MWA, CRA was associated with more probes (2.1±1.2 vs 1.4±0.2 probes; $p<0.0001$) and longer procedural time (94±3.4 vs 79±6.3 min; $p=0.03$), but did not exhibit a significant difference in other peri- or post-procedural variables (total CT dose (2.9±0.2 vs 2.6±0.3 Gy*cm; $p=0.4$), hematoma incidence (30% vs 22%; $p=0.4$), Grade =1 creatinine AE (5% vs 12%, $p=0.3$), critical structure involvement (30% vs 22%; $p=0.4$), post-op hospitalization (24% vs 14%; $p=0.2$), Clavien-Dindo Class =1 (25% vs 14%; $p=0.2$), complete response (93% vs 90%; $p=0.4$), and overall-survival (4.1 vs 4.7 yrs; $p=0.8$))

CONCLUSION

s For patients with RCC, CRA and MWA offer similar effectiveness and safety profiles despite CRA being associated with more ablation probes and procedural time.

CLINICAL RELEVANCE/APPLICATION

For patients with renal cell carcinoma, percutaneous microwave and cryoablation offer similar effectiveness and safety profiles despite cryoablation being associated with more ablation probes and procedural time.

W2-SPIR-6 Customized MR-guided Transurethral Ultrasound Ablation (TULSA) for Treatment of Localized Prostate Cancer and Concurrent Benign Prostate Hyperplasia: A Single Centre Retrospective Analysis of One Hundred Patients

Participants
Leonhard Steinmeister, MD, (*Presenter*) Nothing to Disclose

PURPOSE

MR-guided transurethral ultrasound ablation (TULSA) has primarily been investigated for whole-gland prostate ablation, but is also well-suited for partial gland treatment. The purpose was to perform a clinical service evaluation of partial to whole-gland TULSA for patients with localized prostate cancer (CaP). TULSA was also evaluated as a combined therapy for a subset of patients presenting with both cancer and concurrent benign prostate hyperplasia (BPH).

METHODS AND MATERIALS

This retrospective, consecutive clinical service evaluation included men with histopathologically-confirmed CaP who underwent TULSA either as primary or salvage treatment. The planned ablation was dependent on the individual tumor characteristics, concurrent BPH and patient preferences. The Clavien-Dindo classification was used to record complications. Surgeon-assessed functional outcomes were reported. Early treatment success was defined by negative multiparametric MRI (mpMRI) and lack of prostate specific antigen (PSA) recurrence.

RESULTS

One hundred consecutive patients (95 treatment-naïve and 5 salvage) were included, with median follow-up of 14 months and a max of 36 months. Baseline median (IQR) age and PSA were 65 years (51-90) and 8.1 ng/ml (2.3-21), respectively. Three Grade IIIa adverse events were observed, with no bowel-related complications. For urinary continence outcomes, 1 patient worsened to 1 pad per day. All patients who were previously potent maintained erectile potency. Of the patient subgroup also seeking treatment for BPH, 85% reported symptom improvement. Median (IQR) PSA nadir after primary treatment was 1.3 ng/ml (0.4-2.5). Early treatment success when including all repeat treatments was 92%.

CONCLUSION

s Customized prostate ablation with TULSA offers flexible ablation according to patients' disease characteristics and treatment expectations, providing favorable safety and promising early MRI and PSA results. TULSA is a feasible combination therapy for patients with both cancer and concurrent BPH. Local recurrence after initial treatment failure can be successfully retreated with TULSA.

CLINICAL RELEVANCE/APPLICATION

Customized prostate ablation with MR-guided transurethral ultrasound ablation (TULSA) is a feasible combination therapy for patients with localized prostate cancer and concurrent benign prostate hyperplasia (BPH).

W2-SPIR-7 Quantitative Image-Guided Intervention for Hepatocellular Carcinoma: DECT for In Vivo Application of Thermochemical Ablation

Participants
Emily Thompson, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

Thermochemical ablation (TCA) is a minimally invasive therapy under development for hepatocellular carcinoma. TCA delivers acid (AcOH) and base (NaOH) into tumors simultaneously, which react to completion in a mixing catheter at the time of injection, producing acetate salt, water, and releasing heat (?>50°C) to induce lethal osmotic and thermal stress. However, these reagents are not distinguishable from tissues on computed tomography (CT), which makes imaging the delivery of TCA difficult. We address this issue by incorporating radiopaque cesium hydroxide (CsOH) as a novel theranostic reagent in TCA that is detectable with CT.

METHODS AND MATERIALS

VX2 tumor fragments (0.3mL) were inoculated into New Zealand white rabbits' right and left flanks (n=16 rabbits). When tumor diameter reached 1-2cm, TCA was delivered as one of three treatment groups: untreated control, 5M TCA, or 10M TCA. The TCA base reagent was doped with 250mM CsOH. Catheters were placed under ultrasound guidance, and TCA was delivered. Dual-energy CT (DECT) was acquired pre-and post-TCA (Definition Edge, Siemens Healthineers). Material-specific images (Cs) were post-processed (Siemens Syngo Via) based on previous phantom calibrations to determine Cs concentration. Line profiles were drawn through the ablation center (ImageJ, NIH). 24-hours after TCA, subjects were euthanized, and the resulting damage was evaluated with histopathology.

RESULTS

Cs was detected on CT following delivery of TCA in all tumors (n=21). Line profiles indicated the highest concentrations at the injection site and decreased concentrations at the tumor margins. Beyond the ablation zone, no Cs was detected. A dose-dependent trend in tissue necrosis was demonstrated between the 10M TCA treatment group and 5M TCA treatment group (p=0.0005) and untreated controls (p=0.0089).

CONCLUSION

s CsOH is a viable theranostic reagent for the interventional application of TCA. With the inclusion of CsOH, DECT can provide

image guidance for the delivery, localization, and quantification of ablation agent.

CLINICAL RELEVANCE/APPLICATION

Quantitative assessment of CsOH distribution enables the use of DECT as a viable technique to track injectable image-guided ablations, such as TCA, and ensure therapeutic delivery.

W2-SPIR-8 Assessing the Impact of Perfusion on Microwave Ablation Measurements in an Ex Vivo Bovine Kidney Model

Participants
Annie Dang, BS, MS, San Antonio, TX (*Presenter*) Nothing to Disclose

PURPOSE

The use of microwave ablation (MWA) for treating early-stage renal cell cancer is on the rise. Currently, manufacturers provide guidance on anticipated treatment margins based on data from nonperfused organs. Organ perfusion has been shown to impact ablation size and understanding this impact is critical to maximize treatment outcomes.?We aim to assess the impact of perfusion on MWA volumes using a perfused ex vivo bovine kidney model.

METHODS AND MATERIALS

Nine bovine kidneys were harvested and kept on ice following transplant protocol. An ex vivo perfusion system consisting of membrane oxygenator, warmer, and blood pressure monitor was used to perfuse the organ using defibrinated bovine blood. Perfusion was initiated within 8 hours of procurement. A MWA system (AngioDynamics Solero) was used to perform 72 ablations (36 perfused, 36 nonperfused) at 9 different power and time device settings (60 W, 100 W, and 140 W for 2, 4, and 6 minutes). Perfused and nonperfused ablations for each kidney were performed at the same device setting to limit variability between kidneys. Each ablation was sectioned along the trajectory of the probe for long axis diameter (LAD) and short axis diameter (SAD) measurements of the zone of coagulation. Two-tailed t-tests were used to compare perfused and non-perfused conditions and linear regression was used to determine the association between ablation volume and device setting.

RESULTS

Collapsed across time settings, there were the following differences in coagulation zone volume by power: 60 W) perfused 2.3 + 1.0 mL versus nonperfused 7.2 + 2.7 mL, p-value < 0.001; 100 W) perfused 5.4 + 2.1 mL versus nonperfused 11.5 + 5.6 mL, p-value < 0.01; and 140 W) perfused 11.2 + 3.7 mL versus nonperfused 18.7 + 6.3 mL, p < 0.01. For all ablation conditions, LAD, SAD, and volume were smaller in perfused groups compared to nonperfused groups. There was a statistically significant difference in ablation volume for 6 of the 9 device settings ($p < 0.05$). Ablation volume positively correlated with applied power for both perfused and non-perfused ablations, with the following association: perfused, 0.021 cm3/W, $R = 0.462$, $p = 0.004$; nonperfused, 0.029 cm3/W, $R = 0.565$, $p < 0.001$.?No observed association was identified for applied time and ablation volume ($R = 0.001$, $p = 0.32$).

CONCLUSION

s Observed ablation volumes were restricted to the size of the renal lobule, limiting translation of measurements to the clinical setting. This study demonstrates kidneys are highly vascular structures susceptible to the effects of perfusion mediated tissue cooling during MWA.

CLINICAL RELEVANCE/APPLICATION

These findings support clinical anticipation of significantly smaller renal MWA volumes compared to manufacturer data from nonperfused organs.??

W2-SPIR-9 Future Liver Remnant Hypertrophy Following Y-90 Radioembolization Lobectomy with Resin Microspheres

Participants
Muhammad Malik, MD, Boston, MA (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the hypertrophy and kinetic growth rate of the future liver remnant (FLR) following Y-90 radioembolization lobectomy with resin microspheres in primary liver cancer.

METHODS AND MATERIALS

A HIPAA compliant, IRB-approved, retrospective review of patients treated with radioembolization lobectomy (RL) using resin microspheres for primary liver cancer from March 2016 to October 2021. Imaging studies were reviewed at three different time points; pre Y90-TARE (T0), < 4 months post Y90-TARE (T1) and > 4 months post Y90-TARE (T2). Exclusion criteria included prior portal vein embolization, Y-90 treatment to contralateral lobe <6-months apart, and tumor in both hepatic lobes. Total liver volume (TLV), treated area volume (TAV), untreated area volume (UAV), and future liver remnant (FLR) at T0, T1 and T2 were manually calculated by a radiology fellow on TeraRecon software. Percentage of hypertrophy of treated lobe was calculated at T1 and T2, and kinetic growth rate (KGR) was calculated by the degree of hypertrophy at T1 over the number of weeks elapsed from the treatment date. Procedure characteristics and patient demographics were recorded. Statistical analysis was performed with paired t-test.

RESULTS

A total of 20 patients (Age: 69+/-10 years, 40% females) with primary liver cancer (40% cholangiocarcinoma, 60% hepatocellular carcinoma) underwent Y-90 radioembolization lobectomy (Table 1). Average Tumor size was 9 cm ± 4 (2-16). 6/15 (40%) tumors were multifocal and 5/15 (33%) were unifocal. The FLR at T0, T1 and T2 was 853 cc (IQR: 597-1291), 1117 cc (IQR: 631-1526) and 1424 cc (IQR: 594-1768), respectively. At T1, the average KGR/week was 2.3% and hypertrophy of 21.4% ($p<0.001$) and at T2 average KGR/week of 1.3%, with hypertrophy of 30% compared to T0 ($P<0.001$). Complete response was found in 13/20 (65%) and partial response in 5/20 (25%) patients. 2/20 (10%) patients progressed in their liver disease. Only 4 (20%) of patients underwent surgical resection.

CONCLUSION

s There is significant difference in hypertrophy of the future liver remnant volume following Y-90 radiation lobectomy with resin microspheres. A 65% of patients had complete treatment response, and only 20% of patients undergoing surgical resection.

CLINICAL RELEVANCE/APPLICATION

Future liver remnant hypertrophy following Y-90 radiation lobectomy is a potential indicator for future liver resection.

Radiogenomic Biomarkers for Microvascular Invasion predict the Clinical Outcome in Patients with Hepatocellular Carcinoma after Locoregional Therapies

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - IR DPS

Participants
Robin Schmidt, (*Presenter*) Nothing to Disclose

PURPOSE

Microvascular invasion (MVI) in hepatocellular carcinoma (HCC) represents an independent risk factor for early recurrence and poor survival outcome. MVI can only be determined invasively after operative treatments by histopathology. However, its clinical utility for minimally invasive locoregional therapies (LRT) as guideline-approved standard of care for many unresectable HCC patients remains limited. Radiogenomic venous invasion (RVI) and two-trait predictor of MVI (TTPVI) are two imaging biomarkers derived from linking imaging features to HCC-specific gene profile analyses to predict the presence of MVI. This study aims to compare their predictive value for the outcome of patients with HCC receiving LRT.

METHODS AND MATERIALS

This study included 95 HCC patients, who received either CT-guided brachytherapy alone (n=48) or combined with transarterial chemoembolization (TACE, n=47) between 01/2016-12/2017. Patients were stratified according to RVI and TTPVI being assessed on baseline contrast-enhanced MRI using decision-tree-models: Presence of internal vessels in arterial (TTPVI) or portalvenous phase (RVI), followed by absence of an hypointense halo (TTPVI/RVI) and a sharp tumor-liver-transition in portalvenous phase (RVI). Primary endpoints were overall survival (OS), progression-free survival (PFS), time to progression (TTP). Statistics included Fisher's exact test and Kaplan-Meier analysis.

RESULTS

Median OS (26.7 vs 23.7 months), median PFS (9.3 vs 7.3 months) and median TTP (9.8 vs 9.3 months) did not sigificantly differ between patients receiving brachytherapy and TACE/brachytherapy, respectively (Figure 1). While TTPVI was frequently observed in TACE/brachytherapy treated patients (60.9% vs 40.4%, p=0.063) than after brachytherapy alone, the presence of RVI occurred equally in both groups (32.6% vs 29.8%, p=0.825). As for brachytherapy, TTPVI achieved significant separation of OS (p=<0.001) and PFS (p=0.029) but not TTP (p=0.142), while RVI was predictive of TTP (p=0.032), PFS (p=0.004) but not OS (p=0.078). Both biomarkers revealed poorer outcome after brachytherapy for positively scored patients at baseline. On the contrary, they did not achieve significant separation for any endpoint in patients following TACE/brachytherapy (Figure 2).

CONCLUSION

s The findings underscore the potential of TTPVI/RVI to predict early recurrence and poor survival in HCC patients receiving brachytherapy. Those patients could potentially benefit from a prior TACE.

CLINICAL RELEVANCE/APPLICATION

RVI/TTPVI represent non-invasive prognostic biomarkers, that could be implemented into treatment allocation and monitoring strategies for unresectable HCC.

Ultrasound-guided Radiofrequency Ablation Treatment in Early Stage Breast Cancer: Efficacy of Ablation with Vacuum Assisted Biopsy and Magnetic Resonance

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - IR DPS

Participants
Jaime Jimenez, MD, Barcelona, Spain (*Presenter*) Nothing to Disclose

PURPOSE

To clinically validate the efficacy and safety of the cool-tip ablation method in breast tumors smaller than 2 cm.

METHODS AND MATERIALS

Eleven patients aged more than 70 years-old with luminal infiltrating ductal carcinoma of the breast were treated with ultrasonography (US)-guided percutaneous RFA between 2020-2022. Tumors measured less than 2 cm and were located more than 1 cm from the chest wall and skin. Effectiveness of the treatment was assessed with breast MRI and vacuum assisted biopsy (BAB) one month after RFA. Tumor viability was assessed with Nicotinamide adenine dinucleotide (NADH)-diaphorase.

RESULTS

MRI evaluation demonstrated round ablation area without tumor enhancement in all cases. Ten cases showed no evidence of viable tumor after BAB. One tumor with inconclusive pathological changes after BAB was surgically removed, nevertheless final analysis showed no residual viable tumor. No recurrences have occurred after MRI follow-up for less than 6 months (5 cases), 6 months (1 case) and one year (3 cases). Breast cosmesis is excellent in all patients.

CONCLUSION

s Preliminary results show that, in early stage tumors smaller than 2cm, cool-tip RFA ablation achieves complete tumor ablation with so far no signs of tumor recurrence in the patients included.

CLINICAL RELEVANCE/APPLICATION

Preliminary studies on treatment of breast tumors with radiofrequency ablation (RFA) followed by surgical resection have demonstrated its feasibility, effectiveness, and safety in tumors smaller than 2 cm, with percentage of complete tumor ablation between 76-100%.

Evaluation of Chemotherapy-free Interval Overall Survival and Progression-free Survival of Patients Undergoing Ablation of Pulmonary Sarcoma Metastases

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - IR DPS

Participants
Jose Maluf, MD, MD, Sao Paulo, Brazil (*Presenter*) Nothing to Disclose

PURPOSE

To assess the chemotherapy-free interval, overall survival and progression-free survival of patients undergoing ablation of pulmonary sarcoma metastasis.

METHODS AND MATERIALS

Retrospective study, carried out from the analysis of data from electronic medical record. Patients submitted to radiofrequency ablation of sarcoma pulmonary metastasis between 2013 and 2020 were included. Were excluded patients: with other primary tumors than sarcoma; with extrapulmonary metastases; who discontinued chemotherapy after ablation of lung metastases; as well as those who lost follow-up to the institution after ablative treatment. The data obtained were entered into Excel and later exported to the IBM SPSS version 20.0 program for statistical analysis. The Kaplan Meier curve was used to estimate the mean and median of overall survival and disease-free survival. It was considered a significance level of 5%.

RESULTS

A total of 30 patients were included, with the majority (56.7%) being under 50 years old at the first ablation. The absolute majority (93.3%) of the tumors had high histological grade. Synovial sarcoma and fibrosarcoma were the most frequent histological subtypes (prevalences of 23.3% and 13.3%). Most patients (63.3%) had undergone previous chemotherapy treatment, while only 30% underwent previous surgical resection of lung metastases. Almost all underwent single lung ablations, with only 20% undergoing more than one metastasis ablation session. The median of treated nodules was 2 nodules per patient and only 6 patients died by the end of the study. The mean chemotherapy-free interval after lung metastases ablation treatment in the study population was 23.2 months, with a mean overall survival time of 69.3 months (95% confidence interval: 51.1 - 87.6 months) and median progression-free survival of 13 months (95% confidence interval: 9.2 to 16.8 months).

CONCLUSION

s The results of this study show a significant chemotherapy-free interval in patients undergoing ablation of pulmonary sarcoma metastases, with relevant results for overall survival and progression-free survival.

CLINICAL RELEVANCE/APPLICATION

Strategies that can promote a chemotherapy-free interval for patients with metastatic sarcomas are increasingly valued, aiming to reduce side effects and increase quality of life during cancer follow-up. The ablation of pulmonary metastases, used in other scenarios as curative therapy, emerged as a possible candidate for palliative measures, aiming to stop the natural course of the disease and promote a period without from chemotherapy to the patient.

Percutaneous Cryoablation vs Microwave Ablation of Renal Cell Carcinoma: A Comparative Study of Effectiveness and Safety

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - IR DPS

Participants
Lilit Aslanyan, DO, MS, Atlanta, GA (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate differences in efficacy and safety between percutaneous cryoablation (CRA) and microwave ablation (MWA) of renal cell carcinoma (RCC).

METHODS AND MATERIALS

From 2013-2017, consecutive RCC patients treated with CRA and MWA were retrospectively included. Baseline characteristics (age, gender, race, BMI, tumor size, RENAL-nephrometry score) were evaluated. Peri- and post-procedural variables (number of probes utilized, total CT dose, procedural time, incidence of hematoma and creatinine adverse-event (AE) grade =1, critical structure involvement, post-op hospitalization, Clavien-Dindo Class =1, complete response) were also evaluated. Overall-survival from initial treatment was calculated using Kaplan-Meier estimation and compared using log-rank analysis. Differences in variables were assessed with chi-square and student's t-test using JMP statistical software.

RESULTS

176 patients were evaluated (130 CRA; 46 MWA). Overall mean age and gender was 68 years and 56% male. No significant differences in baseline characteristics (age, gender, race, BMI, tumor size, RENAL-nephrometry score) were noted. Compared to MWA, CRA was associated with more probes (2.1±1.2 vs 1.4±0.2 probes; p<0.0001) and longer procedural time (94±3.4 vs 79±6.3 min; p=0.03), but did not exhibit a significant difference in other peri- or post-procedural variables (total CT dose (2.9±0.2 vs 2.6±0.3 Gy*cm; p=0.4), hematoma incidence (30% vs 22%; p=0.4), Grade =1 creatinine AE (5% vs 12%, p=0.3), critical structure involvement (30% vs 22%; p=0.4), post-op hospitalization (24% vs 14%; p=0.2), Clavien-Dindo Class =1 (25% vs 14%; p=0.2), complete response (93% vs 90%; p=0.4), and overall-survival (4.1 vs 4.7 yrs; p=0.8))

CONCLUSION

s For patients with RCC, CRA and MWA offer similar effectiveness and safety profiles despite CRA being associated with more ablation probes and procedural time.

CLINICAL RELEVANCE/APPLICATION

For patients with renal cell carcinoma, percutaneous microwave and cryoablation offer similar effectiveness and safety profiles despite cryoablation being associated with more ablation probes and procedural time.

Customized MR-guided Transurethral Ultrasound Ablation (TULSA) for Treatment of Localized Prostate Cancer and Concurrent Benign Prostate Hyperplasia: A Single Centre Retrospective Analysis of One Hundred Patients

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - IR DPS

Participants
Leonhard Steinmeister, MD, (*Presenter*) Nothing to Disclose

PURPOSE

MR-guided transurethral ultrasound ablation (TULSA) has primarily been investigated for whole-gland prostate ablation, but is also well-suited for partial gland treatment. The purpose was to perform a clinical service evaluation of partial to whole-gland TULSA for patients with localized prostate cancer (CaP). TULSA was also evaluated as a combined therapy for a subset of patients presenting with both cancer and concurrent benign prostate hyperplasia (BPH).

METHODS AND MATERIALS

This retrospective, consecutive clinical service evaluation included men with histopathologically-confirmed CaP who underwent TULSA either as primary or salvage treatment. The planned ablation was dependent on the individual tumor characteristics, concurrent BPH and patient preferences. The Clavien-Dindo classification was used to record complications. Surgeon-assessed functional outcomes were reported. Early treatment success was defined by negative multiparametric MRI (mpMRI) and lack of prostate specific antigen (PSA) recurrence.

RESULTS

One hundred consecutive patients (95 treatment-naïve and 5 salvage) were included, with median follow-up of 14 months and a max of 36 months. Baseline median (IQR) age and PSA were 65 years (51-90) and 8.1 ng/ml (2.3-21), respectively. Three Grade IIIa adverse events were observed, with no bowel-related complications. For urinary continence outcomes, 1 patient worsened to 1 pad per day. All patients who were previously potent maintained erectile potency. Of the patient subgroup also seeking treatment for BPH, 85% reported symptom improvement. Median (IQR) PSA nadir after primary treatment was 1.3 ng/ml (0.4-2.5). Early treatment success when including all repeat treatments was 92%.

CONCLUSION

s Customized prostate ablation with TULSA offers flexible ablation according to patients' disease characteristics and treatment expectations, providing favorable safety and promising early MRI and PSA results. TULSA is a feasible combination therapy for patients with both cancer and concurrent BPH. Local recurrence after initial treatment failure can be successfully retreated with TULSA.

CLINICAL RELEVANCE/APPLICATION

Customized prostate ablation with MR-guided transurethral ultrasound ablation (TULSA) is a feasible combination therapy for patients with localized prostate cancer and concurrent benign prostate hyperplasia (BPH).

Quantitative Image-Guided Intervention for Hepatocellular Carcinoma: DECT for In Vivo Application of Thermochemical Ablation

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - IR DPS

Participants
Emily Thompson, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

Thermochemical ablation (TCA) is a minimally invasive therapy under development for hepatocellular carcinoma. TCA delivers acid (AcOH) and base (NaOH) into tumors simultaneously, which react to completion in a mixing catheter at the time of injection, producing acetate salt, water, and releasing heat (?>50°C) to induce lethal osmotic and thermal stress. However, these reagents are not distinguishable from tissues on computed tomography (CT), which makes imaging the delivery of TCA difficult. We address this issue by incorporating radiopaque cesium hydroxide (CsOH) as a novel theranostic reagent in TCA that is detectable with CT.

METHODS AND MATERIALS

VX2 tumor fragments (0.3mL) were inoculated into New Zealand white rabbits' right and left flanks (n=16 rabbits). When tumor diameter reached 1-2cm, TCA was delivered as one of three treatment groups: untreated control, 5M TCA, or 10M TCA. The TCA base reagent was doped with 250mM CsOH. Catheters were placed under ultrasound guidance, and TCA was delivered. Dual-energy CT (DECT) was acquired pre-and post-TCA (Definition Edge, Siemens Healthineers). Material-specific images (Cs) were post-processed (Siemens Syngo Via) based on previous phantom calibrations to determine Cs concentration. Line profiles were drawn through the ablation center (ImageJ, NIH). 24-hours after TCA, subjects were euthanized, and the resulting damage was evaluated with histopathology.

RESULTS

Cs was detected on CT following delivery of TCA in all tumors (n=21). Line profiles indicated the highest concentrations at the injection site and decreased concentrations at the tumor margins. Beyond the ablation zone, no Cs was detected. A dose-dependent trend in tissue necrosis was demonstrated between the 10M TCA treatment group and 5M TCA treatment group (p=0.0005) and untreated controls (p=0.0089).

CONCLUSION

s CsOH is a viable theranostic reagent for the interventional application of TCA. With the inclusion of CsOH, DECT can provide image guidance for the delivery, localization, and quantification of ablation agent.

CLINICAL RELEVANCE/APPLICATION

Quantitative assessment of CsOH distribution enables the use of DECT as a viable technique to track injectable image-guided ablations, such as TCA, and ensure therapeutic delivery.

Assessing the Impact of Perfusion on Microwave Ablation Measurements in an Ex Vivo Bovine Kidney Model

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - IR DPS

Participants
Annie Dang, BS, MS, San Antonio, TX (*Presenter*) Nothing to Disclose

PURPOSE

The use of microwave ablation (MWA) for treating early-stage renal cell cancer is on the rise. Currently, manufacturers provide guidance on anticipated treatment margins based on data from nonperfused organs. Organ perfusion has been shown to impact ablation size and understanding this impact is critical to maximize treatment outcomes.?We aim to assess the impact of perfusion on MWA volumes using a perfused ex vivo bovine kidney model.

METHODS AND MATERIALS

Nine bovine kidneys were harvested and kept on ice following transplant protocol. An ex vivo perfusion system consisting of membrane oxygenator, warmer, and blood pressure monitor was used to perfuse the organ using defibrinated bovine blood. Perfusion was initiated within 8 hours of procurement. A MWA system (AngioDynamics Solero) was used to perform 72 ablations (36 perfused, 36 nonperfused) at 9 different power and time device settings (60 W, 100 W, and 140 W for 2, 4, and 6 minutes). Perfused and nonperfused ablations for each kidney were performed at the same device setting to limit variability between kidneys. Each ablation was sectioned along the trajectory of the probe for long axis diameter (LAD) and short axis diameter (SAD) measurements of the zone of coagulation. Two-tailed t-tests were used to compare perfused and non-perfused conditions and linear regression was used to determine the association between ablation volume and device setting.

RESULTS

Collapsed across time settings, there were the following differences in coagulation zone volume by power: 60 W) perfused 2.3 + 1.0 mL versus nonperfused 7.2 + 2.7 mL, p-value < 0.001; 100 W) perfused 5.4 + 2.1 mL versus nonperfused 11.5 + 5.6 mL, p-value < 0.01; and 140 W) perfused 11.2 + 3.7 mL versus nonperfused 18.7 + 6.3 mL, p < 0.01. For all ablation conditions, LAD, SAD, and volume were smaller in perfused groups compared to nonperfused groups. There was a statistically significant difference in ablation volume for 6 of the 9 device settings (p < 0.05). Ablation volume positively correlated with applied power for both perfused and non-perfused ablations, with the following association: perfused, 0.021 cm3/W, R = 0.462, p = 0.004; nonperfused, 0.029 cm3/W, R = 0.565, p < 0.001.?No observed association was identified for applied time and ablation volume (R = 0.001, p = 0.32).

CONCLUSION

s Observed ablation volumes were restricted to the size of the renal lobule, limiting translation of measurements to the clinical setting. This study demonstrates kidneys are highly vascular structures susceptible to the effects of perfusion mediated tissue cooling during MWA.

CLINICAL RELEVANCE/APPLICATION

These findings support clinical anticipation of significantly smaller renal MWA volumes compared to manufacturer data from nonperfused organs.??

W2-SPIR-9

Future Liver Remnant Hypertrophy Following Y-90 Radioembolization Lobectomy with Resin Microspheres

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - IR DPS

Participants
Muhammad Malik, MD, Boston, MA (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the hypertrophy and kinetic growth rate of the future liver remnant (FLR) following Y-90 radioembolization lobectomy with resin microspheres in primary liver cancer.

METHODS AND MATERIALS

A HIPAA compliant, IRB-approved, retrospective review of patients treated with radioembolization lobectomy (RL) using resin microspheres for primary liver cancer from March 2016 to October 2021. Imaging studies were reviewed at three different time points; pre Y90-TARE (T0), < 4 months post Y90-TARE (T1) and > 4 months post Y90-TARE (T2). Exclusion criteria included prior portal vein embolization, Y-90 treatment to contralateral lobe <6-months apart, and tumor in both hepatic lobes. Total liver volume (TLV), treated area volume (TAV), untreated area volume (UAV), and future liver remnant (FLR) at T0, T1 and T2 were manually calculated by a radiology fellow on TeraRecon software. Percentage of hypertrophy of treated lobe was calculated at T1 and T2, and kinetic growth rate (KGR) was calculated by the degree of hypertrophy at T1 over the number of weeks elapsed from the treatment date. Procedure characteristics and patient demographics were recorded. Statistical analysis was performed with paired t-test.

RESULTS

A total of 20 patients (Age: 69+/-10 years, 40% females) with primary liver cancer (40% cholangiocarcinoma, 60% hepatocellular carcinoma) underwent Y-90 radioembolization lobectomy (Table 1). Average Tumor size was 9 cm ± 4 (2-16). 6/15 (40%) tumors were multifocal and 5/15 (33%) were unifocal. The FLR at T0, T1 and T2 was 853 cc (IQR: 597-1291), 1117 cc (IQR: 631-1526) and 1424 cc (IQR: 594-1768), respectively. At T1, the average KGR/week was 2.3% and hypertrophy of 21.4% ($p<0.001$) and at T2 average KGR/week of 1.3%, with hypertrophy of 30% compared to T0 ($P<0.001$). Complete response was found in 13/20 (65%) and partial response in 5/20 (25%) patients. 2/20 (10%) patients progressed in their liver disease. Only 4 (20%) of patients underwent surgical resection.

CONCLUSION

s There is significant difference in hypertrophy of the future liver remnant volume following Y-90 radiation lobectomy with resin microspheres. A 65% of patients had complete treatment response, and only 20% of patients undergoing surgical resection.

CLINICAL RELEVANCE/APPLICATION

Future liver remnant hypertrophy following Y-90 radiation lobectomy is a potential indicator for future liver resection.

W2-SPMK-1 Transient Osteoporosis of the Hip: A Fleeting Diagnosis?

Participants
Aishwarya Gulati, MD, Philadelphia, PA (*Presenter*) Nothing to Disclose

PURPOSE

Transient osteoporosis of the hip (TOH) is a rare, self-limiting clinical diagnosis with unclear etiology. We hypothesize that TOH represents an underlying subchondral insufficiency fracture, and in nearly all cases a discrete fracture is visible on MRI.

METHODS AND MATERIALS

Retrospective PACS query identified patients with intense bone marrow edema (BME) in the femoral head on a hip MRI including small field of view (FOV) sequences, meeting imaging criteria for TOH. Those with avascular necrosis, marrow replacing processes, or history of antecedent trauma were excluded. Demographics and pre-MRI patient questionnaires were reviewed. Three musculoskeletal radiologists independently reviewed each case for presence of a definite subchondral fracture line on small FOV images. Extent of BME, reciprocal BME in the acetabulum, and size of joint effusion were also recorded.

RESULTS

50 patients meeting inclusion criteria were identified (29 females). Mean age was 62±12 years (range 35-84). Average symptom duration before MRI was 102±135 days. 10 patients had DEXA performed within 2 years of MRI, 6 demonstrating osteopenia/osteoporosis. Subchondral fractures were unanimously identified by readers in 44/50 (88%) cases. Interclass correlations coefficient with absolute agreement was 0.73 with 95% CI (0.57-0.84), indicating near-excellent agreement. Most cases demonstrated large joint effusion (24/50, 48%) and acetabular edema (32/50, 64%). Binomial logistic regression assessing impact of age, gender, pain duration, extent of BME and joint effusion identified increasing size of joint effusion as a statistically significant predictor of subchondral fracture ($p=0.05$), with 6.9 higher odds of fracture. There was a strong correlation between osteopenia/osteoporosis on DEXA and presence of subchondral fracture ($p<.001$).

CONCLUSION

s A subchondral fracture line was identified on small FOV imaging in most cases identified as TOH. Findings such as a joint effusion and osteopenia/ osteoporosis have a higher association with subchondral fractures.

CLINICAL RELEVANCE/APPLICATION

The diagnosis of TOH remains pervasive throughout medical literature and radiology reports. We argue that this term is misleading, as the underlying pathology likely reflects underlying subchondral insufficiency fracture. Accurate reporting of this finding is essential for ensuring appropriate conservative treatment.

W2-SPMK-2 The Effect of Pre-Operative MRI Coracoid Dimensions on Latarjet Surgical Outcomes

Participants
Sarah Kamel, MD, Philadelphia, PA (*Presenter*) Nothing to Disclose

PURPOSE

To determine if pre-operative coracoid dimensions correspond with post-operative outcomes in patients treated for recurrent anterior shoulder dislocation by Latarjet coracoid transfer.

METHODS AND MATERIALS

Patients who underwent primary Latarjet surgery between 2009-2019 were identified. Included patients had pre-operative shoulder MRI and minimum of 2-year post-operative follow-up. Coracoid length was measured on axial MRI sequences as the distance from the coracoclavicular (CC) ligament insertion to the distal tip. Width measurements were obtained perpendicular to length at three locations (base, midpoint, tip) and averaged. Comparisons were made between shorter vs. longer coracoid length and width. Outcomes were recurrent instability, re-operation, complications, rate of and time until return-to-sport (RTS), and American Shoulder and Elbow Surgeons (ASES) score.

RESULTS

56 patients were included, 16% female and with a mean age of 28.4 years. Patients with a shorter coracoid length (<22 mm, n=30) had similar rate of recurrent instability (shorter length 6.7% vs. longer length 3.8%; p=0.640), complication (10.0% vs. 15.4%; p=0.543), re-operation (3.3% vs. 7.7%; p=0.592), rate of RTS (76.5% vs. 58.8%; p=0.298), and post-operative ASES scores (85.0 vs. 81.6; p=0.612), relative to patients with a longer coracoid length (>22 mm, n=26). Likewise, patients with a narrower coracoid width (<10 mm, n=29) had similar prevalence of recurrent instability (narrower width 6.9% vs. wider width 3.7%; p=0.596), complication (17.2% vs. 7.4%; p=0.266), re-operation (3.5% vs. 7.4%; p=0.605), rate of RTS (66.7% vs. 68.4%; p=1.000), and post-operative ASES scores (87.1 vs. 80.0; p=0.286), relative to patients with a wider coracoid length (>10 mm, n=27).

CONCLUSION

s Patients undergoing Latarjet coracoid transfer had similar rates of recurrent instability and post-operative outcomes regardless of pre-operative coracoid dimensions.

CLINICAL RELEVANCE/APPLICATION

This MRI protocol for measuring coracoid dimensions closely accounts for the specific landmarks utilized during the Latarjet osteotomy by focusing on identification of the CC ligament insertion.

W2-SPMK-3 Combined Femoral and Acetabular Version is Sex Related in Symptomatic Patients with Hip Dysplasia and Acetabular Retroversion

Participants
Till Lerch, MD, PhD, Bern, Switzerland (*Presenter*) Nothing to Disclose

PURPOSE

Frequency of abnormal femoral and acetabular version(AV) and combined version is unclear in patients with developmental dysplasia of the hip(DDH). This study aimed to investigate mean femoral version(FV), the prevalence of increased FV and femoral retroversion, and combined version (combination of FV and AV) in patients with DDH and acetabular retroversion.

METHODS AND MATERIALS

A retrospective IRB-approved observational study was performed with 78 symptomatic patients(90 hips) with hip pain due to DDH and with 65 patients with femoroacetabular impingement(FAI) due to acetabular retroversion (77 hips). Diagnosis was based on reference values calculated on AP radiographs. CT/MRI-based measurement of FV(Murphy method) and central AV were compared. Frequency of increased FV(FV>25°), severely increased FV(FV>35°) and excessive FV(FV>45°) and of femoral retroversion (FV<10°) was analysed. Combined version is the sum of FV and AV, equal to McKibbin index or COTAV index.

RESULTS

Mean FV and combined version was significantly($p<0.001$) increased of patients with DDH (mean±SD of 25±11° and 47±18°) compared to patients with acetabular retroversion (16±11° and 28±13°). Mean FV of female patients with DDH (27±16°) and acetabular retroversion (19±12°) was significantly($p<0.001$) increased compared to male patients with DDH(18±13°) and acetabular retroversion (13±8°). Frequency of increased FV(FV>25°) was 47%, of severely increased FV(FV>35°) was 23% and excessive FV (FV>45°) was 8% for patients with DDH. Prevalence of femoral retroversion(FV<10°) was significantly($p<0.001$) higher in patients acetabular retroversion(31%) compared to patients with DDH(17%). Combined version of female patients with DDH (51±17°) was significantly($p<0.001$) increased compared to male patients with DDH(37±14°). Of patients with DDH, 18% had AV>25° combined with FV>25°. Of patients with acetabular retroversion, 12% had FV<10° combined with AV<10°.

CONCLUSION

s Patients with DDH have remarkable sex differences of FV(9°) and combined version(14°). Patients with acetabular retroversion can be combined with femoral retroversion. Frequency of severely increased FV>35° (23%) is considerable for patients with DDH, but 17% had femoral retroversion.

CLINICAL RELEVANCE/APPLICATION

Patients with DDH can be combined with increased FV but also with femoral retroversion. This underlines the importance of patient-specific evaluation and could influence internal rotation and postoperative outcome after hip preservation surgery.

W2-SPMK-4 Automatic Segmentation of Pelvic Bones and Measurement of Center Edge Angle on Plain Radiographs Using Deep-Learning Network Trained With Digitally Reconstructed Radiography From CT

Participants
Yisak Kim, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

For the automatic measurement of many orthopedic parameters, accurate bone segmentation is necessary. However, it is often difficult to determine the exact boundary of bone structures on a 2D projection image such as a plain radiograph due to the overlap of bone with other tissues. The digitally reconstructed radiography (DRR) is a synthetic X-ray generated from the CT by projecting the 3D volumetric data onto the 2D plane. We trained a deep-learning model with DRRs to automatically segment pelvic bones and measure lateral center edge angle (CEA) on the actual pelvis anteroposterior (AP).

METHODS AND MATERIALS

A total of 90 pelvis CT scans were used to generate 90 DRRs, and five bone segmentation masks (left and right pelvis, proximal femurs, and sacrum) were also generated for each DRR using the CT segmentation mask. DeepLab v3+ with EfficientNet-B0 encoder was used to develop the segmentation model. The model was validated in the external data of 173 pelvis AP with manually segmented femur masks. The model's performance was evaluated using the Dice similarity score (DSC) and intersection-over-union (IoU). We further developed an automated measurement algorithm of lateral CEA on pelvis AP. First, we found the best fit circle to the femur head using Hough transform. Then, CEA was measured using two lines passing through the center of the circle: a vertical line through the center of the femoral head and a line passing through the lateral acetabular rim.

RESULTS

On DRRs, the deep-learning model showed good performance for the segmentation of five pelvic bones (DSC range, 0.95-0.99; IoU range, 0.91-0.97). On real pelvis AP, the model achieved DSC of 0.97 and IoU of 0.94 for segmenting proximal femur. The medians of manually measured right and left CEA were 41.1 (37.1-45.7) and 37.9 (34.4-43.2), respectively. The predicted CEA had significant correlations with manually measured CEA (right CEA: Pearson's r=0.54, P<.001; left CEA: Pearson's r=0.45, P<.001). The mean absolute errors of predicted right and left CEA were 4.8° and 6.1°, respectively (mean absolute percentage errors, 11.9% and 14.4%).

CONCLUSION

s We developed a deep-learning based bone segmentation model on pelvis AP using DRRs with high accuracy. This segmentation model can be used as a core module for fully automatic radiographic measurement algorithms such as CEA measurements.

CLINICAL RELEVANCE/APPLICATION

Automatic measurements of various orthopedic parameters can overcome the shortcomings of manual measurement, which is time-consuming and suffers from high inter- and intraobserver variability.

There was a strong correlation between osteopenia/osteoporosis on DEXA and presence of subchondral fracture ($p<.001$).

CONCLUSION

s A subchondral fracture line was identified on small FOV imaging in most cases identified as TOH. Findings such as a joint effusion and osteopenia/ osteoporosis have a higher association with subchondral fractures.

CLINICAL RELEVANCE/APPLICATION

The diagnosis of TOH remains pervasive throughout medical literature and radiology reports. We argue that this term is misleading, as the underlying pathology likely reflects underlying subchondral insufficiency fracture. Accurate reporting of this finding is essential for ensuring appropriate conservative treatment.

The Effect of Pre-Operative MRI Coracoid Dimensions on Latarjet Surgical Outcomes

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - MK DPS

Participants
Sarah Kamel, MD, Philadelphia, PA (*Presenter*) Nothing to Disclose

PURPOSE

To determine if pre-operative coracoid dimensions correspond with post-operative outcomes in patients treated for recurrent anterior shoulder dislocation by Latarjet coracoid transfer.

METHODS AND MATERIALS

Patients who underwent primary Latarjet surgery between 2009-2019 were identified. Included patients had pre-operative shoulder MRI and minimum of 2-year post-operative follow-up. Coracoid length was measured on axial MRI sequences as the distance from the coracoclavicular (CC) ligament insertion to the distal tip. Width measurements were obtained perpendicular to length at three locations (base, midpoint, tip) and averaged. Comparisons were made between shorter vs. longer coracoid length and width. Outcomes were recurrent instability, re-operation, complications, rate of and time until return-to-sport (RTS), and American Shoulder and Elbow Surgeons (ASES) score.

RESULTS

56 patients were included, 16% female and with a mean age of 28.4 years. Patients with a shorter coracoid length (<22 mm, n=30) had similar rate of recurrent instability (shorter length 6.7% vs. longer length 3.8%; p=0.640), complication (10.0% vs. 15.4%; p=0.543), re-operation (3.3% vs. 7.7%; p=0.592), rate of RTS (76.5% vs. 58.8%; p=0.298), and post-operative ASES scores (85.0 vs. 81.6; p=0.612), relative to patients with a longer coracoid length (>22 mm, n=26). Likewise, patients with a narrower coracoid width (<10 mm, n=29) had similar prevalence of recurrent instability (narrower width 6.9% vs. wider width 3.7%; p=0.596), complication (17.2% vs. 7.4%; p=0.266), re-operation (3.5% vs. 7.4%; p=0.605), rate of RTS (66.7% vs. 68.4%; p=1.000), and post-operative ASES scores (87.1 vs. 80.0; p=0.286), relative to patients with a wider coracoid length (>10 mm, n=27).

CONCLUSION

s Patients undergoing Latarjet coracoid transfer had similar rates of recurrent instability and post-operative outcomes regardless of pre-operative coracoid dimensions.

CLINICAL RELEVANCE/APPLICATION

This MRI protocol for measuring coracoid dimensions closely accounts for the specific landmarks utilized during the Latarjet osteotomy by focusing on identification of the CC ligament insertion.

Combined Femoral and Acetabular Version is Sex Related in Symptomatic Patients with Hip Dysplasia and Acetabular Retroversion

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - MK DPS

Participants
Till Lerch, MD, PhD, Bern, Switzerland (*Presenter*) Nothing to Disclose

PURPOSE

Frequency of abnormal femoral and acetabular version(AV) and combined version is unclear in patients with developmental dysplasia of the hip(DDH). This study aimed to investigate mean femoral version(FV), the prevalence of increased FV and femoral retroversion, and combined version (combination of FV and AV) in patients with DDH and acetabular retroversion.

METHODS AND MATERIALS

A retrospective IRB-approved observational study was performed with 78 symptomatic patients(90 hips) with hip pain due to DDH and with 65 patients with femoroacetabular impingement(FAI) due to acetabular retroversion (77 hips). Diagnosis was based on reference values calculated on AP radiographs. CT/MRI-based measurement of FV(Murphy method) and central AV were compared. Frequency of increased FV(FV>25°), severely increased FV(FV>35°) and excessive FV(FV>45°) and of femoral retroversion (FV<10°) was analysed. Combined version is the sum of FV and AV, equal to McKibbin index or COTAV index.

RESULTS

Mean FV and combined version was significantly($p<0.001$) increased of patients with DDH (mean±SD of 25±11° and 47±18°) compared to patients with acetabular retroversion (16±11° and 28±13°). Mean FV of female patients with DDH (27±16°) and acetabular retroversion (19±12°) was significantly($p<0.001$) increased compared to male patients with DDH(18±13°) and acetabular retroversion (13±8°). Frequency of increased FV(FV>25°) was 47%, of severely increased FV(FV>35°) was 23% and excessive FV (FV>45°) was 8% for patients with DDH. Prevalence of femoral retroversion(FV<10°) was significantly($p<0.001$) higher in patients acetabular retroversion(31%) compared to patients with DDH(17%). Combined version of female patients with DDH (51±17°) was significantly($p<0.001$) increased compared to male patients with DDH(37±14°). Of patients with DDH, 18% had AV>25° combined with FV>25°. Of patients with acetabular retroversion, 12% had FV<10° combined with AV<10°.

CONCLUSION

s Patients with DDH have remarkable sex differences of FV(9°) and combined version(14°). Patients with acetabular retroversion can be combined with femoral retroversion. Frequency of severely increased FV>35° (23%) is considerable for patients with DDH, but 17% had femoral retroversion.

CLINICAL RELEVANCE/APPLICATION

Patients with DDH can be combined with increased FV but also with femoral retroversion. This underlines the importance of patient-specific evaluation and could influence internal rotation and postoperative outcome after hip preservation surgery.

Automatic Segmentation of Pelvic Bones and Measurement of Center Edge Angle on Plain Radiographs Using Deep-Learning Network Trained With Digitally Reconstructed Radiography From CT

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - MK DPS

Participants
Yisak Kim, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

For the automatic measurement of many orthopedic parameters, accurate bone segmentation is necessary. However, it is often difficult to determine the exact boundary of bone structures on a 2D projection image such as a plain radiograph due to the overlap of bone with other tissues. The digitally reconstructed radiography (DRR) is a synthetic X-ray generated from the CT by projecting the 3D volumetric data onto the 2D plane. We trained a deep-learning model with DRRs to automatically segment pelvic bones and measure lateral center edge angle (CEA) on the actual pelvis anteroposterior (AP).

METHODS AND MATERIALS

A total of 90 pelvis CT scans were used to generate 90 DRRs, and five bone segmentation masks (left and right pelvis, proximal femurs, and sacrum) were also generated for each DRR using the CT segmentation mask. DeepLab v3+ with EfficientNet-B0 encoder was used to develop the segmentation model. The model was validated in the external data of 173 pelvis AP with manually segmented femur masks. The model's performance was evaluated using the Dice similarity score (DSC) and intersection-over-union (IoU). We further developed an automated measurement algorithm of lateral CEA on pelvis AP. First, we found the best fit circle to the femur head using Hough transform. Then, CEA was measured using two lines passing through the center of the circle: a vertical line through the center of the femoral head and a line passing through the lateral acetabular rim.

RESULTS

On DRRs, the deep-learning model showed good performance for the segmentation of five pelvic bones (DSC range, 0.95-0.99; IoU range, 0.91-0.97). On real pelvis AP, the model achieved DSC of 0.97 and IoU of 0.94 for segmenting proximal femur. The medians of manually measured right and left CEA were 41.1 (37.1-45.7) and 37.9 (34.4-43.2), respectively. The predicted CEA had significant correlations with manually measured CEA (right CEA: Pearson's r=0.54, P<.001; left CEA: Pearson's r=0.45, P<.001). The mean absolute errors of predicted right and left CEA were 4.8° and 6.1°, respectively (mean absolute percentage errors, 11.9% and 14.4%).

CONCLUSION

s We developed a deep-learning based bone segmentation model on pelvis AP using DRRs with high accuracy. This segmentation model can be used as a core module for fully automatic radiographic measurement algorithms such as CEA measurements.

CLINICAL RELEVANCE/APPLICATION

Automatic measurements of various orthopedic parameters can overcome the shortcomings of manual measurement, which is time-consuming and suffers from high inter- and intraobserver variability.

Multisystem Wednesday Poster Discussion

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - MS DPS

Sub-Events

W2-SPMS-1 Splenic Size and Volume Measurements in Patients with Chronic Lymphocytic Leukemia

Participants
Olanrewaju Ogunleye, MBBS, Bethesda, MD (*Presenter*) Nothing to Disclose

PURPOSE

To determine which methods of assessment of splenic size most accurately represent the actual spleen volume in patients with Chronic Lymphocytic Leukemia (CLL).

METHODS AND MATERIALS

The Abdominal Computed Tomography images of 48 patients with CLL enrolled on a phase 2 clinical trial at two time-points before and after 2-months of continous acalabrutinib treatment were analyzed. Linear one-dimensional measurements of the spleen were taken in different planes. Two-dimensional and three-dimensional measurements were calculated from the linear measurements using mathematical formulae. The spleen volume was determined by manual segmentation as the ground truth. Data derived were analyzed using the Pearson correlation and statistical significance was set at $p<0.05$.

RESULTS

Among the single-dimensional measurements, the strongest correlation with the segmented splenic volume was the sagittal long axis diameter (LAD) ($r=0.89$, $p<0.05$), followed closely by Coronal LAD ($r=0.87$, $p<0.05$) and craniocaudal length (iwCLL) ($r=0.84$, $p<0.05$). For the two-dimensional indices, the sum of LAD and short axis diameter (SAD) of the spleen in axial plane showed good correlation with the splenic volume ($r=0.77$, $p<0.05$). Among the three-dimensional indices, the splenic index (0.523 x axial LAD x axial SAD x coronal height) and a formula for volume (30 + 0.58 x axial LAD x axial SAD x coronal height) had the strongest correlation (both $r=0.92$, $p<0.05$) with the spleen volume.

CONCLUSION

s Three-dimensional formulae showed the strongest correlation with volumetric reference spleen measurement in patients with CLL. Among unidimensional measurements, the sagittal LAD had the best correlation with the actual splenic volume. The two-dimensional calculation methods were less reliable.

CLINICAL RELEVANCE/APPLICATION

In patients with CLL, when volumetric measurement is not available, the three-dimensional formulae is the best estimate of absolute splenic volume. Among the various types of unidirectional measurements, the sagittal LAD most accurately estimates absolute splenic volume.

W2-SPNMMI-1 Standardization of Quantitative Imaging Biomarkers of Lung Cancer Using Simulated 18F-FDG PET/CT Studies

Participants
Pablo Aguiar, (*Presenter*) Research Consultant, Qubiotech Health Intelligence

PURPOSE

To develop and validate a new methodology for the standardization of PET biomarkers in lung cancer based on simulated 18F-FDG PET/CT studies.

METHODS AND MATERIALS

Our methodology is based on the generation of simulated 18F-FDG PET/CT studies using a large database of lung tumour maps cropped from patient images. All lung tumour maps were randomly positioned into whole-body physiological 18F-FDG activity and attenuation maps. These activity/attenuation maps (which defines our ground-truth values) were entered as inputs for Monte Carlo simulation models of PET scanners from the SimPET platform (sim-pet.org), leading to the generation of simulated 18F-FDG PET/CT studies. This simulated database was used for the standardization of PET biomarkers in terms of tumour segmentation methods, both CT-based volumes (VOICT) and PET-based volumes with different thresholds (VOIPET25, VOIPET35 and VOIPET45). The standardization procedure was carried out through comparison between commonly used PET biomarkers in lung cancer and their corresponding ground-truth values.

RESULTS

We generated a large database of simulated 18F-FDG PET/CT images from 70 lung cancer patients [age: 47-87 years; stages I (11), II (2), III (23) and IV(25)]. It was characterized by the following ground-truth PET biomarkers (range): SUVr (0.7-8.9), MTV (0.94-140.9), Entropy (6.6-7.7), Dissimilarity (5.0-16.6), Homogeneity (0.12-0.28), Contrast (44.7-407.5), ZP (788-22408) and HILAE (0.04-0.6). The standardization analysis showed SUVr was strongly underestimated when using VOICT (-30%), but not when using VOIPET45 (2%) or VOIPET35(5%). Instead, MTV was strongly underestimated using VOIPET45 (-48%) but not using VOICT. Regarding texture features, Entropy, Dissimilarity and ZP were accurately estimated using VOIPET35 (8%) and Homogeneity, Contrast and HILAE using VOIPET45 (7%), while VOICT and VOICPET25 showed larger biases.

CONCLUSION

s A new methodology was developed and validated for the standardization of PET biomarkers commonly used in lung cancer diagnosis using simulated 18F-FDG PET/CT studies. Our standardization study was carried out in terms of tumour delineation methods but our methodology can be used for the standardization of many others quantification methods or PET biomarkers.

CLINICAL RELEVANCE/APPLICATION

This is the first study proposing the standardization of quantitative PET biomarkers based on ground-truth measurements from patient 18F-FDG PET studies (other standardization procedures are commonly based on phantom measurements).All databases will be made available for the scientific community through the SimPET platform (sim-pet.org) for the further standardization of quantification methods or additional PET biomarkers.

W2-SPNMMI-2 Cartilage-targeting MnOx Nanoparticles Enhance Magnetic Resonance Detection and Cartilage Repair in Early Osteoarthritis

Participants
Ting Lin, Guangzhou, China (*Presenter*) Nothing to Disclose

PURPOSE

Osteoarthritis (OA) is one of the leading causes of adult morbidity and disability worldwide. While the early detection and repair of cartilage lesions are crucial in the treatment of OA, they remain challenging because neither clinically used medicines nor magnetic resonance (MR) contrast agents can achieve detection and repair simultaneously. The purpose of this study was to develop theragnostic nanomaterials with optimal sizes, good biocompatibility, MR imaging and cartilage repair capability for OA therapy.

METHODS AND MATERIALS

We conjugated carboxymethyl chitosan (CMC) with a cartilage-targeting peptide (WY) and then synthesized CMC-assisted manganese oxide (MnOx) NPs. The in vitro T1 relaxivity values of the NPs were quantified using a 3T MR scanner (Ingenia, Philip Healthcare, Best, Netherlands). The r1 relaxivity was calculated by linearly fitting the inverse T1 relaxation time against the Mn2+ concentration of the NPs. WY-CMC-MnOx, non-cartilage-targeting LR-CMC-MnOx, or CMC-MnOx NPs were intraarticularly injected into the right knee joints of OA rats (destabilization of the medial meniscus model). The MR scans were conducted using a 7.0T animal MR imaging scanner (PharmaScan70/16 US, Bruker BioSpin MRI GmbH, Germany) equipped with a volumetric transmitter coil with an 86-mm inner diameter and a rat head surface receiver coil. The sagittal fat-saturated T1-weighted images were acquired with the following parameters: TR = 867.5 ms, TE = 6.5 ms, field of view = 22 × 32 mm, slice thickness = 0.7 mm, matrix dimensions = 184 × 266 × 16 slices, pixel bandwidth = 1050, and acquisition time = 3 min, 59 s. All rats underwent MR scans before the injections of the NPs (baseline images) and at 24 h after injection. The T1-weighted MR signal intensities within the regions of interest (ROIs; ~0.002 cm2) were acquired. The trend of signal changes was determined by plotting ?SNR versus time. In vivo therapeutic effects of the NPs in DMM rat models were studied.

RESULTS

WY-CMC-MnOx NPs demonstrated an excellent biocompatibility and a good T1 relaxivity of 1.72 Mm-1·s-1. Owing to their ultrasmall size and cartilage-targeting ability, the WY-CMC-MnOx NPs considerably increased the MR imaging quality of cartilage lesions compared to non-cartilage-targeting LR-CMC-MnOx and CMC-MnOx NPs. In contrast, clinically used Gd-DPTA failed to detect the cartilage lesions. Furthermore, WY-CMC-MnOx enhanced OA therapy through efficient cartilage regeneration after intraarticularly injection in rats with early OA .

CONCLUSION

s WY-CMC-MnOx NPs were successfully developed as new theranostic agents for OA therapy.

CLINICAL RELEVANCE/APPLICATION

WY-CMC-MnOx NPs are promising for use in the diagnosis and treatment of early OA.

W2-SPNPM-1 Impact of Neighborhood Socioeconomic Deprivation on Access to ACR Accredited Cross Sectional Imaging Facilities

Participants
Anand Narayan, MD, PhD, Verona, WI (*Presenter*) Nothing to Disclose

PURPOSE

Evaluate the effects of neighborhood deprivation at the zip code level on access to ACR accredited cross sectional imaging facilities.

METHODS AND MATERIALS

Area deprivation index (ADI) values were obtained from the University of Wisconsin Neighborhood Atlas, based on a validated HRSA measure that allows for national rankings of zip code level socioeconomic disadvantage. Disadvantage was dichotomized (high >=97th ADI percentile, low <=3rd ADI percentile). Urban/rural status was defined from US Department of Agriculture rural-urban commuting area (RUCA) codes. Outcomes included the presence or absence of ACR accredited cross sectional imaging facilities (yes/no). Chi square tests were used to evaluate the association between access and geographic disadvantage, stratified by urban/rural status.

RESULTS

Among 41,683 zip codes across the US, 2,796 were disadvantaged (1,160 rural, 1,636 urban) and 1,028 were advantaged (39 rural, 989 urban). Disdvantaged zip codes were more likely to be located in rural areas ($p < 0.001$). Disadvantaged zip codes were less likely to have access to ACR accredited CT facilities (21 vs 32%, $p < 0.001$), MRI (19 vs 32%, $p < 0.001$), nuclear medicine (11 vs 18%, $p < 0.001$), PET (7 vs 13%, $p < 0.001$), ultrasound (14 vs 29%, $p < 0.001$), lung cancer screening centers of excellence (5 vs 12%, $p < 0.001$), diagnostic centers of excellence (1 vs 4%, $p < 0.001$), and accredited radiation oncology facilities (3 vs 8%, $p < 0.001$). Among urban areas, disadvantaged zip codes were less likely to have access to ACR accredited CT facilities (26 vs 33%, $p < 0.001$), MRI (25 vs 33%, $p < 0.001$), nuclear medicine (15 vs 19%, $p = 0.007$), PET (9 vs 13%, $p = 0.003$), ultrasound (20 vs 30%, $p < 0.001$), lung cancer screening centers of excellence (7 vs 13%, $p < 0.001$), diagnostic centers of excellence (2 vs 4%, $p < 0.001$), and accredited radiation oncology facilities (5 vs 8%, $p = 0.001$). Analyses for rural areas were limited by small numbers of advantaged zip codes.

CONCLUSION

s Zip codes with high levels of socioeconomic disadvantage were less likely to have ACR accredited cross sectional imaging facilities, ACR centers of excellence and accredited radiation oncology facilities.

CLINICAL RELEVANCE/APPLICATION

Reducing disparities in access to quality imaging services will require radiology leaders to expand services in high disadvantage areas.

W2-SPNPM-2 Usability of Hospital Price Estimators for Lumbar Spine MRI

Participants
Meagan Bechel, MD, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

Evaluate usability of online hospital price estimators for a common imaging examination using surrogate patients

METHODS AND MATERIALS

Using the Amazon MTurk platform, we recruited adult English-speaking US-residents as surrogate patients to find the cash price for a non-contrast lumbar spine MRI examination for a self-pay patient using price estimator tools at four hospitals. All were asked to view a 3-minute tutorial video and report their experiences with the task, including the System Usability Scale (SUS) for the estimator, through a paid survey. We queried participants about demographics, insurance, prior imaging exposure, and assessed health literacy and health insurance literacy (HIL) using validated measures. Multivariable analysis for correct price identification and price estimator SUS were performed.

RESULTS

Of 660 respondents, 397 met eligibility criteria (70.8% <45 years; 43.8% female; 83.8% White). 84% found all four estimators; 1.5% were unable to locate any. Only 32% found the correct price at all four hospitals; 20.6% did not find any correct prices. Average SUS for the hospitals' estimators ranged between 63.0 and 78.8. The hospital with a similar estimator to that used in the tutorial video had highest SUS. Accuracy of price identification improved with later tasks. Higher HIL was associated with higher identification of at least one correct price (B,3.0;95%CI,0.6-5.4, p<0.01) and higher SUS (B,14.7; 95%CI, 9.4-20.1, p<0.001).

CONCLUSION

s Surrogate patients were able to locate hospital price estimators, but unable to effectively use them to obtain correct prices. Tutorial videos improved SUS, but correct price identification improved with practice.

CLINICAL RELEVANCE/APPLICATION

Hospital price estimators score average or below average on usability and cannot be successfully utilized by the majority of educated paid surrogate patients. Though usability improves with a tutorial video, both increased usability and health insurance literacy are necessary for price estimator tools to be accessible and beneficial. Therefore, they may represent an additional, but mitigatable barrier to equitable and timely evidence-based care.

Impact of Neighborhood Socioeconomic Deprivation on Access to ACR Accredited Cross Sectional Imaging Facilities

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - NPM DPS

Participants
Anand Narayan, MD, PhD, Verona, WI (*Presenter*) Nothing to Disclose

PURPOSE

Evaluate the effects of neighborhood deprivation at the zip code level on access to ACR accredited cross sectional imaging facilities.

METHODS AND MATERIALS

Area deprivation index (ADI) values were obtained from the University of Wisconsin Neighborhood Atlas, based on a validated HRSA measure that allows for national rankings of zip code level socioeconomic disadvantage. Disadvantage was dichotomized (high >=97th ADI percentile, low <=3rd ADI percentile). Urban/rural status was defined from US Department of Agriculture rural-urban commuting area (RUCA) codes. Outcomes included the presence or absence of ACR accredited cross sectional imaging facilities (yes/no). Chi square tests were used to evaluate the association between access and geographic disadvantage, stratified by urban/rural status.

RESULTS

Among 41,683 zip codes across the US, 2,796 were disadvantaged (1,160 rural, 1,636 urban) and 1,028 were advantaged (39 rural, 989 urban). Disdvantaged zip codes were more likely to be located in rural areas ($p < 0.001$). Disadvantaged zip codes were less likely to have access to ACR accredited CT facilities (21 vs 32%, $p < 0.001$), MRI (19 vs 32%, $p < 0.001$), nuclear medicine (11 vs 18%, $p < 0.001$), PET (7 vs 13%, $p < 0.001$), ultrasound (14 vs 29%, $p < 0.001$), lung cancer screening centers of excellence (5 vs 12%, $p < 0.001$), diagnostic centers of excellence (1 vs 4%, $p < 0.001$), and accredited radiation oncology facilities (3 vs 8%, $p < 0.001$). Among urban areas, disadvantaged zip codes were less likely to have access to ACR accredited CT facilities (26 vs 33%, $p < 0.001$), MRI (25 vs 33%, $p < 0.001$), nuclear medicine (15 vs 19%, $p = 0.007$), PET (9 vs 13%, $p = 0.003$), ultrasound (20 vs 30%, $p < 0.001$), lung cancer screening centers of excellence (7 vs 13%, $p < 0.001$), diagnostic centers of excellence (2 vs 4%, $p < 0.001$), and accredited radiation oncology facilities (5 vs 8%, $p = 0.001$). Analyses for rural areas were limited by small numbers of advantaged zip codes.

CONCLUSION

s Zip codes with high levels of socioeconomic disadvantage were less likely to have ACR accredited cross sectional imaging facilities, ACR centers of excellence and accredited radiation oncology facilities.

CLINICAL RELEVANCE/APPLICATION

Reducing disparities in access to quality imaging services will require radiology leaders to expand services in high disadvantage areas.

Usability of Hospital Price Estimators for Lumbar Spine MRI

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - NPM DPS

Participants
Meagan Bechel, MD, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

Evaluate usability of online hospital price estimators for a common imaging examination using surrogate patients

METHODS AND MATERIALS

Using the Amazon MTurk platform, we recruited adult English-speaking US-residents as surrogate patients to find the cash price for a non-contrast lumbar spine MRI examination for a self-pay patient using price estimator tools at four hospitals. All were asked to view a 3-minute tutorial video and report their experiences with the task, including the System Usability Scale (SUS) for the estimator, through a paid survey. We queried participants about demographics, insurance, prior imaging exposure, and assessed health literacy and health insurance literacy (HIL) using validated measures. Multivariable analysis for correct price identification and price estimator SUS were performed.

RESULTS

Of 660 respondents, 397 met eligibility criteria (70.8% <45 years; 43.8% female; 83.8% White). 84% found all four estimators; 1.5% were unable to locate any. Only 32% found the correct price at all four hospitals; 20.6% did not find any correct prices. Average SUS for the hospitals' estimators ranged between 63.0 and 78.8. The hospital with a similar estimator to that used in the tutorial video had highest SUS. Accuracy of price identification improved with later tasks. Higher HIL was associated with higher identification of at least one correct price (B,3.0;95%CI,0.6-5.4, p<0.01) and higher SUS (B,14.7; 95%CI, 9.4-20.1, p<0.001).

CONCLUSION

s Surrogate patients were able to locate hospital price estimators, but unable to effectively use them to obtain correct prices. Tutorial videos improved SUS, but correct price identification improved with practice.

CLINICAL RELEVANCE/APPLICATION

Hospital price estimators score average or below average on usability and cannot be successfully utilized by the majority of educated paid surrogate patients. Though usability improves with a tutorial video, both increased usability and health insurance literacy are necessary for price estimator tools to be accessible and beneficial. Therefore, they may represent an additional, but mitigatable barrier to equitable and timely evidence-based care.

W2-SPNR-1 Quantitative Analysis of Ischemic Infarct Lesion Distribution in Term Neonates With Increasing Severity of Hypoxic Ischemic Encephalopathy

Participants
Pratheek Bobba, BS, New Haven, CT (*Presenter*) Nothing to Disclose

PURPOSE

Hypoxic ischemic encephalopathy (HIE) is a serious cause of long-term disability and mortality in neonates. The topographic pattern of HIE parenchymal injury as seen on DWI helps with differentiation of hypoxic brain injury from other potential mechanisms and prognostic categorization of HIE severity. Thus far, topographic patterns of HIE distribution and their relationship with HIE severity have been described subjectively. In this study, we use quantitative methodologies to characterize the location of ischemic lesions in term neonates with varying severity of HIE.

METHODS AND MATERIALS

We analyzed the imaging and health records of term neonates (>36 postmenstrual gestational week) who had MRI/DWI at our center (01/2013 to 03/2021) with radiological and clinical findings of HIE. Neonates were then categorized into mild, moderate, and severe HIE based on Sarnat classification (Arch Neurol 1976;33:695-705), inferred from medical records. We manually segmented ischemic lesions from DWI scans and co-registered them to a standard brain space. We mapped all lesions to one hemisphere for generation of lesion summation maps; and used voxel wise general linear models (GLM) to identify regions of the brain more likely to be infarcted in neonates with increasing severity of HIE.

RESULTS

We included 33 neonates; 20 with mild, 7 with moderate, and 6 with severe HIE. Median gestational ages at scan (interquartile) were 40.18 (37.81 - 41.77), 40.14 (38.77 - 41.25), and 41.33 (39.69 - 41.79) weeks respectively for the mild, moderate, and severe groups (p=0.31). Median infarct volumes (interquartile) were 2.32 (0.71 - 15.42), 115.24 (65.14 - 124.16), and 28.56 (18.62 - 52.24) mL respectively for the mild, moderate, and severe groups (p=0.15). In summation maps, ischemic lesions in neonates with mild and moderate HIE were predominantly in subcortical and deep white matter along the border zone of arterial supply territories, while ischemic lesions in neonates with severe HIE involved basal ganglia, hippocampus, and thalamus in addition to white matter (Figure 1A). In voxel wise GLM analysis, higher severity of HIE was significantly associated with the presence of ischemic lesions in hippocampus, medial thalamus, and posterior putamen, after correction for infant volume as a covariate (Figure 1B).

CONCLUSION

s In quantitative analysis of term neonates, mild and moderate HIE infarct lesions were mostly localized to arterial territory border zone white matter, while severe HIE was significantly associated with infarction of basal ganglia and hippocampi.

CLINICAL RELEVANCE/APPLICATION

Objective and quantitative assessment of ischemic lesion topography helps with diagnostic differentiation of mechanisms of brain injury and prognostication of HIE in term neonates.

W2-SPNR-10 Achieving Human-Level Performance for Artificial Intelligence-Based Brain Metastasis Detection by Combining Black-Blood Contrast-Enhanced MRI

Participants
Ji Eun Park, MD, PhD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To validate updated AI adding black-blood imaging for detection of brain metastasis by comparing its performance with AI based on GRE-T1WI alone and human readers.

METHODS AND MATERIALS

In this retrospective study, AI was developed with GRE-T1WI (GRE AI) and adding black-blood imaging (combined AI) using 503 brain metastasis dataset. The AI was validated in 62 consecutive patients who underwent both black-blood imaging and GRE-T1WI for diagnostic purposes and subsequent GRE-T1WI for planning of stereotactic radiosurgery between September 2021 and January 2022. Per-lesion detection sensitivity and positive predictive value (PPV) were measured. Two human readers independently performed lesion detection on both exams. The relative difference (RD) from the reference standard numbers of metastases was

compared between human readers and AI.

RESULTS

Sixty-two patients were included for clinical validation (mean age 63.3 years, 53% male). Sensitivity was similar between GRE AI (93%, 95% confidence interval [CI]: 90-96%) and combined AI (92%, 95% CI: 89-94%, p=.506). The positive predictive value of the combined AI was significantly higher (89%, 95% CI: 86-92%, p<.001) than that of GRE AI (76%, 95% CI: 72-80%). GRE AI significantly overestimated metastases (RD: 0.05, 95% CI: 0.00-0.58) compared with human readers (RD: 0.00, 95% CI: -0.28, 0.15, p<.001), whereas the combined AI (RD: 0.00, 95% CI: 0.00-0.15) did not show a significant difference from human readers (RD: 0.00, 95% CI: -0.20-0.10, p=.913).

CONCLUSION

s The brain metastasis detection AI combined with black-blood imaging showed improved detection of true positive metastases and reduced overestimation, achieving similar performance to human readers.

CLINICAL RELEVANCE/APPLICATION

Artificial intelligence-based brain metastasis detection algorithm that incorporates black-blood imaging can help to increase true positive detections and reduce overestimation, achieving similar performance to a human reader.

W2-SPNR-11 Comparing Machine Learning Techniques to Recognize Parathyroid Adenomas from 4D CT Data

Participants
Cynthia Greene, MD, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

Support vector machine (SVM) analysis is a linear learning approach using measurements on images to make predictions. Convolutional neural network (CNN) analysis is a sophisticated technique for machine learning that uses images to make predictions. Both of these methods use known data to build a model for predictions. Parathyroid adenomas are tumors with an early enhancement pattern that is used to help identify them to aid in detection and surgical planning. This study aims to compare SVM and CNN analyses on the accuracy of identifying parathyroid adenomas.

METHODS AND MATERIALS

This is a HIPPA compliant retrospective study with IRB approval. Informed consent was waived. Ninety-three 4D-CTs of patients with pathology-proven parathyroid adenomas were reviewed; 94 parathyroid adenomas (1 case had 2 adenomas) and 112 lymph nodes. The mean attenuation of the lesion of interest in HU of each acquired phase (0, 25, 50, 75 sec) is used to build a model in the SVM analysis. A 2D slice through the lesions in each phase is used to perform sequence classification with ResNet50 as the pre-trained network to construct the CNN model in MatLab. The data is split randomly between a model and validation data set in a 2:1 ratio. The area under the curve (AUC) and accuracy are calculated for the model and validation data sets.

RESULTS

The plot of the enhancement curves of parathyroid adenomas demonstrates early enhancement with washout, while lymph nodes have persistent enhancement. On the model data, the AUC of the CNN is 0.99 while the SVM is 0.95. The overall accuracy of the CNN on the validation data set is 92%, while the SVM is 88%. The accuracy for parathyroid adenomas specifically is 93% for the CNN and 83% for the SVM model.

CONCLUSION

s Both SVM and CNN models discriminate between parathyroid adenomas and lymph nodes well (88% vs. 92%), showing that lesion enhancement alone plays a significant role in distinguishing tissue types. The CNN more accurately identifies parathyroid adenomas in the validation data set than the SVM analysis, showing that using both spatial and enhancement information helps distinguish between features of parathyroid adenomas and lymph nodes better than enhancement alone. One of the limitations of this study is the limited number of lesions; more lesions would help clarify the statistics for these models, especially with variation in lesion shape and size. Comparing techniques like the SVM and CNN models can help identify imaging features to differentiate between lesions.

CLINICAL RELEVANCE/APPLICATION

Machine learning algorithms will enhance detection and provide insight into imaging features identifiable with parathyroid adenomas using 4D CT data.

W2-SPNR-12 NeuroScreener: Quantized Vector Embedded Autoencoder-based Abnormality Classifier from Brain MRI

Participants
Jimin Kang, (*Presenter*) Employee, NEUROPHET, Inc

PURPOSE

In this work, we propose a novel framework that is the first of its kind to detect identifiable abnormalities that may be present in the images to reduce time and effort in the clinical practice by assisting clinicians' brain image reading.

METHODS AND MATERIALS

A dataset for this study was a T1-weighted brain MRI dataset with normal and anomalous images collected from the multicenter including ADNI, SNUH, CMCH, and YUHS. The anomalous images were categorized into three. First was defined as MR images with a severe artifact such as insufficient field of view (FOV), external foreign body (EFB), motion, and a spike which may not be proper for further interpretation of the image. We further included de-faced or skull-stripped images, which are preprocessed unintentionally and/or improperly for further processing or interpretation. Lastly, we also included MR images with large infarction, which may produce inferior results for the routine segmentation process. The normal MR image has no aforementioned abnormality. In this study, we utilized a residual block-based variational autoencoder (VAE) as a backbone network. The vector quantization (VQ) module performs that the continuous feature of the latent space was mapped to a trainable discrete embedding vector by a predetermined number. The output value of the discrete embedding space is then connected to the fully connected layer to classify the input T1 MR image. We trained our VQ-based network using the weighted summation of VQ loss, reconstruction loss,

and Binary Cross Entropy (BCE) loss. The VQ loss was then used to calculate the loss for the VQ module. The Mean Squared Error (MSE) loss was calculated between the generated output image from the decoder and the input image. Additionally, we empirically adjusted the parameters for the loss function by histogram analysis of the distribution of the output loss.

RESULTS

Our results presented the accuracy as high as 95%, and Area Under Receiver Operating Characteristic (AUROC) showed as high as 0.9778. The mean accuracy of seven types of anomalies we investigated showed 89%.

CONCLUSION

s In this study, an image generator-based classifier was proposed to detect abnormality present in MR images using VAE, which is applied to the VQ module adaptively. The proposed framework has shown high performance in all matrices.

CLINICAL RELEVANCE/APPLICATION

We hope this study could assist the radiologists by replacing the time-consuming image reading process with a faster and more efficient image reading, which could provide the anomaly information that MRI may have.

W2-SPNR-13 Value Proposition of Food and Drug Administration (FDA)-Approved Artificial Intelligence (AI) Algorithms for Neuroimaging

Awards
Trainee Research Prize - Resident

Participants
Suryansh Bajaj, MD, New Haven, CT (*Presenter*) Nothing to Disclose

PURPOSE

The number of FDA-approved artificial intelligence (AI) algorithms for neuroimaging has grown in the last decade. The adoption of these algorithms into clinical practice depends largely on whether this technology provides significant value to radiologists in the clinical setting. The objective of this study is to understand current trends in FDA-cleared AI algorithms for neuroimaging and understand the value proposition of these algorithms as advertised by the developer.

METHODS AND MATERIALS

We extracted a list of FDA-approved neuroimaging AI algorithms from the American College of Radiology (ACR) Data Science Institute AI Central database from May 2008 to January 2022. Product information of each device was collected from the database. For each device, we collected information of advertised value as presented on the developer's website.

RESULTS

The database includes a total of 54 AI neuroimaging algorithms that were cleared by the FDA between May 2008 and January 2022. A majority of the algorithms (28/54, 51.9%) were compatible with CT images with 22 (40.7%) compatible with MR and 4 compatible with CTP and CTA (7.4%). Nine algorithms (16.7%) were compatible with multiple imaging modalities. Of these algorithms, 53 (98.1%) were approved with a 510(k) clearance and 1 (1.9%) received de novo clearance. Out of the 54 algorithms, we found websites that discussed the product for 51 algorithms. The most widely advertised value proposition was improved quality of care (34/51, 66.7%). A total of 19 algorithms (37.3%) argued they saved the user time, 8 (15.7%) decreased costs, and 6 (11.8%) increased revenue. Product websites for 24 algorithms (47.1%) showed testimonials advertising the value of the technology. Subgroup analysis was performed to compare algorithms compatible with CT to those with MRI and the algorithms involved in ICH to those in LVO.

CONCLUSION

s Our results indicate a wide range of value propositions advertised by developers to indicate the value of their product. Most developers argued that their product would improve patient care. Further research is necessary to determine whether the value advertised by the developer is actually demonstrated in clinical practice.

CLINICAL RELEVANCE/APPLICATION

Given the rapid growth in the number, availability, and clinical application of AI algorithms across the US, it is important to understand different uses and value propositions provided by these software in current practice.

W2-SPNR-14 Exploring Functional Connectivity in Chronic SCI Patients with Neuropathic Pain versus without Neuropathic Pain

Participants
Adam Flanders, MD, Philadelphia, PA (*Presenter*) Nothing to Disclose

PURPOSE

Spinal cord injury (SCI) causes debilitating chronic pain. Despite decades of research, the pain pathway of neuropathic pain (NP) is unknown. Several lines of evidence show abnormal functioning of the brain in patients with SCI. We hypothesize that in patients with SCI and neuropathic pain the pain matrix is altered compared to patients with SCI without neuropathic pain.

METHODS AND MATERIALS

This study examines the functional connectivity (FC) in SCI patients with moderate-severe chronic neuropathic pain compared to SCI patients with mild-no neuropathic pain. These groups were compared to control subjects. Subjects completed the Neuropathic Pain questionnaire and completed a neurological evaluation based on the International Standard Neurological Classification of SCI to define severity and level of injury. Of the 8 participants with SCI, 5 (44.8±17.56 y.o, 4M and 1F) indicated they had NP and 3 did not have NP (37.33±9.24 y.o, 2M and 1F). We also included 10 uninjured neurologically intact controls (24.8±4.61 y.o, 5M and 5F). FC metrics were obtained from the comparisons of resting state functional magnetic resonance imaging amongst our various groups (uninjured controls, SCI with NP and SCI without NP). For each comparison, an ROI-to-ROI connectivity analysis was pursued, encompassing a total of 170 ROIs based on a customized atlas derived from AAL3 atlas. The analysis accounted for covariates such as age and gender. To correct for multiple comparisons, a strict Bonferroni correction was applied with a significance level of

p<0.05/NROIs.

RESULTS

When comparing the SCI cohort with uninjured subjects our results show statistically significant decreased FC in various thalamic nuclei including: medial and lateral pulvinar, lateral geniculate nucleus, and mediodorsal magnocellular. We postulate these findings are associated with suppressed inhibitory inputs from the zona incerta (ZI) and the anterior pretectal nucleus (APT) in those with NP following SCI. The suppressed inhibitory input causes enhanced activity at the posterior nucleus of the thalamus, S1 and thalamic nuclei regulated by ZI/APT. There were no significant differences of FC in patients with SCI without NP pain compared to controls.

CONCLUSION

s Manipulations that enhance the activity of ZI/APT can improve the treatment in SCI pain. Additionally, the loss of inhibition within the thalamus and abnormal thalamocortical interactions can predispose patients for the development of chronic pain.

CLINICAL RELEVANCE/APPLICATION

Our findings complement results from other neuroimaging studies and provide multi-modal evidence for identifying novel regions of the brain specific to the SCI cohort. These regions can serve as therapeutic targets to improve SCI neuropathic pain patients.

W2-SPNR-15 A Deep Learning Algorithm Trained with Multiphase CTA Images Could Improve Collateral Circulation Assessment in Acute Ischemic Stroke

Participants
Jingjie Wang, (*Presenter*) Nothing to Disclose

PURPOSE

We tried to build a deep learning-based, objective, fast, and accurate collateral circulation assessment model.

METHODS AND MATERIALS

We collected 92 acute ischemic stroke (AIS) patients with large vessel occlusion in the anterior circulation in our hospital from June 2020 to August 2021. We analyzed their baseline one-stop whole-brain four-dimensional computed tomography angiography (4D-CTA)/CT perfusion. The images of the arterial, arteriovenous, venous, and late venous phases were extracted from 4D-CTA according to the perfusion time density curve. The subtraction images of each phase were created by subtracting the non-contrast CT scan. Each patient was marked with good or poor collateral circulation.

RESULTS

Based on the ResNet34 classification network, we developed a single-image input and a multi-image input network for binary classification of collateral circulation. The training and test sets were 65 and 27 patients, respectively, and Monte Carlo cross-validation was employed for five iterations. The network performance was evaluated by precision, accuracy, recall, F1 score, and AUC. All the five performance indicators of the single-image input model were higher than those of the other.

CONCLUSION

s The single-image input processing network, combining multiphase CTA images, can better classify the AIS collateral circulation. This automated collateral assessment tool can help streamline clinical workflows, and screen patients for reperfusion therapy.

CLINICAL RELEVANCE/APPLICATION

Collateral circulation is important for the treatment plan and prognosis of patients with acute ischemic stroke (AIS). However, due to the complexity and difficulty of quantifying the neurological vessels' structure, the evaluation of collateral circulation is challenging. Although scholars have tried and reported various methods for assessing collateral circulation, there is no unified standard for assessing collateral circulation. Even when the same assessment method is used, physicians have significant subjective differences. The development of computerized deep learning algorithms has brought new solutions to this difficulty. This study uses deep learning methods to achieve a rapid, objective, and accurate collateral circulation evaluation of the AIS patients.

W2-SPNR-16 Brain MRI Automated Volumetry vs Non-automated Planimetric Assessment for Differentiating Progressive Supranuclear Palsy From Parkinson's Disease and Healthy Subjects: Can Machine Learning Help the Radiologist Choice?

Participants
Francisco Mendoza, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Develop a machine learning model to determine the more accurate tool, between automated volumetry and non-automated planimetric assessment in differentiating Progressive Supranuclear Palsy (PSP) from Parkinson's disease (PD) and healthy subjects (HS).

METHODS AND MATERIALS

We retrospectively assessed 141 patients with a clinical diagnosis of Parkinsonism paired by age and sex and with a group of HS (PSP n = 47, PE n = 68, HS=26) between January 2003 and April 2021. Patients without T1-MPRAGE were excluded, leaving 83 subjects (PSP n = 29, PD n = 54, HS n=26). We included different clinical subtypes of PSP: PSP-RS (n= 19), PSP-P (n= 5), PSP-PGF (n= 4), and PSP-F (n= 1). Using automatized SyngoviaBrainMorphometry software (Siemens), we obtained 109 volumes of interest (VOIs) for each brain MRI study, including absolute and normalized values. Two independent radiologists blind to diagnosis performed a planimetric assessment (Massey ratio, Oba ratio, MPRI 1.0, and MRP 2.0). The intraclass correlation coefficient (ICC) was used to assess interobserver agreement. We developed a machine-learning model based on multivariate feature selection and an extreme gradient boosting (XGB) vs. univariate feature selection and random forest (RF) with automated volumetric data and planimetric assessment to differentiate PSP from PD and HS. All subjects were randomly divided into training (85%) and validation (15%) data sets with the same proportions for each clinical group. The most relevant data obtained from each model were ordered by importance score (F-score: where 1.0 represents perfect precision and recall). Additionally, we assessed the diagnostic

accuracy of each tool using ROC curves.

RESULTS

The global diagnostic performance of the volumetric model to differentiate between the three groups was 70.6% and 70.5% for the planimetric assessment. The most relevant automated brain volumetry was the mesencephalic-normalized volume (0.068), with an area under de curve (AUC) of 0.87. For planimetric assessment, the most important measurements were the mesencephalic width (0.33) with an AUC of 0.99, followed by the mesencephalic area (0.19) with an AUC of 0.94. The planimetric measurements presented very good reproducibility with interobserver intraclass correlation coefficients (ICC) of > 0.75.

CONCLUSION

s There is no significant difference between automatized volumetric volumes or planimetric assessment models in predicting the diagnosis of PSP or PD. The classic measurements of mesencephalic width or mesencephalic have better diagnostic accuracy than volumetric values.

CLINICAL RELEVANCE/APPLICATION

Automatized volumetric assessment of brain MRI is a helpful tool for differentiating Progressive Supranuclear Palsy from Parkinson's disease.

W2-SPNR-18 Accurate Cerebellar Cortex Segmentation: A Deep-Learning-Based Approach

Participants
Fabiano Reis, Campinas, Brazil (*Presenter*) Nothing to Disclose

PURPOSE

Cerebellum segmentation is a challenging task due to the intricately folded cortex and proximity with the cerebral cortex. Several tools reach excellent results in healthy controls, but in patients with cerebellar damage the segmentation might be catastrophic. Hence, we propose to develop an MRI tool to segment with accuracy abnormal and non-abnormal cerebellums using deep-learning algorithms.

METHODS AND MATERIALS

We used T1-weighted MRI sequences acquired in a 3 T Philips Achieva at the University of Campinas. The dataset is composed of healthy controls, SCA1 (spinocerebellar ataxia), SCA3, and FRDA (Friedreich's Ataxia) subjects' acquisitions, 15 images of each group. A group of expert neuroradiologists labeled the images following a protocol to ensure quality and correctly identify the cerebellar fissures. We chose the 3D U-net architecture with a few modifications which is a consolidated model for segmentation tasks in the medical imaging domain. In order to assess the gains of our specialist segmented data, a segmentation model was trained. After that, we compared it along with ACAPULCO and CERES models to evaluate differences in segmentation performance.

RESULTS

Our initial U-Net model was trained on Google Colab and achieved 0.921 for Dice score (DS) on the validation set. We randomly selected 14 images from the training set to assess the main segmentation tools (Our model, ACAPULCO and CERES). We found a mean DS of 0.928±0.030 for our model, DS=0.909±0.043 for ACAPULCO and DS=0.918±0.039 for Ceres. When we compared patients with the highest level of cerebellar damage, this difference of performance increases a lot (our model: DS=0.904±0.041; ACAPULCO: DS=0.870±0.052; CERES: DS=0.888±0.052). In addition, comparing the segmentation volume of our model against ACAPULCO and CERES outputs of 71 and 72 images from FRDA (subtle damage) and SCA3 (severe damage) patients, respectively, we found volumetric difference between our model and ACAPULCO for both group of patients (plt0.001). For CERES, we only identify volumetric differences for the SCA3 patients (plt0.001).

CONCLUSION

s Initial results show a promising methodology, whereas we are still working on gathering more expert-segmented images, in order to obtain sensitive variables to measure the impact of modifier agents of new therapies for several neurodegenerative disorders.

CLINICAL RELEVANCE/APPLICATION

Cerebellum segmentation is a challenging task due to the intricately folded cortex and proximity with the cerebral cortex. Our initial results show a promising methodology, whereas we are still working on gathering more expert-segmented images, in order to obtain sensitive variables to measure the impact of modifier agents of new therapies for several neurodegenerative disorders.

W2-SPNR-19 A Large-scale Granger Causality Approach for Functional MRI Data Analysis - Identification of Schizophrenia Patients

Participants
Ali Vosoughi, Rochester, NY (*Presenter*) Nothing to Disclose

PURPOSE

To develop and evaluate a novel machine learning method for identifying patients with schizophrenia using large-scale Granger Causality (lsGC) by capturing connectivity differences in resting-state functional MRI (rsfMRI).

METHODS AND MATERIALS

From the publicly available Centers of Biomedical Research Excellence (COBRE) fMRI data repository on 146 subjects (72 schizophrenia patients, 62 controls), we included the subsample of all 62 subjects under the age of 32 years (29 schizophrenia patients, 33 controls) using standard preprocessing by the Nilearn Python library and the NIAK resting-state pipeline, with functional parcellation into 122 brain regions [Bellec, NIAK, 2016]. For calculating directed functional connectivity between brain regions, we have recently developed the large-scale Granger Causality (lsGC) algorithm [Citation blinded for review] that combines dimension reduction with multivariate predictive causal modeling in high-dimensional fMRI time series. A 100-iteration cross-validation approach with 80%/20% train/test ratio was applied, where feature selection was performed on each training set using Kendall's tau rank correlation, followed by support vector machine classification. To quantitatively evaluate diagnostic accuracy of lsGC for correctly classifying schizophrenia patients and normal controls, we compare its performance with both a recent state-of-the-art causal discovery method (PCMCI, [Runge et al., Science, 2019]), and the current clinical fMRI analysis standard of cross-

correlation (CC), reporting accuracy, area under ROC curve (AUC), and f1-score.

RESULTS

The lsGC rsfMRI analysis method significantly outperformed both PCMCI and the clinical standard CC techniques at classifying schizophrenia patients from healthy subjects, with accuracy/AUC/f1 score of 100%/1.0/100% for lsGC, 86.4%/0.81/78.4% for PCMCI, and 65.8%/0.62/60.4% for CC, respectively.

CONCLUSION

s Our results suggest that lsGC significantly improves the diagnostic accuracy of correctly identifying patients with schizophrenia from rsfMRI neuroimaging. We conclude that, when compared to both conventional CC analysis and state-of-the-art PCMCI, lsGC is better suited to capture disease-related brain network connectivity changes in schizophrenia patients.

CLINICAL RELEVANCE/APPLICATION

The lsGC method classifies schizophrenia subjects and controls by identifying relevant changes in fMRI connectivity, suggesting its potential use as a diagnostic imaging biomarker for neurologic disease.

W2-SPNR-2 Accelerating Susceptibility Weighted Imaging With Deep Learning Validated in Acute Ischemic Stroke

Participants
Qi Duan, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

Susceptibility weighted imaging (SWI) can display low-flow rapid vessels and arterial thrombosis and provide cerebral hemodynamic information without the use of contrast media by its strong detection ability for the paramagnetic properties of deoxyhemoglobin, which is helpful for acute ischemic stroke (AIS) clinical diagnostic and treat strategy made. However, SWI imaging requires a long acquisition time, which increases the possibility of motion artifacts, and limits the spatial resolution and slice thickness. We aimed to evaluate the clinical feasibility of the accelerating SWI generated by a deep learning model in patients with AIS.

METHODS AND MATERIALS

SWI data were collected from 45 AIS patients who underwent 3.0T MR examination in our hospital from January 2019 to January 2020. Using a sampling pattern library consisting of 3000 different two-dimensional variable-density random undersampling masks by referencing the k-space data retrospectively generated the undersampled SWI data, then using the complex-valued convolutional neural network (ComplexNet) to develop reconstruct high-quality SWI from highly accelerated k-space data. The data set was split into training (36 patients) and test (9 patients) sets (80% training and 20% test). The presence of susceptibility vessel sign (SVS) of each patient was assessed by two experienced radiologists.

RESULTS

A total of 45 patients (mean age, 66.67 years ±14.05, 30 men). ComplexNet achieved high image quality with acceleration rates of 5, and there was no significant diagnostic performance difference between fully sampled and ComplexNet in image quality ($p > 0.05$). The intraclass correlation coefficient (ICC) was excellent for the results of the assessment using ComplexNet SWI images between two readers (ICC = 0.750, p=0.006).

CONCLUSION

s ComplexNet can accelerate SWI effectively and generate the image of high quality while showing superior ability in detecting SVS in AIS. Further use of the accelerating SWI, such as cerebral microbleeds detection, needs to be proven in large cohorts.

CLINICAL RELEVANCE/APPLICATION

Susceptibility weighted imaging (SWI) can display low-flow rapid vessels and arterial thrombosis and provide cerebral hemodynamic information without the use of contrast media by its detection ability for paramagnetic properties of deoxyhemoglobin, which is of great value in acute ischemic stroke (AIS) patients' arterial thrombosis and cerebral microbleeds detection. However, SWI imaging requires a long acquisition time. We used a deep learning model to accelerate SWI, and evaluated the clinical feasibility of the accelerated SWI in patients with AIS.

W2-SPNR-20 Comparison of Volume Measurements and Reliability of Two Commercial Software for Automatic Brain Volumetry

Participants
Jimin Kim, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Brain atrophy has close correlations with various neurodegenerative diseases. However visual assessment of brain atrophy tend to show high interobserver variability and low sensitivity. We aimed to evaluate the inter-method reliability and volumetric differences between NeuroQuant (NQ) and AQUA (AQ) using T1 sagittal sequence.

METHODS AND MATERIALS

This retrospective study enrolled 202 patients without focal brain lesion. NQ and AQ were used for volumetric analysis of sagittal T1-weighted images with slice thickness of 1 mm. To analyze the inter-method difference, correlation, and reliability, we used the paired t-test, Pearson's correlation coefficient, intraclass correlation coefficient (ICC), and effect size (ES) using the SPSS software.

RESULTS

The paired t-test showed significant volume differences in most regions except for the total and left side of parietal volume, white matter of right cerebral hemisphere, right frontal volume and right cingulate between the two methods. Volume measures by NQ and AQ showed good-to-excellent reliability (r= 0.634-0.892, ICC=0.766-0.940), except for caudate, nucleus accumbens, cingulate and pallidum which showed average to fair reliability (r= 0.371-0.448, ICC= 0.470-0.617). For the measurements of ES, volume differences were large in most regions (r= 0.01-9.52). ES was the largest in the right pallidum and smallest in the right frontal lobe.

CONCLUSION

s In most brain regions, AQ showed significantly larger volume measurements with large ES than NQ. However, NQ and AQ showed good to excellent inter-method reliability in volumetric measurements for most brain regions, with the exception of relative smaller region.

CLINICAL RELEVANCE/APPLICATION

Therefore, clinicians should be aware that the volume measurements may vary by software and by region.

W2-SPNR-21 Automatic Large Vessel Occlusion Detection via a Thrombus Segmentation Approach

Participants
Rotem Golan, PhD, (*Presenter*) Software developer, Circle Cardiovascular Imaging Inc

PURPOSE

To introduce an explainable machine learning (ML) approach for large vessel occlusion (LVO) detection via thrombus segmentation, namely StrokeSENS LVO, and validate its performance on a large heterogenous dataset of single-phase computed tomography angiography (CTA) scans of the head.

METHODS AND MATERIALS

An explainable approach for LVO detection is proposed which is composed of two main components: (1) thrombus segmentation, and (2) segmentation of the large vessels of the anterior circulation of the brain; both of which are performed in three dimensions. Predicted thrombi of any size are flagged and their distance from the large vessels is measured to perform a final yes/no LVO decision. For validation, a total of 400 studies (217 LVO, 183 non-LVO) were used. The LVO group includes internal carotid artery (ICA) and m1 segment of the middle cerebral artery (M1-MCA) occlusions; and the non-LVO group includes more distal or posterior cerebral artery occlusions, no occlusions, and hemorrhagic stroke cases. Expert consensus reads were used as reference standard. Performance was evaluated using sensitivity and specificity and corresponding 95% confidence intervals (CI). Additional analysis was performed on several subgroups of interest.

RESULTS

For detecting LVO, StrokeSENS LVO achieved a sensitivity of 90.3% [86.4%, 94.3%] and specificity of 95.1% [91.9%, 98.2%]. Furthermore, sensitivities of 88.5% [81.4%, 95.6%] on ICA cases (N=78) and 91.4% [86.7%, 96.0%] on M1-MCA cases (N=139) were noted; similarly, specificities of 98.2% [93.6%, 99.5%] on hemorrhagic stroke cases (N=110) and 90.4% [83.7%, 97.2%] on non-LVO-non-hemorrhage cases (N=73) were noted. Similar performances were observed across stratified datasets based on age, sex, scanner manufacturer and slice thickness when compared to the full cohort.

CONCLUSION

s StrokeSENS LVO has demonstrated high sensitivity and specificity in detecting LVOs on a large heterogeneous dataset. The output of its components, i.e., predicted thrombus and vessels, can provide users with valuable information as to why certain predictions are made, and build clinicians' trust in using the tool in clinical practice.

CLINICAL RELEVANCE/APPLICATION

Patients with acute ischemic stroke due to LVO are candidates to receive lifesaving endovascular treatment. Timely and reliable detection of LVO on CTA is challenging in many centers and therefore automating the process and providing an explainable tool to clinicians is of great importance.

W2-SPNR-4 Ultra Low-iodine-load and Low-radiation 70 kVp Cerebral CT Angiography: Application of Deep learning-based Augmented Contrast Enhancement and Denoising Algorithms

Participants
Eun-Suk Cho, MD, PhD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To determine the feasibility of ultra low-iodine-load and low-radiation 70 kVp cerebral CT angiography (CTA) using deep learning-based augmented contrast enhancement (DL-ACE) and deep learning-based denoising (DL-DN) algorithms.

METHODS AND MATERIALS

Forty-seven volunteers were randomly assigned to one of three CTA protocols: group A (100 kVp and 40 mL of 350 mg I/mL iodine contrast media (CM)), group B (70 kVp and 40 mL of 270 mg I/mL CM), or group C (70 kVp and 28 mL of 270 mg I/mL CM). Images of groups B and C were reconstructed using DL-ACE and DL-DN algorithms. DL-ACE (ClariACE, ClariPi) was developed based on the U-net architecture to predict vascular and parenchymal contrast enhancement by being trained with high-energy (150 kVp) and low-energy (80 kVp) datasets of dual-energy CT images. Augmented contrast-enhanced images were obtained by boosting the degree of enhancement in contrast-enhanced organs. DL-DN (ClariCT.AI, ClariPi) was designed to predict possible image noise by low radiation from standard-dose images, and denoised images were acquired by subtracting predicted noise from the originals. The vascular attenuation value and contrast-to-noise ratio (CNR) of cerebral arteries, subjective image quality, and radiation dose were compared among the groups.

RESULTS

The vascular attenuations of groups B (405.0 ± 43.3 HU) and C (393.9 ± 54.1 HU) were significantly higher than that of group A (323.9 ± 50.2 HU). However, the CNR of group A (18.9 ± 4.9) was significantly higher than those of groups B (15.4 ± 2.5) and C (14.9 ± 2.4) because the image noise of groups B and C (23.3 ± 2.2) were significantly higher than that of group A (15.4 ± 2.2). After the application of DL-ACE and DL-DN, the image noise was significantly decreased in groups B and C (14.9 ± 1.8). The vascular attenuation and CNR were significantly increased in group B (768.7 ± 87.5 HU and 49.1 ± 9.3) and group C (748.0 ± 108.5 HU and 46.8 ± 10.1). CTDI of groups B and C (15.4 mGy) was 23.5% lower than that of group A (20.13 mGy).

CONCLUSION

s Application of DL-ACE and DL-DN increased arterial attenuation by 89.8% and decreased image noise by 35.9% in cerebral CTA,

respectively. 70 kVp cerebral CTA using DL-ACE and DL-DE improved significantly higher arterial attenuation and CNR and lower image noise and provided better subjective image quality, although with 46.0% lower iodine load and 23.5% lower radiation dose, compared to 100 kVp CTA protocol.

CLINICAL RELEVANCE/APPLICATION

Deep learning-based augmented contrast enhancement and denoising algorithms produce high arterial enhancement and CNR and good image quality in cerebral CTA, even with ultra low-iodine-load and low-radiation.

W2-SPNR-5 Could High kVp Non-Contrast Brain CT Improve Image Quality without Dose Increase?: Combined Use of Deep Learning Image Reconstruction and Automatic Current Modulation

Participants
Younghen Lee, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the impact of combined use of a new deep learning image reconstruction (DLIR) algorithm and automatic current modulation on image quality and dose reduction of non-contrast brain CT

METHODS AND MATERIALS

After the recent DLIR (TrueFidelity™, GE) launching, we obtained non-contrast brain CT images with different scanning condition during the recent ten-months (Dec,2019~Sep,2020), to optimize image quality and radiation dose (120kVp with ASIR-V 20%, 120/140kVp with DILR-mid, 140kVP with DILR-mid adding smart mA (noise index 7 and 8). For a comparison between those five different conditions, we retrospectively identified the normal brain CT cases of 151 young adults (mean age: 26.2 years). Region of interest based attenuation and noise measurements was done for supra-/infra-tentorial structure to compare SNR (signal to noise ratio), CNR (contrast to noise ratio) and CTDI and DLP

RESULTS

DLIR provided the better CNR and SNR than 20% ASIR-V by significant noise reduction. Compared to 120kVp with ASIR-V 20%, DLIR improved CNR and SNR of non-contrast 140kVp brain CT by mean 53.1% and 66.3% (noise index 7), 22.8%, and 41.5% (noise index 8) at the mean 8%, and 27% reduced doses by adding automatic current modulation

CONCLUSION

s Combined use of DLIR algorithm and automatic current modulation could be the potentially powerful tool for brain CT dose optimization

CLINICAL RELEVANCE/APPLICATION

Combined use of DLIR algorithm and automatic current modulation could be the potentially powerful tool for brain CT dose optimization

W2-SPNR-8 Automatic Tumor Segmentation and Survival Prediction for Children with Diffuse Midline Gliomas

Participants
Zhifan Jiang, PhD, Washington, DC (*Presenter*) Nothing to Disclose

PURPOSE

Diffuse midline glioma (DMG) is a rare but fatal pediatric central nervous system (CNS) tumor with a median overall survival (OS) of 11 months from diagnosis. Tumor volume and appearance on MRI may be important indicators of progression, response to treatment and survival outcomes. However, there is no quantitative imaging tool available to help improve clinical management of DMG. The purpose of this work is to develop a machine learning-based automatic framework to quantitatively analyze DMG from a small dataset and predict patient OS one year after diagnosis.

METHODS AND MATERIALS

We retrospectively collected contrast-enhanced T1 and T2 (mostly FLAIR) weighted MRIs from DMG patients at diagnosis (n=42) and within 1 month after completion of radiation therapy (RT) (n=35). Contrast enhancing tumor region (ET) and the whole tumor (WT) were manually labeled. We first adapted the SegResNet deep learning model developed to automatically segment ET and WT of more common adult CNS tumors (i.e., glioblastoma multiforme [GBM]). The model was pre-trained on 1,000 GBM cases and was fine-tuned using the DMG dataset (n=77 images for 2 timepoints) with a 5-fold cross-validation. DMG cases with data at both timepoints (n=34) were used for survival prediction. We extracted the following MRI features based on automatic segmentations: ET and WT volumes (and relative to the brain volumes), ET relative to WT volumes, changes between the 2 timepoints of these volumes, tumor heterogeneity (i.e., intensity skewness and kurtosis), and voxel percentage for each cluster when applying Gaussian Mixture Model (GMM) clustering algorithm to classify the segmented WT volume into 3 clusters based on T1 and T2 image intensities. A support vector machine was used to predict 1-year survival from combinations of these features with leave-one-out validation.

RESULTS

Our automatic segmentation method resulted in Dice scores of 0.841±0.072 and 0.831±0.073, and relative volume error of 13.1%±11.4% and 16.3%±15.8% for ET and WT, respectively. The 1-year survival prediction accuracy was 73.5% (sensitivity=70.6%, specificity=76.5%), achieved using 3 features: voxel percentage for the 2nd cluster of GMM clustering of WT volume on post-RT T1 images, skewness of WT volume on post-RT T2 images, and ET relative to WT volumes for post-RT images.

CONCLUSION

s Rare pediatric CNS tumor analysis can be efficiently performed from small datasets using transfer learning from comparable adult datasets to yield accurate automatic quantification of tumors and acceptable survival prediction.

CLINICAL RELEVANCE/APPLICATION

The prediction of OS from diagnosis and early post-treatment MR images has the potential to guide and improve the clinical

management of DMG and other rare pediatric conditions.

W2-SPNR-9 Novel Deep Learning Super-Resolution Algorithm Allows Substantial Improvement of Brain MRI Image Quality and Scan Time in a Multi-Site Study

Participants
Tal Aharoni, MSc, Haifa, Israel (*Presenter*) Employee, RadNet, Inc;

PURPOSE

To evaluate image quality, image resolution, and overall diagnostic sufficiency of low-resolution brain MRI images processed by a novel deep-learning (DL) resolution enhancement algorithm, compared to images acquired with higher resolution from multiple sites and MRI scanners.

METHODS AND MATERIALS

73 sequences of 27 subjects (19-88 years) were obtained on 11 different clinical MRI scanners (1.2T, 1.5T and 3T) from different vendors (Philips, Hitachi, Siemens and GE) under multi-site IRB-approval (in USA, Israel and Brazil). Each patient was imaged using the site's routine high-resolution (HR) protocol and with 25-33% faster variants, solely compromising resolution in phase encoding direction. The low-resolution (LR) scans were processed by a novel convolutional-neural network (CNN) based super-resolution algorithm, trained on a vast amount of brain MRI images from scanners of multiple vendors with a variety of clinical indications, to produce enhanced resolution (ER) images. Independent, blinded, side-by-side comparisons of diagnostic quality, spatial resolution, noise level, artifacts appearance and contrast resolution were performed by 6 experienced neuroradiologists, using a 7-point Likert-scale (1=unacceptable, 7=excellent). An additional non-blind review by a highly experienced neuroradiologist (>15 years' experience) was performed comparing image details between the HR and ER scans. Statistical analysis was performed (using JASP 0.15) comparing (i) HR to ER scans and (ii) LR to ER scans. Statistical significance was determined by paired samples t-test testing for either superiority or non-inferiority of ER scans.

RESULTS

Results (n=362 reads) exhibited superiority of the ER images over both the LR and HR images for diagnostic quality, spatial resolution, noise levels and contrast resolution ($p<0.001$) and demonstrated non-inferiority for artifacts appearance (?=0.2, $p<0.001$). 21 out of the 73 reviewed series showed pathologies. Statistical results were reinforced by the nonblinded review, demonstrating equality for image details and diagnostic confidence between the ER and HR images.

CONCLUSION

s Results demonstrate superior overall image quality of low-resolution scans processed by a DL resolution enhancement algorithm compared to the routine HR scans across multiple sites and vendors, enabling MRI image resolution reduction and scan time shortening without adversely affecting image and diagnostic quality.

CLINICAL RELEVANCE/APPLICATION

Substantial improvement of brain MRI Image quality and scan time can be achieved using a robust DL-algorithm, resolving the trade-off between resolution and acquisition time on a variety of scanners.

Quantitative Analysis of Ischemic Infarct Lesion Distribution in Term Neonates With Increasing Severity of Hypoxic Ischemic Encephalopathy

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Pratheek Bobba, BS, New Haven, CT (*Presenter*) Nothing to Disclose

PURPOSE

Hypoxic ischemic encephalopathy (HIE) is a serious cause of long-term disability and mortality in neonates. The topographic pattern of HIE parenchymal injury as seen on DWI helps with differentiation of hypoxic brain injury from other potential mechanisms and prognostic categorization of HIE severity. Thus far, topographic patterns of HIE distribution and their relationship with HIE severity have been described subjectively. In this study, we use quantitative methodologies to characterize the location of ischemic lesions in term neonates with varying severity of HIE.

METHODS AND MATERIALS

We analyzed the imaging and health records of term neonates (>36 postmenstrual gestational week) who had MRI/DWI at our center (01/2013 to 03/2021) with radiological and clinical findings of HIE. Neonates were then categorized into mild, moderate, and severe HIE based on Sarnat classification (Arch Neurol 1976;33:695-705), inferred from medical records. We manually segmented ischemic lesions from DWI scans and co-registered them to a standard brain space. We mapped all lesions to one hemisphere for generation of lesion summation maps; and used voxel wise general linear models (GLM) to identify regions of the brain more likely to be infarcted in neonates with increasing severity of HIE.

RESULTS

We included 33 neonates; 20 with mild, 7 with moderate, and 6 with severe HIE. Median gestational ages at scan (interquartile) were 40.18 (37.81 - 41.77), 40.14 (38.77 - 41.25), and 41.33 (39.69 - 41.79) weeks respectively for the mild, moderate, and severe groups (p=0.31). Median infarct volumes (interquartile) were 2.32 (0.71 - 15.42), 115.24 (65.14 - 124.16), and 28.56 (18.62 - 52.24) mL respectively for the mild, moderate, and severe groups (p=0.15). In summation maps, ischemic lesions in neonates with mild and moderate HIE were predominantly in subcortical and deep white matter along the border zone of arterial supply territories, while ischemic lesions in neonates with severe HIE involved basal ganglia, hippocampus, and thalamus in addition to white matter (Figure 1A). In voxel wise GLM analysis, higher severity of HIE was significantly associated with the presence of ischemic lesions in hippocampus, medial thalamus, and posterior putamen, after correction for infant volume as a covariate (Figure 1B).

CONCLUSION

s In quantitative analysis of term neonates, mild and moderate HIE infarct lesions were mostly localized to arterial territory border zone white matter, while severe HIE was significantly associated with infarction of basal ganglia and hippocampi.

CLINICAL RELEVANCE/APPLICATION

Objective and quantitative assessment of ischemic lesion topography helps with diagnostic differentiation of mechanisms of brain injury and prognostication of HIE in term neonates.

W2-SPNR-10

Achieving Human-Level Performance for Artificial Intelligence-Based Brain Metastasis Detection by Combining Black-Blood Contrast-Enhanced MRI

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Ji Eun Park, MD, PhD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To validate updated AI adding black-blood imaging for detection of brain metastasis by comparing its performance with AI based on GRE-T1WI alone and human readers.

METHODS AND MATERIALS

In this retrospective study, AI was developed with GRE-T1WI (GRE AI) and adding black-blood imaging (combined AI) using 503 brain metastasis dataset. The AI was validated in 62 consecutive patients who underwent both black-blood imaging and GRE-T1WI for diagnostic purposes and subsequent GRE-T1WI for planning of stereotactic radiosurgery between September 2021 and January 2022. Per-lesion detection sensitivity and positive predictive value (PPV) were measured. Two human readers independently performed lesion detection on both exams. The relative difference (RD) from the reference standard numbers of metastases was compared between human readers and AI.

RESULTS

Sixty-two patients were included for clinical validation (mean age 63.3 years, 53% male). Sensitivity was similar between GRE AI (93%, 95% confidence interval [CI]: 90-96%) and combined AI (92%, 95% CI: 89-94%, p=.506). The positive predictive value of the combined AI was significantly higher (89%, 95% CI: 86-92%, p<.001) than that of GRE AI (76%, 95% CI: 72-80%). GRE AI significantly overestimated metastases (RD: 0.05, 95% CI: 0.00-0.58) compared with human readers (RD: 0.00, 95% CI: -0.28, 0.15, p<.001), whereas the combined AI (RD: 0.00, 95% CI: 0.00-0.15) did not show a significant difference from human readers (RD: 0.00, 95% CI: -0.20-0.10, p=.913).

CONCLUSION

s The brain metastasis detection AI combined with black-blood imaging showed improved detection of true positive metastases and reduced overestimation, achieving similar performance to human readers.

CLINICAL RELEVANCE/APPLICATION

Artificial intelligence-based brain metastasis detection algorithm that incorporates black-blood imaging can help to increase true positive detections and reduce overestimation, achieving similar performance to a human reader.

W2-SPNR-11

Comparing Machine Learning Techniques to Recognize Parathyroid Adenomas from 4D CT Data

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Cynthia Greene, MD, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

Support vector machine (SVM) analysis is a linear learning approach using measurements on images to make predictions. Convolutional neural network (CNN) analysis is a sophisticated technique for machine learning that uses images to make predictions. Both of these methods use known data to build a model for predictions. Parathyroid adenomas are tumors with an early enhancement pattern that is used to help identify them to aid in detection and surgical planning. This study aims to compare SVM and CNN analyses on the accuracy of identifying parathyroid adenomas.

METHODS AND MATERIALS

This is a HIPPA compliant retrospective study with IRB approval. Informed consent was waived. Ninety-three 4D-CTs of patients with pathology-proven parathyroid adenomas were reviewed; 94 parathyroid adenomas (1 case had 2 adenomas) and 112 lymph nodes. The mean attenuation of the lesion of interest in HU of each acquired phase (0, 25, 50, 75 sec) is used to build a model in the SVM analysis. A 2D slice through the lesions in each phase is used to perform sequence classification with ResNet50 as the pre-trained network to construct the CNN model in MatLab. The data is split randomly between a model and validation data set in a 2:1 ratio. The area under the curve (AUC) and accuracy are calculated for the model and validation data sets.

RESULTS

The plot of the enhancement curves of parathyroid adenomas demonstrates early enhancement with washout, while lymph nodes have persistent enhancement. On the model data, the AUC of the CNN is 0.99 while the SVM is 0.95. The overall accuracy of the CNN on the validation data set is 92%, while the SVM is 88%. The accuracy for parathyroid adenomas specifically is 93% for the CNN and 83% for the SVM model.

CONCLUSION

s Both SVM and CNN models discriminate between parathyroid adenomas and lymph nodes well (88% vs. 92%), showing that lesion enhancement alone plays a significant role in distinguishing tissue types. The CNN more accurately identifies parathyroid adenomas in the validation data set than the SVM analysis, showing that using both spatial and enhancement information helps distinguish between features of parathyroid adenomas and lymph nodes better than enhancement alone. One of the limitations of this study is the limited number of lesions; more lesions would help clarify the statistics for these models, especially with variation in lesion shape and size. Comparing techniques like the SVM and CNN models can help identify imaging features to differentiate between lesions.

CLINICAL RELEVANCE/APPLICATION

Machine learning algorithms will enhance detection and provide insight into imaging features identifiable with parathyroid adenomas using 4D CT data.

NeuroScreener: Quantized Vector Embedded Autoencoder-based Abnormality Classifier from Brain MRI

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Jimin Kang, (*Presenter*) Employee, NEUROPHET, Inc

PURPOSE

In this work, we propose a novel framework that is the first of its kind to detect identifiable abnormalities that may be present in the images to reduce time and effort in the clinical practice by assisting clinicians' brain image reading.

METHODS AND MATERIALS

A dataset for this study was a T1-weighted brain MRI dataset with normal and anomalous images collected from the multicenter including ADNI, SNUH, CMCH, and YUHS. The anomalous images were categorized into three. First was defined as MR images with a severe artifact such as insufficient field of view (FOV), external foreign body (EFB), motion, and a spike which may not be proper for further interpretation of the image. We further included de-faced or skull-stripped images, which are preprocessed unintentionally and/or improperly for further processing or interpretation. Lastly, we also included MR images with large infarction, which may produce inferior results for the routine segmentation process. The normal MR image has no aforementioned abnormality. In this study, we utilized a residual block-based variational autoencoder (VAE) as a backbone network. The vector quantization (VQ) module performs that the continuous feature of the latent space was mapped to a trainable discrete embedding vector by a predetermined number. The output value of the discrete embedding space is then connected to the fully connected layer to classify the input T1 MR image. We trained our VQ-based network using the weighted summation of VQ loss, reconstruction loss, and Binary Cross Entropy (BCE) loss. The VQ loss was then used to calculate the loss for the VQ module. The Mean Squared Error (MSE) loss was calculated between the generated output image from the decoder and the input image. Additionally, we empirically adjusted the parameters for the loss function by histogram analysis of the distribution of the output loss.

RESULTS

Our results presented the accuracy as high as 95%, and Area Under Receiver Operating Characteristic (AUROC) showed as high as 0.9778. The mean accuracy of seven types of anomalies we investigated showed 89%.

CONCLUSION

s In this study, an image generator-based classifier was proposed to detect abnormality present in MR images using VAE, which is applied to the VQ module adaptively. The proposed framework has shown high performance in all matrices.

CLINICAL RELEVANCE/APPLICATION

We hope this study could assist the radiologists by replacing the time-consuming image reading process with a faster and more efficient image reading, which could provide the anomaly information that MRI may have.

Value Proposition of Food and Drug Administration (FDA)-Approved Artificial Intelligence (AI) Algorithms for Neuroimaging

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - NR DPS

Awards
Trainee Research Prize - Resident

Participants
Suryansh Bajaj, MD, New Haven, CT (*Presenter*) Nothing to Disclose

PURPOSE

The number of FDA-approved artificial intelligence (AI) algorithms for neuroimaging has grown in the last decade. The adoption of these algorithms into clinical practice depends largely on whether this technology provides significant value to radiologists in the clinical setting. The objective of this study is to understand current trends in FDA-cleared AI algorithms for neuroimaging and understand the value proposition of these algorithms as advertised by the developer.

METHODS AND MATERIALS

We extracted a list of FDA-approved neuroimaging AI algorithms from the American College of Radiology (ACR) Data Science Institute AI Central database from May 2008 to January 2022. Product information of each device was collected from the database. For each device, we collected information of advertised value as presented on the developer's website.

RESULTS

The database includes a total of 54 AI neuroimaging algorithms that were cleared by the FDA between May 2008 and January 2022. A majority of the algorithms (28/54, 51.9%) were compatible with CT images with 22 (40.7%) compatible with MR and 4 compatible with CTP and CTA (7.4%). Nine algorithms (16.7%) were compatible with multiple imaging modalities. Of these algorithms, 53 (98.1%) were approved with a 510(k) clearance and 1 (1.9%) received de novo clearance. Out of the 54 algorithms, we found websites that discussed the product for 51 algorithms. The most widely advertised value proposition was improved quality of care (34/51, 66.7%). A total of 19 algorithms (37.3%) argued they saved the user time, 8 (15.7%) decreased costs, and 6 (11.8%) increased revenue. Product websites for 24 algorithms (47.1%) showed testimonials advertising the value of the technology. Subgroup analysis was performed to compare algorithms compatible with CT to those with MRI and the algorithms involved in ICH to those in LVO.

CONCLUSION

s Our results indicate a wide range of value propositions advertised by developers to indicate the value of their product. Most developers argued that their product would improve patient care. Further research is necessary to determine whether the value advertised by the developer is actually demonstrated in clinical practice.

CLINICAL RELEVANCE/APPLICATION

Given the rapid growth in the number, availability, and clinical application of AI algorithms across the US, it is important to understand different uses and value propositions provided by these software in current practice.

Exploring Functional Connectivity in Chronic SCI Patients with Neuropathic Pain versus without Neuropathic Pain

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Adam Flanders, MD, Philadelphia, PA (*Presenter*) Nothing to Disclose

PURPOSE

Spinal cord injury (SCI) causes debilitating chronic pain. Despite decades of research, the pain pathway of neuropathic pain (NP) is unknown. Several lines of evidence show abnormal functioning of the brain in patients with SCI. We hypothesize that in patients with SCI and neuropathic pain the pain matrix is altered compared to patients with SCI without neuropathic pain.

METHODS AND MATERIALS

This study examines the functional connectivity (FC) in SCI patients with moderate-severe chronic neuropathic pain compared to SCI patients with mild-no neuropathic pain. These groups were compared to control subjects. Subjects completed the Neuropathic Pain questionnaire and completed a neurological evaluation based on the International Standard Neurological Classification of SCI to define severity and level of injury. Of the 8 participants with SCI, 5 (44.8±17.56 y.o, 4M and 1F) indicated they had NP and 3 did not have NP (37.33±9.24 y.o, 2M and 1F). We also included 10 uninjured neurologically intact controls (24.8±4.61 y.o, 5M and 5F). FC metrics were obtained from the comparisons of resting state functional magnetic resonance imaging amongst our various groups (uninjured controls, SCI with NP and SCI without NP). For each comparison, an ROI-to-ROI connectivity analysis was pursued, encompassing a total of 170 ROIs based on a customized atlas derived from AAL3 atlas. The analysis accounted for covariates such as age and gender. To correct for multiple comparisons, a strict Bonferroni correction was applied with a significance level of $p<0.05/NROIs$.

RESULTS

When comparing the SCI cohort with uninjured subjects our results show statistically significant decreased FC in various thalamic nuclei including: medial and lateral pulvinar, lateral geniculate nucleus, and mediodorsal magnocellular. We postulate these findings are associated with suppressed inhibitory inputs from the zona incerta (ZI) and the anterior pretectal nucleus (APT) in those with NP following SCI. The suppressed inhibitory input causes enhanced activity at the posterior nucleus of the thalamus, S1 and thalamic nuclei regulated by ZI/APT. There were no significant differences of FC in patients with SCI without NP pain compared to controls.

CONCLUSION

s Manipulations that enhance the activity of ZI/APT can improve the treatment in SCI pain. Additionally, the loss of inhibition within the thalamus and abnormal thalamocortical interactions can predispose patients for the development of chronic pain.

CLINICAL RELEVANCE/APPLICATION

Our findings complement results from other neuroimaging studies and provide multi-modal evidence for identifying novel regions of the brain specific to the SCI cohort. These regions can serve as therapeutic targets to improve SCI neuropathic pain patients.

A Deep Learning Algorithm Trained with Multiphase CTA Images Could Improve Collateral Circulation Assessment in Acute Ischemic Stroke

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Jingjie Wang, (*Presenter*) Nothing to Disclose

PURPOSE

We tried to build a deep learning-based, objective, fast, and accurate collateral circulation assessment model.

METHODS AND MATERIALS

We collected 92 acute ischemic stroke (AIS) patients with large vessel occlusion in the anterior circulation in our hospital from June 2020 to August 2021. We analyzed their baseline one-stop whole-brain four-dimensional computed tomography angiography (4D-CTA)/CT perfusion. The images of the arterial, arteriovenous, venous, and late venous phases were extracted from 4D-CTA according to the perfusion time density curve. The subtraction images of each phase were created by subtracting the non-contrast CT scan. Each patient was marked with good or poor collateral circulation.

RESULTS

Based on the ResNet34 classification network, we developed a single-image input and a multi-image input network for binary classification of collateral circulation. The training and test sets were 65 and 27 patients, respectively, and Monte Carlo cross-validation was employed for five iterations. The network performance was evaluated by precision, accuracy, recall, F1 score, and AUC. All the five performance indicators of the single-image input model were higher than those of the other.

CONCLUSION

s The single-image input processing network, combining multiphase CTA images, can better classify the AIS collateral circulation. This automated collateral assessment tool can help streamline clinical workflows, and screen patients for reperfusion therapy.

CLINICAL RELEVANCE/APPLICATION

Collateral circulation is important for the treatment plan and prognosis of patients with acute ischemic stroke (AIS). However, due to the complexity and difficulty of quantifying the neurological vessels' structure, the evaluation of collateral circulation is challenging. Although scholars have tried and reported various methods for assessing collateral circulation, there is no unified standard for assessing collateral circulation. Even when the same assessment method is used, physicians have significant subjective differences. The development of computerized deep learning algorithms has brought new solutions to this difficulty. This study uses deep learning methods to achieve a rapid, objective, and accurate collateral circulation evaluation of the AIS patients.

Brain MRI Automated Volumetry vs Non-automated Planimetric Assessment for Differentiating Progressive Supranuclear Palsy From Parkinson's Disease and Healthy Subjects: Can Machine Learning Help the Radiologist Choice?

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Francisco Mendoza, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Develop a machine learning model to determine the more accurate tool, between automated volumetry and non-automated planimetric assessment in differentiating Progressive Supranuclear Palsy (PSP) from Parkinson's disease (PD) and healthy subjects (HS).

METHODS AND MATERIALS

We retrospectively assessed 141 patients with a clinical diagnosis of Parkinsonism paired by age and sex and with a group of HS (PSP n = 47, PE n = 68, HS=26) between January 2003 and April 2021. Patients without T1-MPRAGE were excluded, leaving 83 subjects (PSP n = 29, PD n = 54, HS n=26). We included different clinical subtypes of PSP: PSP-RS (n= 19), PSP-P (n= 5), PSP-PGF (n= 4), and PSP-F (n= 1). Using automatized SyngoviaBrainMorphometry software (Siemens), we obtained 109 volumes of interest (VOIs) for each brain MRI study, including absolute and normalized values. Two independent radiologists blind to diagnosis performed a planimetric assessment (Massey ratio, Oba ratio, MPRI 1.0, and MRP 2.0). The intraclass correlation coefficient (ICC) was used to assess interobserver agreement. We developed a machine-learning model based on multivariate feature selection and an extreme gradient boosting (XGB) vs. univariate feature selection and random forest (RF) with automated volumetric data and planimetric assessment to differentiate PSP from PD and HS. All subjects were randomly divided into training (85%) and validation (15%) data sets with the same proportions for each clinical group. The most relevant data obtained from each model were ordered by importance score (F-score: where 1.0 represents perfect precision and recall). Additionally, we assessed the diagnostic accuracy of each tool using ROC curves.

RESULTS

The global diagnostic performance of the volumetric model to differentiate between the three groups was 70.6% and 70.5% for the planimetric assessment. The most relevant automated brain volumetry was the mesencephalic-normalized volume (0.068), with an area under de curve (AUC) of 0.87. For planimetric assessment, the most important measurements were the mesencephalic width (0.33) with an AUC of 0.99, followed by the mesencephalic area (0.19) with an AUC of 0.94. The planimetric measurements presented very good reproducibility with interobserver intraclass correlation coefficients (ICC) of > 0.75.

CONCLUSION

s There is no significant difference between automatized volumetric volumes or planimetric assessment models in predicting the diagnosis of PSP or PD. The classic measurements of mesencephalic width or mesencephalic have better diagnostic accuracy than volumetric values.

CLINICAL RELEVANCE/APPLICATION

Automatized volumetric assessment of brain MRI is a helpful tool for differentiating Progressive Supranuclear Palsy from Parkinson’s disease.

Accurate Cerebellar Cortex Segmentation: A Deep-Learning-Based Approach

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Fabiano Reis, Campinas, Brazil (*Presenter*) Nothing to Disclose

PURPOSE

Cerebellum segmentation is a challenging task due to the intricately folded cortex and proximity with the cerebral cortex. Several tools reach excellent results in healthy controls, but in patients with cerebellar damage the segmentation might be catastrophic. Hence, we propose to develop an MRI tool to segment with accuracy abnormal and non-abnormal cerebellums using deep-learning algorithms.

METHODS AND MATERIALS

We used T1-weighted MRI sequences acquired in a 3 T Philips Achieva at the University of Campinas. The dataset is composed of healthy controls, SCA1 (spinocerebellar ataxia), SCA3, and FRDA (Friedreich's Ataxia) subjects' acquisitions, 15 images of each group. A group of expert neuroradiologists labeled the images following a protocol to ensure quality and correctly identify the cerebellar fissures. We chose the 3D U-net architecture with a few modifications which is a consolidated model for segmentation tasks in the medical imaging domain. In order to assess the gains of our specialist segmented data, a segmentation model was trained. After that, we compared it along with ACAPULCO and CERES models to evaluate differences in segmentation performance.

RESULTS

Our initial U-Net model was trained on Google Colab and achieved 0.921 for Dice score (DS) on the validation set. We randomly selected 14 images from the training set to assess the main segmentation tools (Our model, ACAPULCO and CERES). We found a mean DS of 0.928±0.030 for our model, DS=0.909±0.043 for ACAPULCO and DS=0.918±0.039 for Ceres. When we compared patients with the highest level of cerebellar damage, this difference of performance increases a lot (our model: DS=0.904±0.041; ACAPULCO: DS=0.870±0.052; CERES: DS=0.888±0.052). In addition, comparing the segmentation volume of our model against ACAPULCO and CERES outputs of 71 and 72 images from FRDA (subtle damage) and SCA3 (severe damage) patients, respectively, we found volumetric difference between our model and ACAPULCO for both group of patients (plt0.001). For CERES, we only identify volumetric differences for the SCA3 patients (plt0.001).

CONCLUSION

s Initial results show a promising methodology, whereas we are still working on gathering more expert-segmented images, in order to obtain sensitive variables to measure the impact of modifier agents of new therapies for several neurodegenerative disorders.

CLINICAL RELEVANCE/APPLICATION

Cerebellum segmentation is a challenging task due to the intricately folded cortex and proximity with the cerebral cortex. Our initial results show a promising methodology, whereas we are still working on gathering more expert-segmented images, in order to obtain sensitive variables to measure the impact of modifier agents of new therapies for several neurodegenerative disorders.

A Large-scale Granger Causality Approach for Functional MRI Data Analysis - Identification of Schizophrenia Patients

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Ali Vosoughi, Rochester, NY (*Presenter*) Nothing to Disclose

PURPOSE

To develop and evaluate a novel machine learning method for identifying patients with schizophrenia using large-scale Granger Causality (lsGC) by capturing connectivity differences in resting-state functional MRI (rsfMRI).

METHODS AND MATERIALS

From the publicly available Centers of Biomedical Research Excellence (COBRE) fMRI data repository on 146 subjects (72 schizophrenia patients, 62 controls), we included the subsample of all 62 subjects under the age of 32 years (29 schizophrenia patients, 33 controls) using standard preprocessing by the Nilearn Python library and the NIAK resting-state pipeline, with functional parcellation into 122 brain regions [Bellec, NIAK, 2016]. For calculating directed functional connectivity between brain regions, we have recently developed the large-scale Granger Causality (lsGC) algorithm [Citation blinded for review] that combines dimension reduction with multivariate predictive causal modeling in high-dimensional fMRI time series. A 100-iteration cross-validation approach with 80%/20% train/test ratio was applied, where feature selection was performed on each training set using Kendall's tau rank correlation, followed by support vector machine classification. To quantitatively evaluate diagnostic accuracy of lsGC for correctly classifying schizophrenia patients and normal controls, we compare its performance with both a recent state-of-the-art causal discovery method (PCMCI, [Runge et al., Science, 2019]), and the current clinical fMRI analysis standard of cross-correlation (CC), reporting accuracy, area under ROC curve (AUC), and f1-score.

RESULTS

The lsGC rsfMRI analysis method significantly outperformed both PCMCI and the clinical standard CC techniques at classifying schizophrenia patients from healthy subjects, with accuracy/AUC/f1 score of 100%/1.0/100% for lsGC, 86.4%/0.81/78.4% for PCMCI, and 65.8%/0.62/60.4% for CC, respectively.

CONCLUSION

s Our results suggest that lsGC significantly improves the diagnostic accuracy of correctly identifying patients with schizophrenia from rsfMRI neuroimaging. We conclude that, when compared to both conventional CC analysis and state-of-the-art PCMCI, lsGC is better suited to capture disease-related brain network connectivity changes in schizophrenia patients.

CLINICAL RELEVANCE/APPLICATION

The lsGC method classifies schizophrenia subjects and controls by identifying relevant changes in fMRI connectivity, suggesting its potential use as a diagnostic imaging biomarker for neurologic disease.

W2-SPNR-2

Accelerating Susceptibility Weighted Imaging With Deep Learning Validated in Acute Ischemic Stroke

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Qi Duan, Beijing, China (*Presenter*) Nothing to Disclose

PURPOSE

Susceptibility weighted imaging (SWI) can display low-flow rapid vessels and arterial thrombosis and provide cerebral hemodynamic information without the use of contrast media by its strong detection ability for the paramagnetic properties of deoxyhemoglobin, which is helpful for acute ischemic stroke (AIS) clinical diagnostic and treat strategy made. However, SWI imaging requires a long acquisition time, which increases the possibility of motion artifacts, and limits the spatial resolution and slice thickness. We aimed to evaluate the clinical feasibility of the accelerating SWI generated by a deep learning model in patients with AIS.

METHODS AND MATERIALS

SWI data were collected from 45 AIS patients who underwent 3.0T MR examination in our hospital from January 2019 to January 2020. Using a sampling pattern library consisting of 3000 different two-dimensional variable-density random undersampling masks by referencing the k-space data retrospectively generated the undersampled SWI data, then using the complex-valued convolutional neural network (ComplexNet) to develop reconstruct high-quality SWI from highly accelerated k-space data. The data set was split into training (36 patients) and test (9 patients) sets (80% training and 20% test). The presence of susceptibility vessel sign (SVS) of each patient was assessed by two experienced radiologists.

RESULTS

A total of 45 patients (mean age, 66.67 years ±14.05, 30 men). ComplexNet achieved high image quality with acceleration rates of 5, and there was no significant diagnostic performance difference between fully sampled and ComplexNet in image quality ($p > 0.05$). The intraclass correlation coefficient (ICC) was excellent for the results of the assessment using ComplexNet SWI images between two readers (ICC = 0.750, $p=0.006$).

CONCLUSION

s ComplexNet can accelerate SWI effectively and generate the image of high quality while showing superior ability in detecting SVS in AIS. Further use of the accelerating SWI, such as cerebral microbleeds detection, needs to be proven in large cohorts.

CLINICAL RELEVANCE/APPLICATION

Susceptibility weighted imaging (SWI) can display low-flow rapid vessels and arterial thrombosis and provide cerebral hemodynamic information without the use of contrast media by its detection ability for paramagnetic properties of deoxyhemoglobin, which is of great value in acute ischemic stroke (AIS) patients' arterial thrombosis and cerebral microbleeds detection. However, SWI imaging requires a long acquisition time. We used a deep learning model to accelerate SWI, and evaluated the clinical feasibility of the accelerated SWI in patients with AIS.

W2-SPNR-20

Comparison of Volume Measurements and Reliability of Two Commercial Software for Automatic Brain Volumetry

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Jimin Kim, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Brain atrophy has close correlations with various neurodegenerative diseases. However visual assessment of brain atrophy tend to show high interobserver variability and low sensitivity. We aimed to evaluate the inter-method reliability and volumetric differences between NeuroQuant (NQ) and AQUA (AQ) using T1 sagittal sequence.

METHODS AND MATERIALS

This retrospective study enrolled 202 patients without focal brain lesion. NQ and AQ were used for volumetric analysis of sagittal T1-weighted images with slice thickness of 1 mm. To analyze the inter-method difference, correlation, and reliability, we used the paired t-test, Pearson's correlation coefficient, intraclass correlation coefficient (ICC), and effect size (ES) using the SPSS software.

RESULTS

The paired t-test showed significant volume differences in most regions except for the total and left side of parietal volume, white matter of right cerebral hemisphere, right frontal volume and right cingulate between the two methods. Volume measures by NQ and AQ showed good-to-excellent reliability (r= 0.634-0.892, ICC=0.766-0.940), except for caudate, nucleus accumbens, cingulate and pallidum which showed average to fair reliability (r= 0.371-0.448, ICC= 0.470-0.617). For the measurements of ES, volume differences were large in most regions (r= 0.01-9.52). ES was the largest in the right pallidum and smallest in the right frontal lobe.

CONCLUSION

s In most brain regions, AQ showed significantly larger volume measurements with large ES than NQ. However, NQ and AQ showed good to excellent inter-method reliability in volumetric measurements for most brain regions, with the exception of relative smaller region.

CLINICAL RELEVANCE/APPLICATION

Therefore, clinicians should be aware that the volume measurements may vary by software and by region.

W2-SPNR-21

Automatic Large Vessel Occlusion Detection via a Thrombus Segmentation Approach

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Rotem Golan, PhD, (*Presenter*) Software developer, Circle Cardiovascular Imaging Inc

PURPOSE

To introduce an explainable machine learning (ML) approach for large vessel occlusion (LVO) detection via thrombus segmentation, namely StrokeSENS LVO, and validate its performance on a large heterogenous dataset of single-phase computed tomography angiography (CTA) scans of the head.

METHODS AND MATERIALS

An explainable approach for LVO detection is proposed which is composed of two main components: (1) thrombus segmentation, and (2) segmentation of the large vessels of the anterior circulation of the brain; both of which are performed in three dimensions. Predicted thrombi of any size are flagged and their distance from the large vessels is measured to perform a final yes/no LVO decision. For validation, a total of 400 studies (217 LVO, 183 non-LVO) were used. The LVO group includes internal carotid artery (ICA) and m1 segment of the middle cerebral artery (M1-MCA) occlusions; and the non-LVO group includes more distal or posterior cerebral artery occlusions, no occlusions, and hemorrhagic stroke cases. Expert consensus reads were used as reference standard. Performance was evaluated using sensitivity and specificity and corresponding 95% confidence intervals (CI). Additional analysis was performed on several subgroups of interest.

RESULTS

For detecting LVO, StrokeSENS LVO achieved a sensitivity of 90.3% [86.4%, 94.3%] and specificity of 95.1% [91.9%, 98.2%]. Furthermore, sensitivities of 88.5% [81.4%, 95.6%] on ICA cases (N=78) and 91.4% [86.7%, 96.0%] on M1-MCA cases (N=139) were noted; similarly, specificities of 98.2% [93.6%, 99.5%] on hemorrhagic stroke cases (N=110) and 90.4% [83.7%, 97.2%] on non-LVO-non-hemorrhage cases (N=73) were noted. Similar performances were observed across stratified datasets based on age, sex, scanner manufacturer and slice thickness when compared to the full cohort.

CONCLUSION

s StrokeSENS LVO has demonstrated high sensitivity and specificity in detecting LVOs on a large heterogeneous dataset. The output of its components, i.e., predicted thrombus and vessels, can provide users with valuable information as to why certain predictions are made, and build clinicians' trust in using the tool in clinical practice.

CLINICAL RELEVANCE/APPLICATION

Patients with acute ischemic stroke due to LVO are candidates to receive lifesaving endovascular treatment. Timely and reliable detection of LVO on CTA is challenging in many centers and therefore automating the process and providing an explainable tool to clinicians is of great importance.

Ultra Low-iodine-load and Low-radiation 70 kVp Cerebral CT Angiography: Application of Deep learning-based Augmented Contrast Enhancement and Denoising Algorithms

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Eun-Suk Cho, MD, PhD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To determine the feasibility of ultra low-iodine-load and low-radiation 70 kVp cerebral CT angiography (CTA) using deep learning-based augmented contrast enhancement (DL-ACE) and deep learning-based denoising (DL-DN) algorithms.

METHODS AND MATERIALS

Forty-seven volunteers were randomly assigned to one of three CTA protocols: group A (100 kVp and 40 mL of 350 mg I/mL iodine contrast media (CM)), group B (70 kVp and 40 mL of 270 mg I/mL CM), or group C (70 kVp and 28 mL of 270 mg I/mL CM). Images of groups B and C were reconstructed using DL-ACE and DL-DN algorithms. DL-ACE (ClariACE, ClariPi) was developed based on the U-net architecture to predict vascular and parenchymal contrast enhancement by being trained with high-energy (150 kVp) and low-energy (80 kVp) datasets of dual-energy CT images. Augmented contrast-enhanced images were obtained by boosting the degree of enhancement in contrast-enhanced organs. DL-DN (ClariCT.AI, ClariPi) was designed to predict possible image noise by low radiation from standard-dose images, and denoised images were acquired by subtracting predicted noise from the originals. The vascular attenuation value and contrast-to-noise ratio (CNR) of cerebral arteries, subjective image quality, and radiation dose were compared among the groups.

RESULTS

The vascular attenuations of groups B (405.0 ± 43.3 HU) and C (393.9 ± 54.1 HU) were significantly higher than that of group A (323.9 ± 50.2 HU). However, the CNR of group A (18.9 ± 4.9) was significantly higher than those of groups B (15.4 ± 2.5) and C (14.9 ± 2.4) because the image noise of groups B and C (23.3 ± 2.2) were significantly higher than that of group A (15.4 ± 2.2). After the application of DL-ACE and DL-DN, the image noise was significantly decreased in groups B and C (14.9 ± 1.8). The vascular attenuation and CNR were significantly increased in group B (768.7 ± 87.5 HU and 49.1 ± 9.3) and group C (748.0 ± 108.5 HU and 46.8 ± 10.1). CTDI of groups B and C (15.4 mGy) was 23.5% lower than that of group A (20.13 mGy).

CONCLUSION

s Application of DL-ACE and DL-DN increased arterial attenuation by 89.8% and decreased image noise by 35.9% in cerebral CTA, respectively. 70 kVp cerebral CTA using DL-ACE and DL-DE improved significantly higher arterial attenuation and CNR and lower image noise and provided better subjective image quality, although with 46.0% lower iodine load and 23.5% lower radiation dose, compared to 100 kVp CTA protocol.

CLINICAL RELEVANCE/APPLICATION

Deep learning-based augmented contrast enhancement and denoising algorithms produce high arterial enhancement and CNR and good image quality in cerebral CTA, even with ultra low-iodine-load and low-radiation.

Could High kVp Non-Contrast Brain CT Improve Image Quality without Dose Increase?: Combined Use of Deep Learning Image Reconstruction and Automatic Current Modulation

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Younghen Lee, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the impact of combined use of a new deep learning image reconstruction (DLIR) algorithm and automatic current modulation on image quality and dose reduction of non-contrast brain CT

METHODS AND MATERIALS

After the recent DLIR (TrueFidelity™, GE) launching, we obtained non-contrast brain CT images with different scanning condition during the recent ten-months (Dec,2019~Sep,2020), to optimize image quality and radiation dose (120kVp with ASIR-V 20%, 120/140kVp with DILR-mid, 140kVP with DILR-mid adding smart mA (noise index 7 and 8). For a comparison between those five different conditions, we retrospectively identified the normal brain CT cases of 151 young adults (mean age: 26.2 years). Region of interest based attenuation and noise measurements was done for supra-/infra-tentorial structure to compare SNR (signal to noise ratio), CNR (contrast to noise ratio) and CTDI and DLP

RESULTS

DLIR provided the better CNR and SNR than 20% ASIR-V by significant noise reduction. Compared to 120kVp with ASIR-V 20%, DLIR improved CNR and SNR of non-contrast 140kVp brain CT by mean 53.1% and 66.3% (noise index 7), 22.8%, and 41.5% (noise index 8) at the mean 8%, and 27% reduced doses by adding automatic current modulation

CONCLUSION

s Combined use of DLIR algorithm and automatic current modulation could be the potentially powerful tool for brain CT dose optimization

CLINICAL RELEVANCE/APPLICATION

Combined use of DLIR algorithm and automatic current modulation could be the potentially powerful tool for brain CT dose optimization

W2-SPNR-8

Automatic Tumor Segmentation and Survival Prediction for Children with Diffuse Midline Gliomas

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Zhifan Jiang, PhD, Washington, DC (*Presenter*) Nothing to Disclose

PURPOSE

Diffuse midline glioma (DMG) is a rare but fatal pediatric central nervous system (CNS) tumor with a median overall survival (OS) of 11 months from diagnosis. Tumor volume and appearance on MRI may be important indicators of progression, response to treatment and survival outcomes. However, there is no quantitative imaging tool available to help improve clinical management of DMG. The purpose of this work is to develop a machine learning-based automatic framework to quantitatively analyze DMG from a small dataset and predict patient OS one year after diagnosis.

METHODS AND MATERIALS

We retrospectively collected contrast-enhanced T1 and T2 (mostly FLAIR) weighted MRIs from DMG patients at diagnosis (n=42) and within 1 month after completion of radiation therapy (RT) (n=35). Contrast enhancing tumor region (ET) and the whole tumor (WT) were manually labeled. We first adapted the SegResNet deep learning model developed to automatically segment ET and WT of more common adult CNS tumors (i.e., glioblastoma multiforme [GBM]). The model was pre-trained on 1,000 GBM cases and was fine-tuned using the DMG dataset (n=77 images for 2 timepoints) with a 5-fold cross-validation. DMG cases with data at both timepoints (n=34) were used for survival prediction. We extracted the following MRI features based on automatic segmentations: ET and WT volumes (and relative to the brain volumes), ET relative to WT volumes, changes between the 2 timepoints of these volumes, tumor heterogeneity (i.e., intensity skewness and kurtosis), and voxel percentage for each cluster when applying Gaussian Mixture Model (GMM) clustering algorithm to classify the segmented WT volume into 3 clusters based on T1 and T2 image intensities. A support vector machine was used to predict 1-year survival from combinations of these features with leave-one-out validation.

RESULTS

Our automatic segmentation method resulted in Dice scores of 0.841±0.072 and 0.831±0.073, and relative volume error of 13.1%±11.4% and 16.3%±15.8% for ET and WT, respectively. The 1-year survival prediction accuracy was 73.5% (sensitivity=70.6%, specificity=76.5%), achieved using 3 features: voxel percentage for the 2nd cluster of GMM clustering of WT volume on post-RT T1 images, skewness of WT volume on post-RT T2 images, and ET relative to WT volumes for post-RT images.

CONCLUSION

s Rare pediatric CNS tumor analysis can be efficiently performed from small datasets using transfer learning from comparable adult datasets to yield accurate automatic quantification of tumors and acceptable survival prediction.

CLINICAL RELEVANCE/APPLICATION

The prediction of OS from diagnosis and early post-treatment MR images has the potential to guide and improve the clinical management of DMG and other rare pediatric conditions.

Novel Deep Learning Super-Resolution Algorithm Allows Substantial Improvement of Brain MRI Image Quality and Scan Time in a Multi-Site Study

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - NR DPS

Participants
Tal Aharoni, MSc, Haifa, Israel (*Presenter*) Employee, RadNet, Inc;

PURPOSE

To evaluate image quality, image resolution, and overall diagnostic sufficiency of low-resolution brain MRI images processed by a novel deep-learning (DL) resolution enhancement algorithm, compared to images acquired with higher resolution from multiple sites and MRI scanners.

METHODS AND MATERIALS

73 sequences of 27 subjects (19-88 years) were obtained on 11 different clinical MRI scanners (1.2T, 1.5T and 3T) from different vendors (Philips, Hitachi, Siemens and GE) under multi-site IRB-approval (in USA, Israel and Brazil). Each patient was imaged using the site's routine high-resolution (HR) protocol and with 25-33% faster variants, solely compromising resolution in phase encoding direction. The low-resolution (LR) scans were processed by a novel convolutional-neural network (CNN) based super-resolution algorithm, trained on a vast amount of brain MRI images from scanners of multiple vendors with a variety of clinical indications, to produce enhanced resolution (ER) images. Independent, blinded, side-by-side comparisons of diagnostic quality, spatial resolution, noise level, artifacts appearance and contrast resolution were performed by 6 experienced neuroradiologists, using a 7-point Likert-scale (1=unacceptable, 7=excellent). An additional non-blind review by a highly experienced neuroradiologist (>15 years' experience) was performed comparing image details between the HR and ER scans. Statistical analysis was performed (using JASP 0.15) comparing (i) HR to ER scans and (ii) LR to ER scans. Statistical significance was determined by paired samples t-test testing for either superiority or non-inferiority of ER scans.

RESULTS

Results (n=362 reads) exhibited superiority of the ER images over both the LR and HR images for diagnostic quality, spatial resolution, noise levels and contrast resolution ($p<0.001$) and demonstrated non-inferiority for artifacts appearance ($?=0.2$, $p<0.001$). 21 out of the 73 reviewed series showed pathologies. Statistical results were reinforced by the nonblinded review, demonstrating equality for image details and diagnostic confidence between the ER and HR images.

CONCLUSION

s Results demonstrate superior overall image quality of low-resolution scans processed by a DL resolution enhancement algorithm compared to the routine HR scans across multiple sites and vendors, enabling MRI image resolution reduction and scan time shortening without adversely affecting image and diagnostic quality.

CLINICAL RELEVANCE/APPLICATION

Substantial improvement of brain MRI Image quality and scan time can be achieved using a robust DL-algorithm, resolving the trade-off between resolution and acquisition time on a variety of scanners.

W2-SPPH-1 Analysis of Noise for the Structural Difference Between Healthy and Destroyed Liver Tissue in CT Images During Microwave Ablation Therapy

Participants
Naghmeh Mahmoodian, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

Microwave ablation (MWA) is a minimally invasive therapy used for ablating the liver tumor in its location. Computed tomography (CT) as an interventional imaging modality is employed to visualize the therapy process. However, because of overlaying macroscopically visible changes in CT images during MWA therapy, it is difficult to distinguish between the lesion, healthy, and ablated tissue. Therefore, we propose a method for distinguishing among different tissue structures to determine the stopping point for ablating tumors using CT images acquired during MWA liver therapy.

METHODS AND MATERIALS

For all patients, CT scans were performed before and after the liver MWA therapy with a tube voltage of 120 KeV. The CT images were acquired before starting and after finishing the therapy, respectively, without and with a contrast agent. The ground truth was prepared manually based on the ablated tissue. The pre- and post-ablated images and corresponding ground truth images were aligned using non-rigid registration. This was then followed by automatic segmentation of the pre- and post-ablated CT images based on the ground truth. The region of interest (ROI) has been selected manually and converted into small patches with the size of 32 x 32 pixels. Different values of Gaussian noise have been added to the pre-ablated images, using two methods of noise power spectrum (NPS) measurement:-Fourier and task-based approaches- for analyzing the effects of noise on different tissue structures.

RESULTS

25 patients with a total of 650 pre-ablated images and a total of 1950 patches were included in the study. Six different Gaussian noise values of 0.005, 0.006, 0.007, 0.008, 0.009, and 0.01 were added on the pre-ablated images. The NPS was measured based on the Fourier- and Noise distributions were evaluated based on task-based methods. Then the best image and corresponding noise value was chosen based on the maximum distance between the NPS of healthy and ablated tissue that leads to the distinction between different tissue structures.

CONCLUSION

s Distinguishing tissue characterization of the healthy, tumor, and ablated liver tissue in CT images has been achieved by analyzing the noise effects on different tissues. The difference appears in healthy and tumor tissue NPS results and increases by adding more noise to the CT images. The results show the possibility of determining the stopping point during an MWA therapy by measuring the change in the anatomical noise of different tissue structures.

CLINICAL RELEVANCE/APPLICATION

An essential issue of tumor ablation therapy is to detect when the entire tumor tissue has completely been destroyed. However, current methods can’t present the changes in the CT images during MWA therapy, we provide a solution for that.

W2-SPPH-2 Artifact Reduction Using Silver Beam Filtration in Interventional CT

Participants
Timothy Szczykutowicz, PhD, Madison, WI (*Presenter*) Consultant, Aidoc Medical Ltd;Consultant, Flowhow.ai;Consultant, medInt Holdings, LLC;Consultant, Alara, Inc;Consultant, AstoCT, Inc;Research Grant, General Electric Company;Research Grant, Canon Medical Systems Corporation

PURPOSE

Intraprocedural visualization of devices such as ablation probes, drainage needles, and biopsy probes is important for avoiding critical structures and ensuring the intervention is accurately reaching the target structure. However, these devices produce strong metal artifacts in CT due to beam hardening and photon starvation which makes accurate visualization of tip and trajectory challenging. This study evaluates the use of silver filtration (SilverBeam, Canon Medical USA) to a biopsy procedure task and quantifies metal artifact as a function of beam energy and the presence of a silver filter.

METHODS AND MATERIALS

An anthropomorphic phantom (Lungman, Kyoto Kagaku) simulating a patient was scanned with a biopsy needle and its sheath (14

gauge) aligned in the axial plane inside the lung field. Images of the phantom and needle were acquired using an MDCT scanner (Aquilion One Prism Edition, Canon Medical USA) at beam energies of 100, 120, 135 kV, and at 120 kV with silver filtration. For each measurement, the CTDIvol (i.e., a surrogate for patient dose) was kept constant at 1 mGy. Metal artifacts from the biopsy probe were quantified by measuring the absolute error in CT numbers directly in front of the needle tip. Errors in CT number were normalized relative to the 120 kV scan with silver filtration. All measurements were repeated 3 times.

RESULTS

Artifacts relative to using silver beam increased for all beam energies not using silver beam. Median artifact increases were 95% (i.e., a near doubling of CT number error) ($p = 0.014$), 79% ($p = 0.009$), and 34% ($p = 0.015$) for 100, 120, and 135 kV respectively. Visually, the biopsy probe exhibited the smallest blooming artifact for 120 kV with silver filtration relative to all other scan conditions.

CONCLUSION

s Use of silver filtration for interventional CT procedures reduces metal artifacts at the device tip.

CLINICAL RELEVANCE/APPLICATION

Device tip localization is essential for physician confidence their device has reached the intended target. This study demonstrated that the use of silver filtration decreases metal artifacts at device tips.

W2-SPPH-3 Investigation of Thermal Injury Risks From High-Pressure Gas Supply Line (HPGSL) During MR Guided Cryoablation

Participants
Liqiang Ren, PhD, Rochester, MN (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the potential RF heating and frostbite risks from the high-pressure gas supply line (HPGSL) during MR guided cryoablation.

METHODS AND MATERIALS

Ex vivo experiments were performed using an MRI-conditional Boston Scientific cryoablation system. An 8ft long HPGSL with a metallic inner tube delivers high pressure gases to the cryoneedle when plugged into the mobile connection panel (MCP). To investigate the potential RF heating risks, three experiments were performed with a cryoneedle inserted into porcine tissue on a 1.5T MRI scanner. The tissue was placed ~10 cm off the patient table center and covered by a single layer of dry operating room (OR) towel (thickness: ~1mm) serving as a thermal insulation layer between tissue and HPGSL. A segment of interest (SOI, ~3 cm) of HPGSL was in contact with the towel. A temperature monitoring system was used to record the temperature during executions of a T2-weighted sequence (~2.3 minutes; specific absorption rate: 2.3 W/kg) via four thermal sensors: three attached to HPGSL and one placed on tissue surface under SOI. Two experiments were performed with HPGSL unplugged and plugged into MCP, respectively. A third one was performed with HPGSL plugged into MCP and a 2.5 cm thick insulation pad inserted between HPGSL and towel. To investigate the frostbite risk, cryoablation experiments were performed with the cryoneedle inserted into a container filled with saline. Temperature changes during a 5-minute and a 7-minute freezing procedure were measured with three thermal sensors attached to HPGSL and one insulated from HPGSL by either a single layer OR towel or both the towel and the pad at ~15 cm away from the cryoneedle shaft, respectively.

RESULTS

For RF heating risk investigations, temperature rises on HPGSL were much lower at the segment close to the tissue compared to other locations along HPGSL. With HPGSL disconnected and connected to MCP, the maximum tissue temperature rises were about 4.9 and 40? when only the towel was used for insulation, respectively. For frostbite risk investigations, the temperature drops along HPGSL reduced with increased distances from the cryoneedle shaft. With only a single layer of OR towel, the maximum temperature drop was about 20? at 15 cm from the shaft end. No temperature rises or drops were observed at the porcine tissue surface when the thick pad was inserted between thermal sensor and HPGSL.

CONCLUSION

s Skin injury could occur during MR guided cryoablation due to HPGSL induced RF heating and/or frostbite. To mitigate these risks, sufficient insulation between HPGSL and patient skin should be applied.

CLINICAL RELEVANCE/APPLICATION

Sufficient insulation between HPGSL and patient should be applied to effectively improve patient safety undergoing MR guided cryoablation procedures.

W2-SPPH-4 Technical Evaluation of Motor Evoked Potential Monitoring During MR-Guided Cryoablation of the Shoulder

Participants
Christopher Favazza, PhD, Rochester, MN (*Presenter*) Nothing to Disclose

PURPOSE

Pre-procedural testing to evaluate potential RF heating risks and image quality penalties associated with motor evoked potential (MEP) monitoring during MR-guided cryoablation of the shoulder.

METHODS AND MATERIALS

Using a porcine tissue phantom, a series of ex vivo experiments were conducted mimicking the clinical configuration for MEP monitoring during MR-guided cryoablation near the brachial plexus. Two needle electrodes were placed on the sides of the phantom "head" to simulate transcranial stimulation. Two needle electrode pairs and a ground electrode were placed in the "arm" to mimic muscle recording. Fluoroptic temperature sensors were inserted near the tips of all 7 electrodes. The phantom was placed "head" first into the scanner. To minimize heating risks, stimulation and recording/ground wires were routed along the center of the bore and exited the back and front of the scanner, respectively. Stimulation and recording wires were routed through a waveguide and

connected to the nerve monitoring system outside the scan room. Along with a single high specific absorption rate (SAR) T2-weighted sequence (2.5 W/kg), a series of proton-density (PD)-weighted sequences used to monitor cryoablations were executed with different combinations of experimental variables that influence heating—wire path, position relative to bore wall, and SAR. Heating was measured with thermal sensors and recorded. Image quality was assessed qualitatively by calculating the average contrast-to-noise ratio (CNR) on the PD images. Clinical workflow of interleaving MEP and image acquisitions was evaluated.

RESULTS

Maximum temperatures rises of 0.6, 0.8 2.8 and 0.4°C were respectively measured for high SAR T2, PD monitoring sequence at 14 minutes (SAR= 1.9 W/kg), PD with phantom shifted to touch the bore wall, and low SAR PD (0.7 W/kg) with phantom touching bore wall. Image quality was adequate with an average CNR=117. Stimulation was successfully interleaved between successive PD monitoring acquisitions with low noise signal reception in absence of active MRI.

CONCLUSION

s RF heating risks can be sufficiently minimized to allow for intraprocedural nerve monitoring during MR-guided cryoablation, especially when a low SAR sequence is used. Image quality is not significantly degraded. MEP monitoring is feasible and can be operated in between MR image acquisitions.

CLINICAL RELEVANCE/APPLICATION

This work demonstrates that intraprocedural MEP monitoring can be safely performed during MR-guided cryoablation procedures without significantly compromising MRI imaging quality. A successful cryoablation treatment using MEP monitoring has been carried out based on these findings.

W2-SPPH-6 Deep Learning Ring Artifact Correction in Photon-Counting Spectral CT

Participants
Dennis Hein, Stockholm, Sweden (*Presenter*) Research Collaborator, General Electric Company

PURPOSE

To develop an image-domain ring artifact correction algorithm for photon-counting spectral CT using deep learning.

METHODS AND MATERIALS

Numerical basis phantoms (soft tissue and bone) were generated by thresholding CT images from the KiTS19 dataset. Imaging was simulated using a fan beam acquisition and a spectral response model of a photon-counting silicon detector with 0.5x0.5 mm2 pixels. The simulation was performed for 120 kVp and 200 mAs with 2000 detectors and 2000 view angles. Detector inhomogeneity was simulated by independently applying a random threshold shift to each of the eight thresholds and each of the detector pixels. Two material decompositions were performed: one with the bin thresholds used in the simulation and one with the nominal bin thresholds—yielding images with ring artifacts. Images were reconstructed on a 1024x1024 grid using FBP. A version of the Unet (2D convolutional neural network), with bilinear upsampling to avoid checkerboard artifacts, was trained using ADAM to map a pair of ring corrupted basis images (observed) to their ring artifact free counterparts (truth). The loss function is the weighted sum of two terms: a L1-penalty for the basis images and a perceptual loss for the virtual monogenetic images at 70 keV. The perceptual loss utilizes VGG16 as feature extractor.

RESULTS

The degree of ring artifact correction is proxied by the change in the loss function between the ring corrupted and processed images (predicted). This metric yields an 83% reduction in the validation set. To measure the change in noise, six 24x24 ROIs are defined in a monoenergetic image at 70 keV. A two-sample F-test for equal variances is conducted against the alternative hypothesis that the variance in predicted is greater than in truth. The p-value for this test is 0.24 (1.8% increase in standard deviation) and hence the null cannot be rejected at any reasonable significance level.

CONCLUSION

s This work proposes a deep learning-based image processing technique for ring artifact correction in photon-counting spectral CT and demonstrates its ability to produce ring corrected virtual monoenergetic images at a range of energy levels.

CLINICAL RELEVANCE/APPLICATION

This work proposes a deep learning-based image processing technique for ring artifact correction in photon-counting spectral CT and demonstrates its ability to produce ring corrected virtual monoenergetic images at a range of energy levels.

W2-SPPH-7 Deep Learning for Automatic Contrast Enhancement Phase Detection on Abdominal Computed Tomography

Participants
Natália Alves, MSc, Nijmegen, Netherlands (*Presenter*) Nothing to Disclose

PURPOSE

Develop and validate a probabilistic convolutional neural network (CNN) for automatic classification of intravenous contrast enhancement (CE) phase on abdominal computed tomography (CT) scans.

METHODS AND MATERIALS

This retrospective study included 2000 abdominal CE-CT scans from our centre, which had information about the CE phase on the DICOM header. In addition to the baseline non-contrast scan (non-CE), three contrast phases were considered at different time intervals after contrast agent administration: the arterial phase (AP) at 40-50 seconds, the portal-venous phase (PVP) at 60-70 seconds and the delayed phase (DP) at 150-240 seconds. The distribution of CE phases on the training/validation dataset was 25.3% non-CE, 25.3% AP, 27.7% PVP and 21.7% DP. Half of the scans were used for model training/validation and a half for independent model testing. A 3-dimensional Inception CNN was trained to perform this multiclass classification task using stratified 4-fold cross-validation for 100 epochs. The model predictions from the 4 folds were ensembled to generate a final likelihood score for each contrast phase in the independent test set. The phase with the highest score was then chosen as the final model output.

RESULTS

The overall accuracy for the multiclass CNN was 92.4%, with only 76 out of the 1000 scans in the independent test set being incorrectly classified. The individual accuracies for each phase were 97.6% (244 out of 250) for non-CE, 95.6% (239 out of 250) for AP, 85.6% (214 out of 250) for PVP and 90.8% (227 out of 250) for DP. The most frequent mistake was in differentiating between the portal venous and delayed phases. This can be explained by the reduced amount of contrast agent in the abdomen and the high patient-specific and varied appearance of these two phases within the same protocol. Increasing the size and variety of the training data may improve performance for these two phases.

CONCLUSION

s Deep learning can accurately determine intravenous CE phase on multi-phase CE abdominal CT scans.

CLINICAL RELEVANCE/APPLICATION

CE information is critical to diagnosis but often lacks from the image metadata. DL can accurately classify CE phases, important for AI automation and the curation of high-quality training datasets.

W2-SPPH-8 Training to Improve Radiologist Performance for Liver Metastasis Detection at Contrast Enhanced CT

Participants
Scott Hsieh, Rochester, MN (*Presenter*) Nothing to Disclose

PURPOSE

The value of a radiology exam depends on the interpreting radiologist. We hypothesized that targeted training would improve liver metastasis detection at contrast enhanced CT.

METHODS AND MATERIALS

After IRB approval, readers (radiology residents, board-certified abdominal or non-abdominal radiologists) attended four sessions, each lasting 4 hours. (Session 1) Pre-training test: readers circumscribed all suspected metastases and rated confidence of malignancy in 40 portal phase abdominal CT exams (91 metastases total) with no feedback provided. (2) Search training: while interpreting 30 exams, readers were told to increase interpretation time to at least 3 min/exam, use liver windows at least 1.5 min/exam, and use coronal stack at least 25% of total time; and received concurrent eye tracker feedback highlighting gaze patterns. (3) Discrimination training: while interpreting 100 additional cropped liver images including 0-3 benign or malignant lesions, readers rated confidence of malignancy of the lesions, with truth revealed immediately. (4) Post-training test (identical to the pre-training test). Ground truth for liver metastases was determined using histopathology or progression. Performance was measured using per-lesion sensitivity and area under the jackknife free ROC curve (AUC), a measure of accuracy that also incorporates confidence ratings.

RESULTS

We recruited 31 readers (8 subspecialized abdominal radiologists, 8 non-abdominal radiologists, 15 residents). Between pre- and post-training tests, mean [SD] sensitivity increased from 82 [8]% to 85 [5]% (paired t-test, $p = 0.009$), but AUC did not significantly change (from 0.72 [0.08] to 0.71 [0.07], $p = 0.36$). Mean changes in sensitivity for subspecialized abdominal radiologists, non-abdominal specialists, and trainees were -0.6%, 4.6%, and 3.5%, respectively; only trainees' change was significant ($p = 0.02$). In the post-training test, use of liver windows ($p < 0.001$) and coronal stack ($p < 0.001$) both increased, but interpretation time did not change ($p = 0.62$). Despite improved use of liver windows and coronal images, sensitivity improvements were modest. Small, peripheral metastases seemed to benefit the most from training.

CONCLUSION

s Targeted training resulted in improvements in sensitivity but not AUC for liver metastasis detection in CT.

CLINICAL RELEVANCE/APPLICATION

Missed hepatic metastases could be reduced by training to improve readers' search behaviors.

W2-SPPH-9 Utility of Variable-Rate Contrast Medium Injection at Computed Tomography: A Simulation Study

Participants
Toru Higaki, PhD, Minami-ku, Hiroshima, Japan (*Presenter*) Nothing to Disclose

PURPOSE

For contrast-enhanced computed tomography (CT), the contrast medium (CM) volume is generally injected at a constant rate and is based on the study's purpose and the patient's body weight. We used computer simulation to evaluate the clinical benefit of a variable-rate CM injection.

METHODS AND MATERIALS

We developed a contrast simulator using the circulation model proposed in 1998 by Bae et al. By inputting the contrast protocol and the patient's body indices, the time density curve (TDC) of any organ can be calculated. Besides the conventional constant-rate CM injection, a variable-rate injection comprised of up to 4 phases can be delivered. By specifying the target TDC shape, an injection protocol can be automatically calculated to obtain the TDC shape closest to the target.We compared the TDC of constant-rate- and variable-rate (4 phases) injections for hepatic dynamic CT (HDCT) and coronary CT angiography (CCTA). The target TDC shape for HDCT was 280 Hounsfield units (HU) and the injection time was 20 seconds at the abdominal aorta, for CCTA it was 300 HU delivered in 5 seconds at the ascending aorta. The CM and the saline were injected simultaneously so that the total injection rate was always 5.0 ml/sec.

RESULTS

The rectangles present our findings. At HDCT, the TDC produced by the constant-rate injection of 96.0 ml CM into the abdominal aorta ascended beyond the target (upper left); the 4-phase injection of 89.9 ml (lower left) yielded a flat TDC almost in line with the target. The CM injection rate was lower in the later phases.At CCTA (upper and lower right), we observed a similar trend. However, the injected CM dose was lower and similar under both injection protocols (40.0 ml and 39.8 ml).

CONCLUSION

s The variable-rate CM injection rate may result in more precise control of the TDC. In protocols with greater CM injection volumes, e.g. for HDCT, it may be possible to obtain the target TDC at a smaller CM dose.

CLINICAL RELEVANCE/APPLICATION

CT contrast studies are less invasive with the variable 4-phase CM injection protocol because the target TDC can be obtained despite the lower CM dose.

Analysis of Noise for the Structural Difference Between Healthy and Destroyed Liver Tissue in CT Images During Microwave Ablation Therapy

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - PH DPS

Participants
Naghmeh Mahmoodian, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

Microwave ablation (MWA) is a minimally invasive therapy used for ablating the liver tumor in its location. Computed tomography (CT) as an interventional imaging modality is employed to visualize the therapy process. However, because of overlaying macroscopically visible changes in CT images during MWA therapy, it is difficult to distinguish between the lesion, healthy, and ablated tissue. Therefore, we propose a method for distinguishing among different tissue structures to determine the stopping point for ablating tumors using CT images acquired during MWA liver therapy.

METHODS AND MATERIALS

For all patients, CT scans were performed before and after the liver MWA therapy with a tube voltage of 120 KeV. The CT images were acquired before starting and after finishing the therapy, respectively, without and with a contrast agent. The ground truth was prepared manually based on the ablated tissue. The pre- and post-ablated images and corresponding ground truth images were aligned using non-rigid registration. This was then followed by automatic segmentation of the pre- and post-ablated CT images based on the ground truth. The region of interest (ROI) has been selected manually and converted into small patches with the size of 32 x 32 pixels. Different values of Gaussian noise have been added to the pre-ablated images, using two methods of noise power spectrum (NPS) measurement:-Fourier and task-based approaches- for analyzing the effects of noise on different tissue structures.

RESULTS

25 patients with a total of 650 pre-ablated images and a total of 1950 patches were included in the study. Six different Gaussian noise values of 0.005, 0.006, 0.007, 0.008, 0.009, and 0.01 were added on the pre-ablated images. The NPS was measured based on the Fourier- and Noise distributions were evaluated based on task-based methods. Then the best image and corresponding noise value was chosen based on the maximum distance between the NPS of healthy and ablated tissue that leads to the distinction between different tissue structures.

CONCLUSION

s Distinguishing tissue characterization of the healthy, tumor, and ablated liver tissue in CT images has been achieved by analyzing the noise effects on different tissues. The difference appears in healthy and tumor tissue NPS results and increases by adding more noise to the CT images. The results show the possibility of determining the stopping point during an MWA therapy by measuring the change in the anatomical noise of different tissue structures.

CLINICAL RELEVANCE/APPLICATION

An essential issue of tumor ablation therapy is to detect when the entire tumor tissue has completely been destroyed. However, current methods can’t present the changes in the CT images during MWA therapy, we provide a solution for that.

Artifact Reduction Using Silver Beam Filtration in Interventional CT

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - PH DPS

Participants
Timothy Szczykutowicz, PhD, Madison, WI (*Presenter*) Consultant, Aidoc Medical Ltd;Consultant, Flowhow.ai;Consultant, medInt Holdings, LLC;Consultant, Alara, Inc;Consultant, AstoCT, Inc;Research Grant, General Electric Company;Research Grant, Canon Medical Systems Corporation

PURPOSE

Intraprocedural visualization of devices such as ablation probes, drainage needles, and biopsy probes is important for avoiding critical structures and ensuring the intervention is accurately reaching the target structure. However, these devices produce strong metal artifacts in CT due to beam hardening and photon starvation which makes accurate visualization of tip and trajectory challenging. This study evaluates the use of silver filtration (SilverBeam, Canon Medical USA) to a biopsy procedure task and quantifies metal artifact as a function of beam energy and the presence of a silver filter.

METHODS AND MATERIALS

An anthropomorphic phantom (Lungman, Kyoto Kagaku) simulating a patient was scanned with a biopsy needle and its sheath (14 gauge) aligned in the axial plane inside the lung field. Images of the phantom and needle were acquired using an MDCT scanner (Aquilion One Prism Edition, Canon Medical USA) at beam energies of 100, 120, 135 kV, and at 120 kV with silver filtration. For each measurement, the CTDIvol (i.e., a surrogate for patient dose) was kept constant at 1 mGy. Metal artifacts from the biopsy probe were quantified by measuring the absolute error in CT numbers directly in front of the needle tip. Errors in CT number were normalized relative to the 120 kV scan with silver filtration. All measurements were repeated 3 times.

RESULTS

Artifacts relative to using silver beam increased for all beam energies not using silver beam. Median artifact increases were 95% (i.e., a near doubling of CT number error) ($p = 0.014$), 79% ($p = 0.009$), and 34% ($p = 0.015$) for 100, 120, and 135 kV respectively. Visually, the biopsy probe exhibited the smallest blooming artifact for 120 kV with silver filtration relative to all other scan conditions.

CONCLUSION

s Use of silver filtration for interventional CT procedures reduces metal artifacts at the device tip.

CLINICAL RELEVANCE/APPLICATION

Device tip localization is essential for physician confidence their device has reached the intended target. This study demonstrated that the use of silver filtration decreases metal artifacts at device tips.

A segment of interest (SOI, ~3 cm) of HPGSL was in contact with the towel. A temperature monitoring system was used to record the temperature during executions of a T2-weighted sequence (~2.3 minutes; specific absorption rate: 2.3 W/kg) via four thermal sensors: three attached to HPGSL and one placed on tissue surface under SOI. Two experiments were performed with HPGSL unplugged and plugged into MCP, respectively. A third one was performed with HPGSL plugged into MCP and a 2.5 cm thick insulation pad inserted between HPGSL and towel. To investigate the frostbite risk, cryoablation experiments were performed with the cryoneedle inserted into a container filled with saline. Temperature changes during a 5-minute and a 7-minute freezing procedure were measured with three thermal sensors attached to HPGSL and one insulated from HPGSL by either a single layer OR towel or both the towel and the pad at ~15 cm away from the cryoneedle shaft, respectively.

RESULTS

For RF heating risk investigations, temperature rises on HPGSL were much lower at the segment close to the tissue compared to other locations along HPGSL. With HPGSL disconnected and connected to MCP, the maximum tissue temperature rises were about 4.9 and 40? when only the towel was used for insulation, respectively. For frostbite risk investigations, the temperature drops along HPGSL reduced with increased distances from the cryoneedle shaft. With only a single layer of OR towel, the maximum temperature drop was about 20? at 15 cm from the shaft end. No temperature rises or drops were observed at the porcine tissue surface when the thick pad was inserted between thermal sensor and HPGSL.

CONCLUSION

s Skin injury could occur during MR guided cryoablation due to HPGSL induced RF heating and/or frostbite. To mitigate these risks, sufficient insulation between HPGSL and patient skin should be applied.

CLINICAL RELEVANCE/APPLICATION

Sufficient insulation between HPGSL and patient should be applied to effectively improve patient safety undergoing MR guided cryoablation procedures.

Technical Evaluation of Motor Evoked Potential Monitoring During MR-Guided Cryoablation of the Shoulder

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - PH DPS

Participants
Christopher Favazza, PhD, Rochester, MN (*Presenter*) Nothing to Disclose

PURPOSE

Pre-procedural testing to evaluate potential RF heating risks and image quality penalties associated with motor evoked potential (MEP) monitoring during MR-guided cryoablation of the shoulder.

METHODS AND MATERIALS

Using a porcine tissue phantom, a series of ex vivo experiments were conducted mimicking the clinical configuration for MEP monitoring during MR-guided cryoablation near the brachial plexus. Two needle electrodes were placed on the sides of the phantom "head" to simulate transcranial stimulation. Two needle electrode pairs and a ground electrode were placed in the "arm" to mimic muscle recording. Fluoroptic temperature sensors were inserted near the tips of all 7 electrodes. The phantom was placed "head" first into the scanner. To minimize heating risks, stimulation and recording/ground wires were routed along the center of the bore and exited the back and front of the scanner, respectively. Stimulation and recording wires were routed through a waveguide and connected to the nerve monitoring system outside the scan room. Along with a single high specific absorption rate (SAR) T2-weighted sequence (2.5 W/kg), a series of proton-density (PD)-weighted sequences used to monitor cryoablations were executed with different combinations of experimental variables that influence heating—wire path, position relative to bore wall, and SAR. Heating was measured with thermal sensors and recorded. Image quality was assessed qualitatively by calculating the average contrast-to-noise ratio (CNR) on the PD images. Clinical workflow of interleaving MEP and image acquisitions was evaluated.

RESULTS

Maximum temperatures rises of 0.6, 0.8 2.8 and 0.4°C were respectively measured for high SAR T2, PD monitoring sequence at 14 minutes (SAR= 1.9 W/kg), PD with phantom shifted to touch the bore wall, and low SAR PD (0.7 W/kg) with phantom touching bore wall. Image quality was adequate with an average CNR=117. Stimulation was successfully interleaved between successive PD monitoring acquisitions with low noise signal reception in absence of active MRI.

CONCLUSION

s RF heating risks can be sufficiently minimized to allow for intraprocedural nerve monitoring during MR-guided cryoablation, especially when a low SAR sequence is used. Image quality is not significantly degraded. MEP monitoring is feasible and can be operated in between MR image acquisitions.

CLINICAL RELEVANCE/APPLICATION

This work demonstrates that intraprocedural MEP monitoring can be safely performed during MR-guided cryoablation procedures without significantly compromising MRI imaging quality. A successful cryoablation treatment using MEP monitoring has been carried out based on these findings.

Deep Learning Ring Artifact Correction in Photon-Counting Spectral CT

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - PH DPS

Participants
Dennis Hein, Stockholm, Sweden (*Presenter*) Research Collaborator, General Electric Company

PURPOSE

To develop an image-domain ring artifact correction algorithm for photon-counting spectral CT using deep learning.

METHODS AND MATERIALS

Numerical basis phantoms (soft tissue and bone) were generated by thresholding CT images from the KiTS19 dataset. Imaging was simulated using a fan beam acquisition and a spectral response model of a photon-counting silicon detector with 0.5x0.5 mm2 pixels. The simulation was performed for 120 kVp and 200 mAs with 2000 detectors and 2000 view angles. Detector inhomogeneity was simulated by independently applying a random threshold shift to each of the eight thresholds and each of the detector pixels. Two material decompositions were performed: one with the bin thresholds used in the simulation and one with the nominal bin thresholds—yielding images with ring artifacts. Images were reconstructed on a 1024x1024 grid using FBP. A version of the Unet (2D convolutional neural network), with bilinear upsampling to avoid checkerboard artifacts, was trained using ADAM to map a pair of ring corrupted basis images (observed) to their ring artifact free counterparts (truth). The loss function is the weighted sum of two terms: a L1-penalty for the basis images and a perceptual loss for the virtual monogenetic images at 70 keV. The perceptual loss utilizes VGG16 as feature extractor.

RESULTS

The degree of ring artifact correction is proxied by the change in the loss function between the ring corrupted and processed images (predicted). This metric yields an 83% reduction in the validation set. To measure the change in noise, six 24x24 ROIs are defined in a monoenergetic image at 70 keV. A two-sample F-test for equal variances is conducted against the alternative hypothesis that the variance in predicted is greater than in truth. The p-value for this test is 0.24 (1.8% increase in standard deviation) and hence the null cannot be rejected at any reasonable significance level.

CONCLUSION

s This work proposes a deep learning-based image processing technique for ring artifact correction in photon-counting spectral CT and demonstrates its ability to produce ring corrected virtual monoenergetic images at a range of energy levels.

CLINICAL RELEVANCE/APPLICATION

This work proposes a deep learning-based image processing technique for ring artifact correction in photon-counting spectral CT and demonstrates its ability to produce ring corrected virtual monoenergetic images at a range of energy levels.

W2-SPPH-7

Deep Learning for Automatic Contrast Enhancement Phase Detection on Abdominal Computed Tomography

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - PH DPS

Participants
Natália Alves, MSc, Nijmegen, Netherlands (*Presenter*) Nothing to Disclose

PURPOSE

Develop and validate a probabilistic convolutional neural network (CNN) for automatic classification of intravenous contrast enhancement (CE) phase on abdominal computed tomography (CT) scans.

METHODS AND MATERIALS

This retrospective study included 2000 abdominal CE-CT scans from our centre, which had information about the CE phase on the DICOM header. In addition to the baseline non-contrast scan (non-CE), three contrast phases were considered at different time intervals after contrast agent administration: the arterial phase (AP) at 40-50 seconds, the portal-venous phase (PVP) at 60-70 seconds and the delayed phase (DP) at 150-240 seconds. The distribution of CE phases on the training/validation dataset was 25.3% non-CE, 25.3% AP, 27.7% PVP and 21.7% DP. Half of the scans were used for model training/validation and a half for independent model testing. A 3-dimensional Inception CNN was trained to perform this multiclass classification task using stratified 4-fold cross-validation for 100 epochs. The model predictions from the 4 folds were ensembled to generate a final likelihood score for each contrast phase in the independent test set. The phase with the highest score was then chosen as the final model output.

RESULTS

The overall accuracy for the multiclass CNN was 92.4%, with only 76 out of the 1000 scans in the independent test set being incorrectly classified. The individual accuracies for each phase were 97.6% (244 out of 250) for non-CE, 95.6% (239 out of 250) for AP, 85.6% (214 out of 250) for PVP and 90.8% (227 out of 250) for DP. The most frequent mistake was in differentiating between the portal venous and delayed phases. This can be explained by the reduced amount of contrast agent in the abdomen and the high patient-specific and varied appearance of these two phases within the same protocol. Increasing the size and variety of the training data may improve performance for these two phases.

CONCLUSION

s Deep learning can accurately determine intravenous CE phase on multi-phase CE abdominal CT scans.

CLINICAL RELEVANCE/APPLICATION

CE information is critical to diagnosis but often lacks from the image metadata. DL can accurately classify CE phases, important for AI automation and the curation of high-quality training datasets.

W2-SPPH-8

Training to Improve Radiologist Performance for Liver Metastasis Detection at Contrast Enhanced CT

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - PH DPS

Participants
Scott Hsieh, Rochester, MN (*Presenter*) Nothing to Disclose

PURPOSE

The value of a radiology exam depends on the interpreting radiologist. We hypothesized that targeted training would improve liver metastasis detection at contrast enhanced CT.

METHODS AND MATERIALS

After IRB approval, readers (radiology residents, board-certified abdominal or non-abdominal radiologists) attended four sessions, each lasting 4 hours. (Session 1) Pre-training test: readers circumscribed all suspected metastases and rated confidence of malignancy in 40 portal phase abdominal CT exams (91 metastases total) with no feedback provided. (2) Search training: while interpreting 30 exams, readers were told to increase interpretation time to at least 3 min/exam, use liver windows at least 1.5 min/exam, and use coronal stack at least 25% of total time; and received concurrent eye tracker feedback highlighting gaze patterns. (3) Discrimination training: while interpreting 100 additional cropped liver images including 0-3 benign or malignant lesions, readers rated confidence of malignancy of the lesions, with truth revealed immediately. (4) Post-training test (identical to the pre-training test). Ground truth for liver metastases was determined using histopathology or progression. Performance was measured using per-lesion sensitivity and area under the jackknife free ROC curve (AUC), a measure of accuracy that also incorporates confidence ratings.

RESULTS

We recruited 31 readers (8 subspecialized abdominal radiologists, 8 non-abdominal radiologists, 15 residents). Between pre- and post-training tests, mean [SD] sensitivity increased from 82 [8]% to 85 [5]% (paired t-test, $p = 0.009$), but AUC did not significantly change (from 0.72 [0.08] to 0.71 [0.07], $p = 0.36$). Mean changes in sensitivity for subspecialized abdominal radiologists, non-abdominal specialists, and trainees were -0.6%, 4.6%, and 3.5%, respectively; only trainees' change was significant ($p = 0.02$). In the post-training test, use of liver windows ($p < 0.001$) and coronal stack ($p < 0.001$) both increased, but interpretation time did not change ($p = 0.62$). Despite improved use of liver windows and coronal images, sensitivity improvements were modest. Small, peripheral metastases seemed to benefit the most from training.

CONCLUSION

s Targeted training resulted in improvements in sensitivity but not AUC for liver metastasis detection in CT.

CLINICAL RELEVANCE/APPLICATION

Missed hepatic metastases could be reduced by training to improve readers' search behaviors.

W2-SPPH-9

Utility of Variable-Rate Contrast Medium Injection at Computed Tomography: A Simulation Study

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - PH DPS

Participants
Toru Higaki, PhD, Minami-ku, Hiroshima, Japan (*Presenter*) Nothing to Disclose

PURPOSE

For contrast-enhanced computed tomography (CT), the contrast medium (CM) volume is generally injected at a constant rate and is based on the study's purpose and the patient's body weight. We used computer simulation to evaluate the clinical benefit of a variable-rate CM injection.

METHODS AND MATERIALS

We developed a contrast simulator using the circulation model proposed in 1998 by Bae et al. By inputting the contrast protocol and the patient's body indices, the time density curve (TDC) of any organ can be calculated. Besides the conventional constant-rate CM injection, a variable-rate injection comprised of up to 4 phases can be delivered. By specifying the target TDC shape, an injection protocol can be automatically calculated to obtain the TDC shape closest to the target.We compared the TDC of constant-rate- and variable-rate (4 phases) injections for hepatic dynamic CT (HDCT) and coronary CT angiography (CCTA). The target TDC shape for HDCT was 280 Hounsfield units (HU) and the injection time was 20 seconds at the abdominal aorta, for CCTA it was 300 HU delivered in 5 seconds at the ascending aorta. The CM and the saline were injected simultaneously so that the total injection rate was always 5.0 ml/sec.

RESULTS

The rectangles present our findings. At HDCT, the TDC produced by the constant-rate injection of 96.0 ml CM into the abdominal aorta ascended beyond the target (upper left); the 4-phase injection of 89.9 ml (lower left) yielded a flat TDC almost in line with the target. The CM injection rate was lower in the later phases.At CCTA (upper and lower right), we observed a similar trend. However, the injected CM dose was lower and similar under both injection protocols (40.0 ml and 39.8 ml).

CONCLUSION

s The variable-rate CM injection rate may result in more precise control of the TDC. In protocols with greater CM injection volumes, e.g. for HDCT, it may be possible to obtain the target TDC at a smaller CM dose.

CLINICAL RELEVANCE/APPLICATION

CT contrast studies are less invasive with the variable 4-phase CM injection protocol because the target TDC can be obtained despite the lower CM dose.

W2-SPRO-1 Establishing Contouring Protocols for Local Organs at Risk for MRI-Guided Radiation Therapy of Adenocarcinoma of the Prostate

Participants
Sarah Dyke, BS, (*Presenter*) Nothing to Disclose

PURPOSE

To establish guidelines for contouring the urethra, penile bulb (PB), corpus cavernosum (CC), corpus spongiosum (CS), and the neurovascular bundle (NVB) for the purpose of consistent definition of regional organs at risk (OAR) for MRI-guided radiation treatment (RT) using a 1.5 Tesla MRI equipped linear accelerator (MR-Linac).

METHODS AND MATERIALS

Patients undergoing RT for prostate cancer on a 1.5 Tesla MRI Linac were enrolled in a prospective clinical trial (NCT04075305). Daily MR images from 10 patients were collected and the urethra, PB, CC, CS, and the NVB were contoured in MIM (MIM Software Inc, Beachwood, OH). Detailed contouring guidelines for identifying each structure were generated and presented to a diagnostic radiologist and four board certified radiation oncologists to test their reproducibility. Recommendations include using T2-weighted images and specific window levels for each structure. In order to show concordance between reference and observer contours, mean Hausdorff distances (HD) (mean distance between contours) and Jaccard coefficients (JC) (contouring area overlap) were obtained.

RESULTS

The mean HD for the CC was 0.2 (SD 0.06), and the mean JC was 0.54 (SD 0.11). The mean HD for the CS was 0.29 (SD 0.22), and the mean JC was 0.47 (SD 0.15). The mean HD for the PB was 0.17 (SD 0.08), and the mean JC was 0.58 (SD 0.12). The mean HD for the NVB was 0.32 (SD 0.18), and the mean JC was 0.32 (SD 0.10). The mean HD for the urethra was 0.19 (SD 0.11), and the mean JC was 0.25 (SD 0.13).

CONCLUSION

s Contouring guidelines were designed for the urethra, PB, CC, CS, and NVB using images from 1.5 Tesla MR-Linac. These OARs are challenging to contour and agreement across observers was modest/poor; additional methods to improve inter-observer variability are needed. Consistent contouring of these OARs is important for prospective evaluation of dosimetric criteria and clinical outcomes related to their exposure.

CLINICAL RELEVANCE/APPLICATION

Erectile dysfunction following RT is thought to be related to damage to structures involved in sexual function located near the prostate. Similarly, a mechanism of urinary toxicity may be related to RT dose to urinary structures. A reliable method for identifying these structures could better inform RT treatment plans and potentially improve erectile and urinary functional outcomes.

Vascular Wednesday Poster Discussions

Wednesday, Nov. 30 9:00AM - 9:30AM Room: Learning Center - VA DPS

Sub-Events

W2-SPVA-1 Comparison of the Quality of Lymphatic Vessel Images Obtained Using Two Photoacoustic Imaging Systems

Participants
Yushi Suzuki, MD, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

Photoacoustic imaging (PAI) has a resolution of 0.2 mm and can evaluate lymphatic vessels in greater detail than existing methods. A new device, the LUB0, has been introduced; this is smaller than the PAI-05(both from Luxonus inc., Kawasaki, Japan), which was the device used until 2020. We aimed to determine the imaging capability of LUB0 by comparing it head-to-head with the PAI-05.

METHODS AND MATERIALS

Two healthy individuals and two lymphedema patients underwent PAI of the area of interest using both the PAI-05 and LUB0. Each participant was injected with indocyanine green subcutaneously to visualize the lymphatic vessels. After confirming with a near-infrared camera that lymphatic flow had moved to the central part of the body, PAI was performed. A physician was requested to select the method with superior image clarity.

RESULTS

The LUB0 produced sharper images of lymphatic vessels and veins than the PAI-05. In addition, the dermal backflow image obtained from a patient with lymphedema delineated the pre-collector lymphatic vessels more clearly.

CONCLUSION

s PAI can visualize detailed lymphatic flow and can be used for preoperative planning of lymphaticovenular anastomosis (LVA). The LUB0 is smaller, occupying about 1/7th of the PAI-05 footprint, and requires a shorter imaging time of 5 minutes instead of the 10 minutes taken previously. Its preview function has also made it easier to capture movement in the target area. Further, observing lymphatic pumps has become easier.

CLINICAL RELEVANCE/APPLICATION

Improved visualization of lymphatic vessels and veins with the new model allows detection and evaluation of lymphatic vessels suitable for anastomosis, which will lead to improved LVA outcomes.Acknowledgment: This research was funded by a grant from The Japan Agency for Medical Research and Development (AMED) 19he2302002h0501.

W5A-SPBR-1 Discrepancy and Clinical Impact of Second Opinion Interpretation in Breast Imaging: A Single Institution Retrospective Analysis

Participants
Lilian Wang, MD, Chicago, IL (*Presenter*) Nothing to Disclose

PURPOSE

The demand for second opinion (SO) interpretations in breast imaging has progressively increased, which may relate to increasing patient education/awareness, increasing complexity of breast cancer treatments, and the desire for subspecialized image interpretation. While this service is often provided at tertiary care centers to facilitate care in breast surgery, the impact of these interpretations on patient care is unclear. The purpose is to examine the impact of SO interpretations in breast imaging by assessing discrepancies between initial and second opinion review and their subsequent impact on clinical management for patients presenting to a tertiary care breast center.

METHODS AND MATERIALS

A retrospective database review was conducted of the SO interpretations rendered at our institution from December 1, 2020 to December 31, 2020. Interpretations were performed by 14 sub-specialized breast radiologists with a range of 1 - 20 years of experience. Outside facility interpretations were compared to second opinion interpretations in terms of BI-RADS assessment and recommendations. The results of additional imaging, biopsies, and surgical treatment were recorded.

RESULTS

All of the patients were adult females (n=85). 8 patients were lost to follow up after the second opinion interpretation was performed, resulting in 77 remaining patients, with an average age of 51 at the time of referral (range 18-79). When comparing the initial BIRADS and SO BIRADS, there was a change in BIRADS in 57%, with a decrease in 13.3%, an increase in 86.7%, and no change in 41.6%. 61.0% underwent additional imaging and 41.6% underwent subsequent imaging guided biopsy, one which was deferred. Of the 31 biopsies, 7 pathology results were malignant (22.6%), 9 were high risk (29.0%), and 15 were benign (48.4%). After additional imaging and biopsy, there was a major change in the surgical management in 22.1% of the cases, the large majority of whom underwent increased extent of disease resection and one whom averted surgical excision. The cancer detection rate was 11.7%. The overall PPV2 based on the recommendation for tissue diagnosis was 21.9%. The overall PPV3 based on the results of the biopsies actually performed was 22.6%.

CONCLUSION

s Second opinion interpretations in breast imaging significantly impact diagnostic assessment and surgical management. The minor discrepancy rate between the initial and second opinion review was 57%. 51.6% of the biopsies yielded high risk or malignant pathology which led to a major change in the final surgical plan in 22% of the patients.

CLINICAL RELEVANCE/APPLICATION

Not only does the second opinion review increase the cancer detection rate, it can also have a substantial impact on the final surgical plan.

W5A-SPBR-2 Disparities Associated with Patient Adherence to BI-RADS 3 Assessment Follow-up Recommendations

Participants
Benjamin Wilson, MD, Lutherville Timonium, MD (*Presenter*) Nothing to Disclose

PURPOSE

To assess the relationship between sociodemographic factors and adherence rates in patients with a Breast Imaging Reporting and Data System (BI-RADS) 3 assessment.

METHODS AND MATERIALS

This retrospective cohort study reviewed data from all patients with a BI-RADS 3 assessment on mammography and ultrasound examinations at a single, multisite academic institution from January 1, 2015 to December 31, 2017. Appropriate follow-up was defined as returning for the first follow-up BI-RADS 3 examination between 3 and 9 months from the index examination. Delayed follow-up was defined as returning after 9 months from the index examination. Associations between BI-RADS 3 adherence rates

and patient sociodemographic characteristics were evaluated using univariate and multivariate logistic regression.

RESULTS

There were 4038 unique patients in our study period, of which 2437 patients (60.4%) had appropriate follow-up, 765 (18.9%) patients had delayed follow-up and 836 patients (20.7%) were lost to follow-up. Univariate analysis demonstrated Black race, single relationship status, Medicaid and self-pay insurance status, and patients whose National Area Deprivation Index (ADI) is in the most disadvantaged 15% of neighborhoods were all sociodemographic factors associated with decreased likelihood adhering to BI-RADS 3 follow-up recommendations in a timely manner. In addition, on multivariate analysis, Medicaid insurance status remained significant for decreased likelihood of having appropriate BI-RADS 3 follow-up. Malignancy rate for all patients who returned for a BI-RADS 3 assessment follow-up in our cohort was 1.7% (55/3202) of which 27 (49%) were diagnosed at the 6-month follow-up, 20 (36%) at the 12-month follow-up, and 8 (15%) at the 24 or 36-month follow-up.

CONCLUSION

s Multiple sociodemographic disparities exist as barriers for appropriate adherence to follow-up recommendations in patients with a BI-RADS 3 assessment.

CLINICAL RELEVANCE/APPLICATION

Adherence to follow-up recommendations and timely follow-up of abnormalities detected on breast imaging are important and could help to avoid a delayed breast cancer diagnosis. This is particularly important for racial minority patients and patients of low socioeconomic status, who are already at risk of having a more aggressive breast cancer course and have been shown to have higher breast cancer mortality rates.

W5A-SPBR-3 Factors Associated with Decision to Undergo Mastectomy among Women with Ductal Carcinoma In Situ

Participants
Manisha Bahl, MD, MPH, Cambridge, MA (*Presenter*) Consultant, Lunit Inc;Expert Advisory Committee, 2nd.MD

PURPOSE

Mastectomy rates among women with ductal carcinoma in situ (DCIS) have dramatically increased over the last 20 years. The purpose of this study is to identify factors associated with the decision to undergo mastectomy among women with DCIS.

METHODS AND MATERIALS

A retrospective study was conducted of women diagnosed with DCIS at an academic center from 2007 to 2016. Study subjects were diagnosed with unilateral DCIS by core needle biopsy and had subsequent surgery. Medical records were reviewed for year of surgery and type of surgical treatment, in addition to patient features, imaging features, and pathological features of DCIS at biopsy. Temporal trends in mastectomy rate by year were graphically visualized, and corresponding incidence rate ratios (IRRs) and 95% confidence intervals (CIs) of mastectomy rate by year were estimated using multivariable Poisson regression. Multivariable logistic regression models were also estimated to assess features associated with mastectomy. Adjusted odds ratios (aORs), 95% CIs, and Wald P values were calculated for each model.

RESULTS

Over a ten-year period, 1313 women underwent surgical treatment for DCIS, of whom 1016 (77.4%) had breast-conserving surgery (BCS), 144 (11.0%) unilateral mastectomy, and 153 (11.7%) bilateral mastectomy. The rate of mastectomy increased over time (IRR 1.08, 95% CI: 1.04-1.13, P<0.001), which was largely attributed to women with dense rather than nondense breasts, but the rate of contralateral prophylactic mastectomy (CPM) did not increase over time (IRR 1.03, 95% CI: 0.97-1.10, P=0.30). With multivariable analysis, features associated with mastectomy were younger patient age, risk factors for breast cancer (such as BRCA1/2 mutations), a personal history of breast cancer, dense breast tissue, and pre-operative evaluation with MRI (all P<0.05). Features associated with CPM were younger patient age, White race, a personal history of breast cancer, a family history of breast cancer in a first-degree relative, and dense breast tissue (all P<0.05). There were no pathological features of DCIS at biopsy associated with mastectomy.

CONCLUSION

s Among women with DCIS, features associated with mastectomy are younger patient age, risk factors for breast cancer, a personal history of breast cancer, dense breast tissue, and pre-operative evaluation with MRI. Features associated with CPM are younger patient age, White race, a personal history of breast cancer, a family history of breast cancer, and dense breast tissue.

CLINICAL RELEVANCE/APPLICATION

Understanding factors associated with the decision to undergo mastectomy rather than BCS will help clinicians improve patient education and better guide women with DCIS through the decision-making process.

W5A-SPBR-4 Granulomatous Mastitis: A Retrospective Cohort Study in a Large County Hospital System

Participants
Ahsan Khan, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Granulomatous mastitis (GM) is a chronic inflammatory breast disease of unclear etiology. We performed this study evaluate the clinical courses of women from our large Northern California county hospital.

METHODS AND MATERIALS

With IRB approval, we retrospectively reviewed our Electronic Medical Records for biopsy-proven GM from 8/27/2015 to 4/2/2021, recording patient demographics, medical history, clinical presentation, imaging findings, microbiology, treatment, and follow-up.

RESULTS

Of 73 women with GM (mean 36.9 years old; range 19 - 64 y), 58 (79.5%) were Hispanic/Latina ethnicity (institutional percentage:

25% Hispanic/Latina ethnicity) and 12 (16.4%) had history of tuberculosis. Presentations were tenderness (61/73, 83.6%), mass (50/73, 68.4%), erythema (25/73, 34.2%), induration (14/73, 19.2%), nipple discharge (11/73, 14.7%), and inverted nipple (5/73, 6.7%). Mammography showed mass (18/73, 24.7%) or asymmetry (14/73, 19.2%); ultrasound showed mass (43/73, 58.9%) and/or abscess (17/72, 23.3%). MRI (4) showed non-mass enhancement (2), rim-enhancing (2) or heterogeneously enhancing (1) lesions, and skin thickening (2). Patients had core biopsy (66/73, 90.4%), FNA (4/73, 5.5%), or surgery (3/73, 4.1%), isolating Corynebacterium (7/73, 9.6%), Propionibacterium (5/73, 6.8%), and Mycobacterium tuberculosis (2/73, 2.7%). Treatments were antibiotics (56/73,74.7%), steroids (26/73, 34.7%) or immunosuppression (9.3%) for an average of 4.6 months. 21 (28%) patients had drainages; 2 (2.7%) had surgical excision.On follow-up, patients were lost (7) or followed clinically (66) (avg. 16.9 months, range 1-63), reporting no symptoms (43/65.2%, avg. 4.5 months), mild residual symptoms not requiring treatment (19/28.8%), or ongoing symptoms requiring treatment (4/6.0%). 10/43 patients with resolved symptoms recurred (avg. 8.9 months). Of 43 patients with follow-up imaging, 35 (81.4%) improved, 4 (9.3%) were stable, and 4 (9.3%) progressed.

CONCLUSION

s In our county hospital, GM most commonly affects young women of Hispanic/Latina descent. Clinical presentation, imaging characteristics, and treatments are variable which may pose clinical dilemmas.

CLINICAL RELEVANCE/APPLICATION

Providers must be aware of risk factors, suspicious features, and potential pitfalls of granulomatous mastitis which requires a multidisciplinary algorithmic approach to treatment.

W5A-SPBR-5 Surgical Outcomes of Lobular Neoplasia Found at MRI Guided Breast Biopsy

Participants
Jonathan Nguyen, MD, Charlottesville, VA (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the upgrade rate of lobular neoplasia found at breast MRI guided core needle biopsy to malignancy on surgical excision.

METHODS AND MATERIALS

A HIPAA compliant, IRB-approved retrospective review was performed at a single institution. Our breast biopsy database was reviewed from 7/1/2010-1/1/2022. Biopsies that demonstrated atypical lobular hyperplasia (ALH) or lobular carcinoma in situ (LCIS) as the most concerning pathology were included in the analysis. Lobular neoplasia associated with malignancy or any other high risk pathology (such as atypical ductal hyperplasia, papilloma or radial scar) were excluded. At our institution, all lobular neoplasia found on biopsy are recommended for surgical excision. The imaging findings and subsequent surgical pathology on excision of each case were reviewed. Statistical analysis was performed with Pearson exact tests to determine if an upgrade to malignancy was significantly associated with any imaging characteristics, including lesion morphology, lesion size, enhancement pattern, enhancement kinetics, T2 intensity, and study indication.

RESULTS

The database yielded 534 MRI guided breast biopsies performed during the study timeframe. Lobular neoplasia was reported as the highest risk pathologic lesion in 29/534 (5.4%) cases. The morphologic characterization of these lesions demonstrated 11 masses (37.9%), 14 areas of non-mass enhancement (48.3%), and 4 foci (13.8%). Two out of the 29 (6.9%) cases of lobular neoplasia were upgraded to malignancy on surgical excision. None of the tested imaging characteristics was significantly associated with an upgrade to malignancy.

CONCLUSION

s The incidence of pure lobular neoplasia at MRI guided core needle biopsy is low, as is the upgrade rate of these lesions to malignancy on surgical excision. None of the tested imaging features are significant predictors of upgrade to malignancy on surgical excision.

CLINICAL RELEVANCE/APPLICATION

Clinicians should be aware of the low upgrade rate of lobular neoplasia so they can better manage and discuss the pathology with patients after MRI guided core needle biopsy.

W5A-SPBR-6 Diagnostic Accuracy in Male Breast Symptomatic Disease: A Single Centre Experience

Participants
Caterina Cazzella, MD, Modena, Italy (*Presenter*) Nothing to Disclose

PURPOSE

To assess the diagnostic imaging accuracy in males with breast disease. To propose a diagnostic algorithm to evaluate the male patients with breast symptoms.

METHODS AND MATERIALS

All men patients who underwent a breast biopsy between 2014 and 2021 were retrospectively enrolled. Mammography (MX) and breast ultrasound (US) results were classified according to BI-RADS (Breast Imaging Reporting and Data System) score from 0 to 6, and Appelbaum's classification (nodular, dendritic or diffuse pattern). Furthermore, all clinical-anamnestic data were reported. To define the diagnostic accuracy, breast imaging classifications were compared with the final histological diagnosis, considered as gold standard.

RESULTS

A total of 223 patients were enrolled. All the patients performed US and, due to clinical conditions and radioprotection, only 52.9% (n=118) underwent MX. The majority (74.9%, n=167) demonstrated benign pathology (gynecomastia). Breast cancer was detected in 13.9% (n=31). Other nonneoplastic breast conditions were 11.2% (n=25). Breast imaging (MX and/or US) demonstrated 89% sensitivity and 91% specificity for gynecomastia and 80% sensitivity and 99% specificity for breast cancer, respectively. Most important malignancy predictors were: age (18 years), skin/nipple retraction, bloody nipple discharge and "nodular pattern" at imaging. Finally, a diagnostic algorithm was proposed. A combined final pattern assessment was assigned based on findings of both

US and MX imaging. Clinical and imaging results were afterwards recorded on a standard three-point classification scale, based on BI-RADS 5th Edition categories: 1 gynecomastia (BI-RADS 1 and 2); 2 undefined entity (BI-RADS 3); 3 malignant (BI-RADS 4 and 5).

CONCLUSION

s Male breast cancer is rare. Integration of imaging and clinical-anamnestic data is useful to confirm the benign pathology, avoiding unnecessary surgery/invasive procedures.

CLINICAL RELEVANCE/APPLICATION

Imaging is recommended for evaluation of male's indeterminate palpable breast mass. Protocols are not yet validated in literature; therefore we proposed an algorithm based on clinical-radiological integration.

W5A-SPBR-7 Incidence and Outcomes of COVID-19 Vaccine Related Lymphadenopathy on Screening Mammography across Vaccine Manufacturers

Participants
Alexander Leyva, MD, Boston, MA (*Presenter*) Nothing to Disclose

PURPOSE

To determine the incidence and outcomes of unilateral axillary lymphadenopathy related to COVID-19 vaccination across vaccine manufacturers at screening mammography.

METHODS AND MATERIALS

This retrospective, multisite study included consecutive patients undergoing screening mammography from 02/8/2021-01/31/2022 with at least 3 months of follow-up. In the setting of documented recent (<6 weeks) vaccination, isolated ipsilateral axillary lymphadenopathy was considered a benign finding (BI-RADS 2). When administered >6 weeks previous, or if accompanied by a breast finding, axillary ultrasound was recommended (BI-RADS 0). Patient demographics and outcomes were retrieved from electronic medical records, COVID-19 vaccination status and manufacturer from a regional vaccine registry, and cancer outcomes from a regional tumor registry. A logistic regression was fit to estimate the association with days since prior COVID-19 vaccination and odds of an ipsilateral axillary finding, adjusted for age.

RESULTS

44,473 patients (mean age 60.4 years +/- 11.4 years) underwent screening mammography at 5 sites. 39,067 (87.8%) underwent at least 1 COVID-19 vaccine dose. Median days since prior vaccine was 99.0 (IQR 40.0-179.0 days). 108 (0.3%) patients presented with unilateral lymphadenopathy in the setting of ipsilateral vaccination that did not vary across manufacturer (p=0.159). 80 (74.1%) presented <6 weeks from vaccination and deemed benign. 3 (3.8%) subsequently returned with a clinical concern in the same axilla and all were attributed BI-RADS 1/2. Of the 28 (25.9%) with ipsilateral lymphadenopathy >6 weeks from vaccination +/- ipsilateral breast finding, 9 (32.1%) were called back for additional evaluation. At diagnostic workup 4 were BI-RADS 1/2, 1 was BI-RADS 3, 4 were BI-RADS 4. Of those biopsied, 2 were malignant (both with ipsilateral breast malignancies) and 2 were benign. 19 (67.9%) were not called back due to a known non-breast malignancy or systemic illness or due to close proximity to the 6-week cutoff. Of the 19, 2 (10.5%) re-presented with a clinical concern in the same axilla and both were attributed BI-RADS 1/2. The odds of having an ipsilateral axillary finding significantly decreased for every 7 days since the prior COVID-19 vaccination dose (aOR 0.86, 95% CI 0.83-0.89, p<0.001).

CONCLUSION

s The incidence of unilateral axillary lymphadenopathy post COVID-19 vaccination on screening mammography is low at 0.3% and does not vary across vaccine manufacturer. Isolated ipsilateral lymphadenopathy <6 weeks from vaccination had a 0% rate of malignancy.

CLINICAL RELEVANCE/APPLICATION

Utilizing a pragmatic approach in managing unilateral lymphadenopathy in the setting of recent ipsilateral COVID-19 vaccination is both safe and effective.

W5A-SPBR-1

Discrepancy and Clinical Impact of Second Opinion Interpretation in Breast Imaging: A Single Institution Retrospective Analysis

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - BR DPS

Participants
Lilian Wang, MD, Chicago, IL (*Presenter*) Nothing to Disclose

PURPOSE

The demand for second opinion (SO) interpretations in breast imaging has progressively increased, which may relate to increasing patient education/awareness, increasing complexity of breast cancer treatments, and the desire for subspecialized image interpretation. While this service is often provided at tertiary care centers to facilitate care in breast surgery, the impact of these interpretations on patient care is unclear. The purpose is to examine the impact of SO interpretations in breast imaging by assessing discrepancies between initial and second opinion review and their subsequent impact on clinical management for patients presenting to a tertiary care breast center.

METHODS AND MATERIALS

A retrospective database review was conducted of the SO interpretations rendered at our institution from December 1, 2020 to December 31, 2020. Interpretations were performed by 14 sub-specialized breast radiologists with a range of 1 - 20 years of experience. Outside facility interpretations were compared to second opinion interpretations in terms of BI-RADS assessment and recommendations. The results of additional imaging, biopsies, and surgical treatment were recorded.

RESULTS

All of the patients were adult females (n=85). 8 patients were lost to follow up after the second opinion interpretation was performed, resulting in 77 remaining patients, with an average age of 51 at the time of referral (range 18-79). When comparing the initial BIRADS and SO BIRADS, there was a change in BIRADS in 57%, with a decrease in 13.3%, an increase in 86.7%, and no change in 41.6%. 61.0% underwent additional imaging and 41.6% underwent subsequent imaging guided biopsy, one which was deferred. Of the 31 biopsies, 7 pathology results were malignant (22.6%), 9 were high risk (29.0%), and 15 were benign (48.4%). After additional imaging and biopsy, there was a major change in the surgical management in 22.1% of the cases, the large majority of whom underwent increased extent of disease resection and one whom averted surgical excision. The cancer detection rate was 11.7%. The overall PPV2 based on the recommendation for tissue diagnosis was 21.9%. The overall PPV3 based on the results of the biopsies actually performed was 22.6%.

CONCLUSION

s Second opinion interpretations in breast imaging significantly impact diagnostic assessment and surgical management. The minor discrepancy rate between the initial and second opinion review was 57%. 51.6% of the biopsies yielded high risk or malignant pathology which led to a major change in the final surgical plan in 22% of the patients.

CLINICAL RELEVANCE/APPLICATION

Not only does the second opinion review increase the cancer detection rate, it can also have a substantial impact on the final surgical plan.

W5A-SPBR-2

Disparities Associated with Patient Adherence to BI-RADS 3 Assessment Follow-up Recommendations

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - BR DPS

Participants
Benjamin Wilson, MD, Lutherville Timonium, MD (*Presenter*) Nothing to Disclose

PURPOSE

To assess the relationship between sociodemographic factors and adherence rates in patients with a Breast Imaging Reporting and Data System (BI-RADS) 3 assessment.

METHODS AND MATERIALS

This retrospective cohort study reviewed data from all patients with a BI-RADS 3 assessment on mammography and ultrasound examinations at a single, multisite academic institution from January 1, 2015 to December 31, 2017. Appropriate follow-up was defined as returning for the first follow-up BI-RADS 3 examination between 3 and 9 months from the index examination. Delayed follow-up was defined as returning after 9 months from the index examination. Associations between BI-RADS 3 adherence rates and patient sociodemographic characteristics were evaluated using univariate and multivariate logistic regression.

RESULTS

There were 4038 unique patients in our study period, of which 2437 patients (60.4%) had appropriate follow-up, 765 (18.9%) patients had delayed follow-up and 836 patients (20.7%) were lost to follow-up. Univariate analysis demonstrated Black race, single relationship status, Medicaid and self-pay insurance status, and patients whose National Area Deprivation Index (ADI) is in the most disadvantaged 15% of neighborhoods were all sociodemographic factors associated with decreased likelihood adhering to BI-RADS 3 follow-up recommendations in a timely manner. In addition, on multivariate analysis, Medicaid insurance status remained significant for decreased likelihood of having appropriate BI-RADS 3 follow-up. Malignancy rate for all patients who returned for a BI-RADS 3 assessment follow-up in our cohort was 1.7% (55/3202) of which 27 (49%) were diagnosed at the 6-month follow-up, 20 (36%) at the 12-month follow-up, and 8 (15%) at the 24 or 36-month follow-up.

CONCLUSION

s Multiple sociodemographic disparities exist as barriers for appropriate adherence to follow-up recommendations in patients with a BI-RADS 3 assessment.

CLINICAL RELEVANCE/APPLICATION

Adherence to follow-up recommendations and timely follow-up of abnormalities detected on breast imaging are important and could help to avoid a delayed breast cancer diagnosis. This is particularly important for racial minority patients and patients of low socioeconomic status, who are already at risk of having a more aggressive breast cancer course and have been shown to have higher breast cancer mortality rates.

W5A-SPBR-3

Factors Associated with Decision to Undergo Mastectomy among Women with Ductal Carcinoma In Situ

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - BR DPS

Participants
Manisha Bahl, MD, MPH, Cambridge, MA (*Presenter*) Consultant, Lunit Inc;Expert Advisory Committee, 2nd.MD

PURPOSE

Mastectomy rates among women with ductal carcinoma in situ (DCIS) have dramatically increased over the last 20 years. The purpose of this study is to identify factors associated with the decision to undergo mastectomy among women with DCIS.

METHODS AND MATERIALS

A retrospective study was conducted of women diagnosed with DCIS at an academic center from 2007 to 2016. Study subjects were diagnosed with unilateral DCIS by core needle biopsy and had subsequent surgery. Medical records were reviewed for year of surgery and type of surgical treatment, in addition to patient features, imaging features, and pathological features of DCIS at biopsy. Temporal trends in mastectomy rate by year were graphically visualized, and corresponding incidence rate ratios (IRRs) and 95% confidence intervals (CIs) of mastectomy rate by year were estimated using multivariable Poisson regression. Multivariable logistic regression models were also estimated to assess features associated with mastectomy. Adjusted odds ratios (aORs), 95% CIs, and Wald P values were calculated for each model.

RESULTS

Over a ten-year period, 1313 women underwent surgical treatment for DCIS, of whom 1016 (77.4%) had breast-conserving surgery (BCS), 144 (11.0%) unilateral mastectomy, and 153 (11.7%) bilateral mastectomy. The rate of mastectomy increased over time (IRR 1.08, 95% CI: 1.04-1.13, P<0.001), which was largely attributed to women with dense rather than nondense breasts, but the rate of contralateral prophylactic mastectomy (CPM) did not increase over time (IRR 1.03, 95% CI: 0.97-1.10, P=0.30). With multivariable analysis, features associated with mastectomy were younger patient age, risk factors for breast cancer (such as BRCA1/2 mutations), a personal history of breast cancer, dense breast tissue, and pre-operative evaluation with MRI (all P<0.05). Features associated with CPM were younger patient age, White race, a personal history of breast cancer, a family history of breast cancer in a first-degree relative, and dense breast tissue (all P<0.05). There were no pathological features of DCIS at biopsy associated with mastectomy.

CONCLUSION

s Among women with DCIS, features associated with mastectomy are younger patient age, risk factors for breast cancer, a personal history of breast cancer, dense breast tissue, and pre-operative evaluation with MRI. Features associated with CPM are younger patient age, White race, a personal history of breast cancer, a family history of breast cancer, and dense breast tissue.

CLINICAL RELEVANCE/APPLICATION

Understanding factors associated with the decision to undergo mastectomy rather than BCS will help clinicians improve patient education and better guide women with DCIS through the decision-making process.

Granulomatous Mastitis: A Retrospective Cohort Study in a Large County Hospital System

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - BR DPS

Participants
Ahsan Khan, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Granulomatous mastitis (GM) is a chronic inflammatory breast disease of unclear etiology. We performed this study evaluate the clinical courses of women from our large Northern California county hospital.

METHODS AND MATERIALS

With IRB approval, we retrospectively reviewed our Electronic Medical Records for biopsy-proven GM from 8/27/2015 to 4/2/2021, recording patient demographics, medical history, clinical presentation, imaging findings, microbiology, treatment, and follow-up.

RESULTS

Of 73 women with GM (mean 36.9 years old; range 19 - 64 y), 58 (79.5%) were Hispanic/Latina ethnicity (institutional percentage: 25% Hispanic/Latina ethnicity) and 12 (16.4%) had history of tuberculosis. Presentations were tenderness (61/73, 83.6%), mass (50/73, 68.4%), erythema (25/73, 34.2%), induration (14/73, 19.2%), nipple discharge (11/73, 14.7%), and inverted nipple (5/73, 6.7%). Mammography showed mass (18/73, 24.7%) or asymmetry (14/73, 19.2%); ultrasound showed mass (43/73, 58.9%) and/or abscess (17/72, 23.3%). MRI (4) showed non-mass enhancement (2), rim-enhancing (2) or heterogeneously enhancing (1) lesions, and skin thickening (2). Patients had core biopsy (66/73, 90.4%), FNA (4/73, 5.5%), or surgery (3/73, 4.1%), isolating Corynebacterium (7/73, 9.6%), Propionibacterium (5/73, 6.8%), and Mycobacterium tuberculosis (2/73, 2.7%). Treatments were antibiotics (56/73,74.7%), steroids (26/73, 34.7%) or immunosuppression (9.3%) for an average of 4.6 months. 21 (28%) patients had drainages; 2 (2.7%) had surgical excision.On follow-up, patients were lost (7) or followed clinically (66) (avg. 16.9 months, range 1-63), reporting no symptoms (43/65.2%, avg. 4.5 months), mild residual symptoms not requiring treatment (19/28.8%), or ongoing symptoms requiring treatment (4/6.0%). 10/43 patients with resolved symptoms recurred (avg. 8.9 months). Of 43 patients with follow-up imaging, 35 (81.4%) improved, 4 (9.3%) were stable, and 4 (9.3%) progressed.

CONCLUSION

s In our county hospital, GM most commonly affects young women of Hispanic/Latina descent. Clinical presentation, imaging characteristics, and treatments are variable which may pose clinical dilemmas.

CLINICAL RELEVANCE/APPLICATION

Providers must be aware of risk factors, suspicious features, and potential pitfalls of granulomatous mastitis which requires a multidisciplinary algorithmic approach to treatment.

W5A-SPBR-5

Surgical Outcomes of Lobular Neoplasia Found at MRI Guided Breast Biopsy

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - BR DPS

Participants
Jonathan Nguyen, MD, Charlottesville, VA (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the upgrade rate of lobular neoplasia found at breast MRI guided core needle biopsy to malignancy on surgical excision.

METHODS AND MATERIALS

A HIPAA compliant, IRB-approved retrospective review was performed at a single institution. Our breast biopsy database was reviewed from 7/1/2010-1/1/2022. Biopsies that demonstrated atypical lobular hyperplasia (ALH) or lobular carcinoma in situ (LCIS) as the most concerning pathology were included in the analysis. Lobular neoplasia associated with malignancy or any other high risk pathology (such as atypical ductal hyperplasia, papilloma or radial scar) were excluded. At our institution, all lobular neoplasia found on biopsy are recommended for surgical excision. The imaging findings and subsequent surgical pathology on excision of each case were reviewed. Statistical analysis was performed with Pearson exact tests to determine if an upgrade to malignancy was significantly associated with any imaging characteristics, including lesion morphology, lesion size, enhancement pattern, enhancement kinetics, T2 intensity, and study indication.

RESULTS

The database yielded 534 MRI guided breast biopsies performed during the study timeframe. Lobular neoplasia was reported as the highest risk pathologic lesion in 29/534 (5.4%) cases. The morphologic characterization of these lesions demonstrated 11 masses (37.9%), 14 areas of non-mass enhancement (48.3%), and 4 foci (13.8%). Two out of the 29 (6.9%) cases of lobular neoplasia were upgraded to malignancy on surgical excision. None of the tested imaging characteristics was significantly associated with an upgrade to malignancy.

CONCLUSION

s The incidence of pure lobular neoplasia at MRI guided core needle biopsy is low, as is the upgrade rate of these lesions to malignancy on surgical excision. None of the tested imaging features are significant predictors of upgrade to malignancy on surgical excision.

CLINICAL RELEVANCE/APPLICATION

Clinicians should be aware of the low upgrade rate of lobular neoplasia so they can better manage and discuss the pathology with patients after MRI guided core needle biopsy.

Diagnostic Accuracy in Male Breast Symptomatic Disease: A Single Centre Experience

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - BR DPS

Participants
Caterina Cazzella, MD, Modena, Italy (*Presenter*) Nothing to Disclose

PURPOSE

To assess the diagnostic imaging accuracy in males with breast disease. To propose a diagnostic algorithm to evaluate the male patients with breast symptoms.

METHODS AND MATERIALS

All men patients who underwent a breast biopsy between 2014 and 2021 were retrospectively enrolled. Mammography (MX) and breast ultrasound (US) results were classified according to BI-RADS (Breast Imaging Reporting and Data System) score from 0 to 6, and Appelbaum's classification (nodular, dendritic or diffuse pattern). Furthermore, all clinical-anamnestic data were reported. To define the diagnostic accuracy, breast imaging classifications were compared with the final histological diagnosis, considered as gold standard.

RESULTS

A total of 223 patients were enrolled. All the patients performed US and, due to clinical conditions and radioprotection, only 52.9% (n=118) underwent MX. The majority (74.9%, n=167) demonstrated benign pathology (gynecomastia). Breast cancer was detected in 13.9% (n=31). Other nonneoplastic breast conditions were 11.2% (n=25). Breast imaging (MX and/or US) demonstrated 89% sensitivity and 91% specificity for gynecomastia and 80% sensitivity and 99% specificity for breast cancer, respectively. Most important malignancy predictors were: age (18 years), skin/nipple retraction, bloody nipple discharge and "nodular pattern" at imaging. Finally, a diagnostic algorithm was proposed. A combined final pattern assessment was assigned based on findings of both US and MX imaging. Clinical and imaging results were afterwards recorded on a standard three-point classification scale, based on BI-RADS 5th Edition categories: 1 gynecomastia (BI-RADS 1 and 2); 2 undefined entity (BI-RADS 3); 3 malignant (BI-RADS 4 and 5).

CONCLUSION

s Male breast cancer is rare. Integration of imaging and clinical-anamnestic data is useful to confirm the benign pathology, avoiding unnecessary surgery/invasive procedures.

CLINICAL RELEVANCE/APPLICATION

Imaging is recommended for evaluation of male's indeterminate palpable breast mass. Protocols are not yet validated in literature; therefore we proposed an algorithm based on clinical-radiological integration.

W5A-SPBR-7

Incidence and Outcomes of COVID-19 Vaccine Related Lymphadenopathy on Screening Mammography across Vaccine Manufacturers

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - BR DPS

Participants
Alexander Leyva, MD, Boston, MA (*Presenter*) Nothing to Disclose

PURPOSE

To determine the incidence and outcomes of unilateral axillary lymphadenopathy related to COVID-19 vaccination across vaccine manufacturers at screening mammography.

METHODS AND MATERIALS

This retrospective, multisite study included consecutive patients undergoing screening mammography from 02/8/2021-01/31/2022 with at least 3 months of follow-up. In the setting of documented recent (<6 weeks) vaccination, isolated ipsilateral axillary lymphadenopathy was considered a benign finding (BI-RADS 2). When administered >6 weeks previous, or if accompanied by a breast finding, axillary ultrasound was recommended (BI-RADS 0). Patient demographics and outcomes were retrieved from electronic medical records, COVID-19 vaccination status and manufacturer from a regional vaccine registry, and cancer outcomes from a regional tumor registry. A logistic regression was fit to estimate the association with days since prior COVID-19 vaccination and odds of an ipsilateral axillary finding, adjusted for age.

RESULTS

44,473 patients (mean age 60.4 years +/- 11.4 years) underwent screening mammography at 5 sites. 39,067 (87.8%) underwent at least 1 COVID-19 vaccine dose. Median days since prior vaccine was 99.0 (IQR 40.0-179.0 days). 108 (0.3%) patients presented with unilateral lymphadenopathy in the setting of ipsilateral vaccination that did not vary across manufacturer (p=0.159). 80 (74.1%) presented <6 weeks from vaccination and deemed benign. 3 (3.8%) subsequently returned with a clinical concern in the same axilla and all were attributed BI-RADS 1/2. Of the 28 (25.9%) with ipsilateral lymphadenopathy >6 weeks from vaccination +/- ipsilateral breast finding, 9 (32.1%) were called back for additional evaluation. At diagnostic workup 4 were BI-RADS 1/2, 1 was BI-RADS 3, 4 were BI-RADS 4. Of those biopsied, 2 were malignant (both with ipsilateral breast malignancies) and 2 were benign. 19 (67.9%) were not called back due to a known non-breast malignancy or systemic illness or due to close proximity to the 6-week cutoff. Of the 19, 2 (10.5%) re-presented with a clinical concern in the same axilla and both were attributed BI-RADS 1/2. The odds of having an ipsilateral axillary finding significantly decreased for every 7 days since the prior COVID-19 vaccination dose (aOR 0.86, 95% CI 0.83-0.89, p<0.001).

CONCLUSION

s The incidence of unilateral axillary lymphadenopathy post COVID-19 vaccination on screening mammography is low at 0.3% and does not vary across vaccine manufacturer. Isolated ipsilateral lymphadenopathy <6 weeks from vaccination had a 0% rate of malignancy.

CLINICAL RELEVANCE/APPLICATION

Utilizing a pragmatic approach in managing unilateral lymphadenopathy in the setting of recent ipsilateral COVID-19 vaccination is both safe and effective.

Cardiac Wednesday Poster Discussions - A

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - CA DPS

Sub-Events

W5A-SPCA-2 Correlation between Quantitative Assessment of Epicardial Adipose Tissue and Atrial Fibrillation in Hypertrophic Cardiomyopathy by Cardiac Magnetic Resonance

Participants
Xiaohu Li, MD, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

To find out the relationship between EAT and atrial fibrillation (AF) in Chinese patients with hypertrophic cardiomyopathy (HCM).

METHODS AND MATERIALS

The study included 79 HCM patients (51 males and 28 females; mean age:53.7± 14.8 years; including 19 patients with AF and 60 patients without AF) and 20 healthy controls (11 males and 9 females; mean age:51.8± 19.8years). All participants underwent Laboratory examination, ECG, and cardiovascular magnetic resonance (CMR) examination. Function, volumes, the presence of late gadolinium enhancement (LGE), and the amount of EAT were assessed.

RESULTS

The epicardial adipose tissue volume index (EATVI) in HCM patients (60.5±18.4 ml/m2) was significantly higher than in healthy controls (47.9±4.5 ml/m2, P< 0.05). And HCM group had significantly bigger EATV and thicker EAT thickness than the healthy controls. Furthermore, EATV and EATVI were significant greater between AF and without AF in HCM (143.4±32.6 ml vs 95.0±25.4 ml, P<0.001, and 81.9±17.1 ml vs 53.7±12.8 ml P< 0.001). The EATVI was associated with left ventricle wall thickness (LVWT), right atrioventricular groove (RAVG), and AF in multivariable linear regression analysis among HCM patients. Applying univariable logistic regression analysis, left ventricle ejection fractions (LVEF, OR, 0.921, P= 0.015), left atrium diameter (LAD, OR, 1.149, P= 0.007), left atrium diameter index (LAVI, OR, 1.028, P= 0.035), EATV (OR, 1.053, P< 0.001), EATVI (OR, 1.129, P< 0.001), RAVG (OR, 1.158, P= 0.029), superior interventricular groove (SIVG, OR, 1.443, P= 0.002) and inferior interventricular groove (IIVG, OR, 1.790, P= 0.001) remained independent predictor of the presence of AF in HCM patients (OR: 5.518, P= 0.038, OR: 1.397, P= 0.004, OR: 0.634, P= 0.022, respectively)

CONCLUSION

s HCM patients exhibited an increased EATVI in comparison to healthy controls, especially in HCM with AF. The EATVI was associated with LVWT, RAVG, and AF in HCM patients. LVEF, LAD, LAVI, EATV, EATVI, RAVG, SIVG, and IIVG is independent predictor of AF occurrence, and EA TV and EA TVI provide better performance.

CLINICAL RELEVANCE/APPLICATION

Increased epicardial adipose tissue (EAT) is a cardiometabolic tissue that is associated with poor cardiovascular outcomes. While the underlying magnetic resonance imaging features of this link are not well understood in hypertrophic cardiomyopathy.

W5A-SPCA-3 Incipient Myocardial Dysfunction and Cardiopulmonary Structural Alterations are Associated with Persistent Symptoms after Infection by SARS-Cov2 Delta Strain

Participants
Yoko Kato, MD, PhD, (*Presenter*) Speaker, Canon Medical Systems Corporation

PURPOSE

To define cardio-pulmonary alterations of structure and function associated with symptoms of Long Covid 3-19 months after infection with Delta Sars-CoV2.

METHODS AND MATERIALS

Patients at least 3 months post-COVID infection were recruited. COVID- related clinical information and demographics were collected from medical records. Comorbidities were obtained through a questionnaire. Ultra-high resolution CT (UHCT) was used to image lungs and perform coronary angiography within 3 weeks of cardiac MRI using CINE, T1/T2 map, and late gadolinium enhancement (LGE) on a 3.0T scanner (Canon Galan 3T). The association of the persistent post-COVID symptom with individual cardiac MRI index of function, deformation, and tissue characteristics in the worst tertile group was investigated with adjustments for the demographics, comorbidities, and other COVID-related information. The association between other COVID-related information with cardiac indices were also investigated.

RESULTS

(A) Forty-two participants at the median of 325 days post COVID diagnosis with the majority of SARS-CoV2 Delta infection

(diagnosis date between 4/7/2020 and 11/27/2021) were enrolled. The cardiac function and tissue characteristics were generally well maintained. (B) Persistent post-COVID symptoms were associated with reduced LVEF and LV strain and marginally associated with RVEF. History of pulmonary disease, 75% of which was asthma (a known risk factor of long COVID), was also associated with persistent post-COVID symptoms. (C) Hospitalization was marginally associated with reduced LVEF. Lung abnormality on UHCT was associated with reduced LAEF total, LA strain, and RVEF. All the 3 cases with LGE were within the worst tertile of LVEF. None of the COVID-related information was associated with native T1 (nT1)/ ECV/ T2 except association of hospitalization with elevated nT1.

CONCLUSION

s In patients with SARS-CoV2 Delta infection, persistent COVID-related symptoms (Long Covid) were associated with LV, LA and RV dysfunction. Patients with cardiac dysfunction were more likely to have UHCT defined lung abnormalities and LGE myocardial fibrosis. There were no associations of Long Covid with changes in ECV or native T1 as well as T2 mapping.

CLINICAL RELEVANCE/APPLICATION

In patients with SARS-CoV2 Delta infection, LV, LA and RV dysfunction were associated with persistent symptoms. Patients with LV dysfunction revealed pulmonary alterations and myocardial scar by cardio-pulmonary phenotyping.

W5A-SPCA-4 Novel Metabolic Imaging Biomarker Using Disease-specific Peak in Single Breath-hold1H-MR Spectroscopy for Assessment of Myocardial Involvement in Patients with Fabry Disease

Participants
Masaru Shiotani, RT, Suita, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Fabry disease is characterized by deposition of sphingolipids caused by a deficiency of the enzyme alpha-galactosidase A and cardiac involvement is crucial for morbidity and mortality. Therefore, measurement of myocardial sphingolipid deposition is an important for evaluation of the early cardiac involvement and the indication of enzyme replacement therapy. Metabolic imaging by 1H-MR Spectroscopy (MRS) has a potential as disease-specific biomarker to directly measure the abnormal accumulation. However, feasibility of for Fabry disease is still uncertain. This study aimed to assess the specific MRS peak of sphingolipids using simulated phantom and evaluate the feasibility of MRS for detection of myocardial metabolic abnormality in patients with Fabry disease.

METHODS AND MATERIALS

Simulated phantom containing the Lyso-GB3 (one of the sphingolipids that is abnormal accumulation in Fabry disease) which were dissolved in methanol underwent MRS. We measured the spectral peak of simulated phantom and pure methanol. Seven patients with genetically proven Fabry disease involving the myocardium diagnosed by standard cardiac MRI and 7 healthy volunteers underwent cardiac MRS.MRS was obtained using single voxel PRESS sequence positioned within the ventricular septum with single breath-hold. The peak of sphingolipids (based on phantom study), lipid (0.9+1.3 ppm) and water (4.7 ppm) were used as metabolic indicators. Each peak ratio was compared between Fabry disease patients and volunteers.

RESULTS

In phantom study, MRS showed specific spectra of Lyso-GB3 with intense resonance from 3.5 ppm compared with only methanol. Compared with the volunteer group, the 3.5ppm/water peak ratio in Fabry group was significantly higher, and there was no significant difference in the 3.5ppm+lipid/water and lipid/water peak ratio. The cut-off value for 3.5ppm/water peak ratio to differentiate between Fabry disease and volunteer was 0.031 (sensitivity 86 %, specificity 57%, AUC 0.78).

CONCLUSION

s In phantom study, the peak of 3.5ppm in MRS was associated with Lyso-GB3 (one of the sphingolipids). This peak ratio showed the higher values in Fabry disease with cardiac involvement and enabled the detection of abnormal sphingolipids deposition with moderate diagnostic accuracy. To our knowledge, this is the first study to assess the myocardial abnormal content in Fabry disease using 3.5ppm peak of MRS.

CLINICAL RELEVANCE/APPLICATION

3.5 ppm peak of MRS could be disease-specific imaging biomarker for direct quantification of myocardial sphingolipid accumulation of Fabry disease beyond the conventional MRI sequences. This metabolic imaging has a potential for evaluation of the early cardiac involvement, disease severity and indication of enzyme replacement therapy.

W5A-SPCA-4

Novel Metabolic Imaging Biomarker Using Disease-specific Peak in Single Breath-hold1H-MR Spectroscopy for Assessment of Myocardial Involvement in Patients with Fabry Disease

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - CA DPS

Participants
Masaru Shiotani, RT, Suita, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Fabry disease is characterized by deposition of sphingolipids caused by a deficiency of the enzyme alpha-galactosidase A and cardiac involvement is crucial for morbidity and mortality. Therefore, measurement of myocardial sphingolipid deposition is an important for evaluation of the early cardiac involvement and the indication of enzyme replacement therapy. Metabolic imaging by 1H-MR Spectroscopy (MRS) has a potential as disease-specific biomarker to directly measure the abnormal accumulation. However, feasibility of for Fabry disease is still uncertain. This study aimed to assess the specific MRS peak of sphingolipids using simulated phantom and evaluate the feasibility of MRS for detection of myocardial metabolic abnormality in patients with Fabry disease.

METHODS AND MATERIALS

Simulated phantom containing the Lyso-GB3 (one of the sphingolipids that is abnormal accumulation in Fabry disease) which were dissolved in methanol underwent MRS. We measured the spectral peak of simulated phantom and pure methanol. Seven patients with genetically proven Fabry disease involving the myocardium diagnosed by standard cardiac MRI and 7 healthy volunteers underwent cardiac MRS.MRS was obtained using single voxel PRESS sequence positioned within the ventricular septum with single breath-hold. The peak of sphingolipids (based on phantom study), lipid (0.9+1.3 ppm) and water (4.7 ppm) were used as metabolic indicators. Each peak ratio was compared between Fabry disease patients and volunteers.

RESULTS

In phantom study, MRS showed specific spectra of Lyso-GB3 with intense resonance from 3.5 ppm compared with only methanol. Compared with the volunteer group, the 3.5ppm/water peak ratio in Fabry group was significantly higher, and there was no significant difference in the 3.5ppm+lipid/water and lipid/water peak ratio. The cut-off value for 3.5ppm/water peak ratio to differentiate between Fabry disease and volunteer was 0.031 (sensitivity 86 %, specificity 57%, AUC 0.78).

CONCLUSION

s In phantom study, the peak of 3.5ppm in MRS was associated with Lyso-GB3 (one of the sphingolipids). This peak ratio showed the higher values in Fabry disease with cardiac involvement and enabled the detection of abnormal sphingolipids deposition with moderate diagnostic accuracy. To our knowledge, this is the first study to assess the myocardial abnormal content in Fabry disease using 3.5ppm peak of MRS.

CLINICAL RELEVANCE/APPLICATION

3.5 ppm peak of MRS could be disease-specific imaging biomarker for direct quantification of myocardial sphingolipid accumulation of Fabry disease beyond the conventional MRI sequences. This metabolic imaging has a potential for evaluation of the early cardiac involvement, disease severity and indication of enzyme replacement therapy.

W5A-SPCH-2 Ultrashort Echo Time (UTE) MRI of The Lung In Term and Pre-term Infants

Participants
Yujie Chen, Chengdu, China (*Presenter*) Nothing to Disclose

PURPOSE

Postnatal lung development is important in infants, especially in preterm births while relevant imaging data is scarce. Ultrashort echo-time (UTE) MRI provides a non-invasive approach to explore the lung tissue architecture in term and preterm infants. The purpose of this study was to explore lung tissue architecture in term and preterm infants using three-dimensional (3D) UTE MRI.

METHODS AND MATERIALS

A total of sixty infants born term or preterm with morphologically normal lungs (26 preterm, 34 full-term, range 2 day to 1 year and 2 months) underwent 3D UTE MRI at a 3T pediatric MR scanner (Alpha, United Imaging Healthcare, Shanghai, China). Average lung parenchymal signal intensity was evaluated by two experienced radiologists. The whole lung signal intensity was calculated as the average signal intensity of both lungs. Paired t-test was used to test the differences of average lung signal intensities between term and preterm infants. Spearman rank correlation was performed to test the correlation of the lung parenchymal signal intensity to age. Interrater agreement was assessed using intraclass correlation coefficients (ICCs).

RESULTS

Interobserver reliability analysis revealed almost perfect agreement (ICC = 0.964). Average lung parenchymal signal intensity was significant different (p=0.038) in preterm (mean 282.4, SD 87.1) and full-term infants.(mean 341.8, SD 128.8)(Figure 1). Lung signal intensity is positively correlated to age in infant period (r=0.319, p=0.013), and positively correlated to age in preterm group (r=0.408, p=0.039).

CONCLUSION

s The UTE MRI technique for lung imaging has potential value in infants, especially in preterm births. This radiation-free technique shows lung structures clearly and is potentially valuable for the detection of disease.

CLINICAL RELEVANCE/APPLICATION

UTE MRI is a promising radiation-free approach for evaluation of lung structure of infants and is potentially valuable for the detection of disease.

W5A-SPCH-3 Imaging of Central Lymphatic Abnormalities in Patients with Trisomy 21

Participants
Karen Ramirez Suarez, MD, Philadelphia, PA (*Presenter*) Nothing to Disclose

PURPOSE

To describe the clinical importance of lymphatic imaging in patients with Trisomy 21 and congenital heart disease and depict the most common imaging findings of the central lymphatic abnormalities in these patients.

METHODS AND MATERIALS

We conducted a single-center retrospective review of all patients with a confirmed history of Trisomy 21 who presented for lymphatic imaging over a 7-year period. Dynamic contrast-enhanced MR lymphangiography evaluation was performed which included unenhanced T2 weighted (T2-W) imaging and T1-weighted dynamic-contrast MR lymphangiography. A pediatric radiologist evaluated the images. The distribution of fluid on T2-W imaging and lymphatic flow of contrast agent are reported. Electronic medical records were reviewed for clinical history and outcomes.

RESULTS

We identified a total of 17 patients (13 male), including 8 infants, 7 children, and 2 adults. Congenital heart disease was present in all patients. Diagnosis included single ventricle physiology (n=9), Tetralogy of Fallot (n=2), atrial septal defect (n=2), and ventricular septal defect (n=4). Presenting symptoms included chylothorax (n=9), plastic bronchitis (n=3), chylous ascites (n=3), protein-losing enteropathy (n=1), and pericardial effusion (n=1). 14 patients had surgical interventions including Fontan in 47% of cases (n=8). Two patients died (12%) by the time the data was collected. In imaging evaluation, abnormal lymphatic flow with

pulmonary and/or mesenteric perfusion was seen in 15 patients (88%) and abnormalities in the thoracic duct were present in 11 patients (65%).

CONCLUSION

s Patients with Trisomy 21 and clinical evidence of lymphatic dysfunction need lymphatic imaging evaluation to diagnose and treat central lymphatic abnormalities. Common imaging findings in these patients include retrograde lymphatic flow, pulmonary and mesenteric lymphatic perfusion, and thoracic duct abnormalities.

CLINICAL RELEVANCE/APPLICATION

Patients with trisomy 21 have an increased risk for the development of lymphatic disorders, and the extent and nature of these abnormalities are poorly understood. Literature regarding lymphatic imaging evaluation and treatment in these patients is scarce. Understanding and recognizing characteristic lymphatic abnormalities in patients with Trisomy 21 may help with the diagnosis and treatment of these patients.

W5A-SPCH-4 Reference Value of Cardiovascular Borders on Frontal Chest X-ray from Echocardiographically Confirmed Normal Subjects.

Participants
Dong Hyun Yang, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this study was to determine the normal reference value of cardiovascular borders (CB) on frontal chest radiography (CXR) from normal cohorts confirmed by transthoracic echocardiography.

METHODS AND MATERIALS

91,736 subjects with normal echocardiography and frontal CXR from a single center were enrolled in this study (study period, 2000 - 2016; mean age 53.7 years; 64.3% of male). Previously validated deep learning-based CB analysis system calculated cardiothoracic ratio (CTR), the width of each CB (right upper/lower, aortic knob, pulmonary artery, left atrial appendage [LAA], left lower, descending aorta), and carinal angle. Reference CB values in each age group and gender were determined. Correlation between CB values and echocardiography-driven measurements was demonstrated. CB values were compared with those of the external datasets (MIMIC-CXR CheXpert)

RESULTS

Normal CTR is 0.44 (<40 years 0.42, >70 years 0.46; external datasets MIMIC-CXR 0.47, ChXpert 0.44). The normal carinal angle was 72 degrees (75 in MIMIC-CXR, 74 in CheXpert). The width (mm) of each CB is as follows: right upper 29.5, right lower 40.3, aortic knob 38.1, pulmonary artery 38.6, LAA 46.2, left lower 84.5, and descending aorta 34.1. The CTR, aortic knob, right upper CB, descending aorta, and left lower CB are increased with age. Ascending aortic diameter on echocardiography was correlated with the width of the right upper CB (r=0.23), aortic knob (r=0.27), descending aorta (r=0.28), and left lower CB (r=0.25).

CONCLUSION

s The normal reference values for CB on frontal chest radiographs were determined using CB analysis software powered by deep learning.

CLINICAL RELEVANCE/APPLICATION

The CB reference values obtained in this study may be used in conjunction with CXR analysis software for the purpose of identifying or classifying cardiovascular disease.

W5A-SPCH-5 Image Quality and Radiation Dose of Contrast-Enhanced Chest CT acquired on a Clinical Photon-Counting Detector CT vs 2nd Generation Dual-Source CT in An Oncologic Cohort

Participants
Lukas Walder, Tuebingen, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Our aim was to compare image quality and patient dose of contrast-enhanced oncologic chest CT of 1st generation photon-counting detector (PCD-CT) and 2nd generation dual-source dual-energy CT (DSCT).

METHODS AND MATERIALS

For this reason one hundred oncologic patients (63 male, 65±11 years, BMI: 16-42 kg/m2) were prospectively enrolled. Clinically indicated contrast-enhanced chest CT were obtained with PCD-CT and compared to previously obtained chest DSCT in the same individuals. The median time interval between the scans was three months. The same contrast media protocol was used for both scans. PCD-CT was performed in QuantumPlus mode (obtaining full spectral information) at 120kVp. DSCT was performed using 100 kV for Tube A and 140 kV for Tube B. "T3D" PCD-CT images were evaluated, which emulate conventional 120 keV polychromatic images. For DSCT, the convolution algorithm was set at I31f with class 1 iterative reconstruction, whereas comparable Br40 kernel and iterative reconstruction (Q1 and Q3) were applied for PCD-CT. Two radiologists assessed image quality using a 5-point Likert scale and performed measurements of vessels and lung parenchyma for signal-to-noise ratio (SNR) and contrast-to-noise ratio (CNR) measurements.

RESULTS

PCD-CT CNRvessel was significantly higher than DSCT CNRvessel (all, p<0.05). Readers rated image contrast of mediastinum, vessels, and lung parenchyma significantly higher on PCD-CT than DSCT images (p<0.001). Q3 PCD-CT CNRlung_parenchyma was significantly higher than DSCT CNRlung_parenchyma and Q1 PCD-CT CNRlung_parenchyma (p<0.01). CTDI, DLP, SSDE mean values for PCD-CT and DSCT were 4.17±1.29 mGy vs. 7.21±0.49 mGy, 151.01±48.56 mGy*cm vs. 288.64±31.17 mGy*cm and 4.23±0.97 vs. 7.48±1.09, respectively.

CONCLUSION

s PCD-CT enables oncologic chest CT with a significantly reduced dose while retaining image quality similar to a 2nd generation

s PCD-CT enables oncologic chest CT with a significantly reduced dose while retaining image quality similar to a 2nd generation DSCT for comparable protocol settings.

CLINICAL RELEVANCE/APPLICATION

The mean SSDE for the PCD-CT could be reduced by 43% compared to the previous DSCT examination

W5A-SPCH-6 Lung Cancer Screening Using Clinical Photon-Counting-Detector CT and Energy-Integrating-Detector CT: A Prospective Patient Study

Participants
Akitoshi Inoue, MD, PhD, Rochester, MN (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the image quality of photon-counting detector (PCD) CT in patients undergoing lung cancer screening compared with energy-integrating detector (EID) CT in a prospective multi-reader study.

METHODS AND MATERIALS

Patients undergoing clinically-indicated lung cancer screening at EID CT (SOMATOM Force, Siemens Healthineers GmbH) were prospectively recruited to undergo same-day research CT on an FDA-approved PCD-CT system (NAEOTOM Alpha, Siemens Healthineers GmbH) using Qr56 kernel, 0.8 mm slice thickness, 512x 512 matrix. Both systems used matched radiation dose (CTDIvol=0.9 mGy) using automatic exposure control. . Three thoracic radiologists blinded to the image type compared PCD-CT and EID-CT images in a side-by-side fashion, using a 5-point Likert comparison score (-2 [left image is worse] to +2 [left image is better]) for artifact, sharpness, image noise, diagnostic image quality, emphysema visualization, and lung nodule evaluation. A post hoc correction of scores was performed (-2 [PCD-CT image is worse than EID-CT] to +2 [PCD-CT image is better than EID-CT]). A non-reader radiologist measured image noise as the standard deviation of CT number (HU).

RESULTS

Thirty-three patients (66.9 ± 5.6 years, 11 female,) were enrolled. 45% (15/33) patients had BMI over 30. Pulmonary nodules (3 ground-glass nodules; 1 part-solid nodule; 7 solid nodules, median diameter 6 mm [range: 4—11 mm]) were identified in 11 of 33 patients. Comparison scores were significantly higher (positive score = PCD-CT better) in sharpness (0.8 ± 0.6, p<0.001), image noise (0.3 ± 0.8, p<0.001), diagnostic image quality (0.4 ± 0.6, p<0.001), emphysema visualization (0.3 ± 0.6, p<0.001), and lung nodule borders (0.8 ± 0.9 p<0.001), but significantly lower for artifact (-0.4 ± 0.6; P<0.001). PCD-CT had significantly lower objective image noise (74.4 ± 10.5 vs. 80.1 ± 8.6; P=0.048) despite slightly lower dose CTDIvol (0.61 ± 0.21 vs. 0.73 ± 0.22; P<0.001).

CONCLUSION

s PCD-CT demonstrated better image quality in the evaluation of pulmonary emphysema and lung nodules compared to EID-CT in the setting of low-dose lung cancer screening CT.

CLINICAL RELEVANCE/APPLICATION

PCD-CT provides improved image quality in low-dose lung cancer screening to evaluate nodule and emphysema.

W5A-SPCH-7 MRI-derived Ventilation Inhomogeneity from 3D-UTE MRI in Patients with Cystic Fibrosis on Therapy with CFTR Modulators

Participants
Julius Heidenreich, MD, Wurzburg, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the image-derived ventilation inhomogeneity of functional 3D UTE MRI compared with lung clearance index in patients under treatment with the new CFTR modulator combination therapy Trikafta.

METHODS AND MATERIALS

3D-UTE MRI imaging of the lungs was performed on a 3T MR-scanner (MAGNETOM Prisma, Siemens Healthcare GmbH, Erlangen, Germany). A prototypical 3D UTE VIBE sequence with a stack of spirals trajectory was used with the following parameters: TE = 0.05 ms; TR = 2.35 ms; flip angle = 4°, non-selective hard pulse duration = 60 µs; FOV = 600 mm x 600 mm; spiral interleaves = 264; readouts per spiral = 265; resolution = 2.3 mm isotrope; number of partitions = 102 ± 10; acquisition time per measurement = 12.3 ± 1.5 s. Sixteen patients with CF underwent MR imaging in 2019 and a follow-up examination in 2021. Images from in- and expiration were co-registered and segmented using a deep-learning approach. Signal intensities were analyzed per voxel. Voxelwise fractional ventilation, expansion rate and interquartile range (IQR) of ventilation as a measurement of ventilation inhomogeneity were obtained. The IQR of MRI ventilation was correlated with the results of pulmonary function tests and lung clearance index (LCI).

RESULTS

8 patients received a new therapy with the triple combination Trikafta (ivacaftor/elexacaftor/tezacaftor) between 2019 and 2021. 8 patients did not receive drug therapy between both examinations. The ventilation inhomogeneity (IQR) correlated almost perfectly with the LCI2.5% in the initial and follow-up examination (Spearman's rho = 0.90, p < 0.01). Between initial and follow-up, LCI and MRI-derived ventilation inhomogeneity changed proportionally. MRI-derived ventilation inhomogeneity decreased significantly in patients on therapy (Wilcoxon p = 0.02). Color-coded ventilation maps could be used for visual and regional functional assessment as well as evaluation of morphology.

CONCLUSION

s Functional lung imaging with single breath-hold 3D-UTE MRI can be used for calculation of an MRI-derived ventilation inhomogeneity, which correlates almost perfectly with the lung clearance index, a sensitive measure for lung function. Using functional lung MRI, the clinical improvement of patients on therapy with the recently approved drug-combination ivacaftor/elexacaftor/tezacaftor can be evaluated based on image analysis.

CLINICAL RELEVANCE/APPLICATION

For CF patients who need recurrent imaging of the lungs a radiation free approach which can be used for simultaneous morphologic and functional imaging is favourable.

W5A-SPCH-8 Quantitative CT in Chronic Lung Diseases: A Real-life Study of Changes in Physician's Decision Making

Participants
Matheus Zanon, MD, MSc, Porto Alegre, Brazil (*Presenter*) Nothing to Disclose

PURPOSE

To determine how physicians' diagnoses, diagnostic certainty, and management decisions are affected by the results of quantitative computed tomography (QCT) in the real-life management of chronic lung diseases.

METHODS AND MATERIALS

Data was collected prospectively during 12 months from 5 different centers. Physicians were surveyed before and after QCT to determine the possible new diagnosis, diagnostic confidence, and management decisions. The doctors have access to all patients' functional and laboratory tests previously to QCT results. The QCT analysis comprised the following parameters: 1) total lung volume; 2) normal lung density volume; 3) normal lung index; 4) emphysema index; 5) percentage of high-attenuation areas; and 6) air trapping index.

RESULTS

QTC analysis was done in 92 patients (men, 54; mean age 67+/- 21 years), and surveys were completed by 11 doctors (senior pulmonologists). The most common new diagnoses were chronic interstitial lung disease (15.2%) and emphysema (9.7%). Patient management was changed in 11 cases (11.9%) as follows: new specialized care by an ILD multidisciplinary team (n=7, 7.6%) and new targeted treatment of small airway disease (n=4, 4.3%). Pre-CT diagnostic confidence was inversely associated with the likelihood of a diagnostic change (p<.001). Diagnosis confidence increased 52.7% in COPD and 45.1% in ILD (both, p<.001). Median confidence post-QCT was high (75%).

CONCLUSION

s After the QTC analysis, physicians frequently changed the final diagnoses, enhancing the diagnostic confidence. Up to 12% of patients with chronic lung diseases had their management changed due to QTC.

CLINICAL RELEVANCE/APPLICATION

QCT substantially influence key attributes of physician decision making. Physicians performed new diagnoses in one-sixth of patients after QCT results became available. In most cases, physicians reported CT to be helpful in addressing certain diagnoses and rule-out diagnoses of concern.

Ultrashort Echo Time (UTE) MRI of The Lung In Term and Pre-term Infants

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - CH DPS

Participants
Yujie Chen, Chengdu, China (*Presenter*) Nothing to Disclose

PURPOSE

Postnatal lung development is important in infants, especially in preterm births while relevant imaging data is scarce. Ultrashort echo-time (UTE) MRI provides a non-invasive approach to explore the lung tissue architecture in term and preterm infants. The purpose of this study was to explore lung tissue architecture in term and preterm infants using three-dimensional (3D) UTE MRI.

METHODS AND MATERIALS

A total of sixty infants born term or preterm with morphologically normal lungs (26 preterm, 34 full-term, range 2 day to 1 year and 2 months) underwent 3D UTE MRI at a 3T pediatric MR scanner (Alpha, United Imaging Healthcare, Shanghai, China). Average lung parenchymal signal intensity was evaluated by two experienced radiologists. The whole lung signal intensity was calculated as the average signal intensity of both lungs. Paired t-test was used to test the differences of average lung signal intensities between term and preterm infants. Spearman rank correlation was performed to test the correlation of the lung parenchymal signal intensity to age. Interrater agreement was assessed using intraclass correlation coefficients (ICCs).

RESULTS

Interobserver reliability analysis revealed almost perfect agreement (ICC = 0.964). Average lung parenchymal signal intensity was significant different (p=0.038) in preterm (mean 282.4, SD 87.1) and full-term infants.(mean 341.8, SD 128.8)(Figure 1). Lung signal intensity is positively correlated to age in infant period (r=0.319, p=0.013), and positively correlated to age in preterm group (r=0.408, p=0.039).

CONCLUSION

s The UTE MRI technique for lung imaging has potential value in infants, especially in preterm births. This radiation-free technique shows lung structures clearly and is potentially valuable for the detection of disease.

CLINICAL RELEVANCE/APPLICATION

UTE MRI is a promising radiation-free approach for evaluation of lung structure of infants and is potentially valuable for the detection of disease.

W5A-SPCH-3

Imaging of Central Lymphatic Abnormalities in Patients with Trisomy 21

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - CH DPS

Participants
Karen Ramirez Suarez, MD, Philadelphia, PA (*Presenter*) Nothing to Disclose

PURPOSE

To describe the clinical importance of lymphatic imaging in patients with Trisomy 21 and congenital heart disease and depict the most common imaging findings of the central lymphatic abnormalities in these patients.

METHODS AND MATERIALS

We conducted a single-center retrospective review of all patients with a confirmed history of Trisomy 21 who presented for lymphatic imaging over a 7-year period. Dynamic contrast-enhanced MR lymphangiography evaluation was performed which included unenhanced T2 weighted (T2-W) imaging and T1-weighted dynamic-contrast MR lymphangiography. A pediatric radiologist evaluated the images. The distribution of fluid on T2-W imaging and lymphatic flow of contrast agent are reported. Electronic medical records were reviewed for clinical history and outcomes.

RESULTS

We identified a total of 17 patients (13 male), including 8 infants, 7 children, and 2 adults. Congenital heart disease was present in all patients. Diagnosis included single ventricle physiology (n=9), Tetralogy of Fallot (n=2), atrial septal defect (n=2), and ventricular septal defect (n=4). Presenting symptoms included chylothorax (n=9), plastic bronchitis (n=3), chylous ascites (n=3), protein-losing enteropathy (n=1), and pericardial effusion (n=1). 14 patients had surgical interventions including Fontan in 47% of cases (n=8). Two patients died (12%) by the time the data was collected. In imaging evaluation, abnormal lymphatic flow with pulmonary and/or mesenteric perfusion was seen in 15 patients (88%) and abnormalities in the thoracic duct were present in 11 patients (65%).

CONCLUSION

s Patients with Trisomy 21 and clinical evidence of lymphatic dysfunction need lymphatic imaging evaluation to diagnose and treat central lymphatic abnormalities. Common imaging findings in these patients include retrograde lymphatic flow, pulmonary and mesenteric lymphatic perfusion, and thoracic duct abnormalities.

CLINICAL RELEVANCE/APPLICATION

Patients with trisomy 21 have an increased risk for the development of lymphatic disorders, and the extent and nature of these abnormalities are poorly understood. Literature regarding lymphatic imaging evaluation and treatment in these patients is scarce. Understanding and recognizing characteristic lymphatic abnormalities in patients with Trisomy 21 may help with the diagnosis and treatment of these patients.

W5A-SPCH-4

Reference Value of Cardiovascular Borders on Frontal Chest X-ray from Echocardiographically Confirmed Normal Subjects.

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - CH DPS

Participants
Dong Hyun Yang, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this study was to determine the normal reference value of cardiovascular borders (CB) on frontal chest radiography (CXR) from normal cohorts confirmed by transthoracic echocardiography.

METHODS AND MATERIALS

91,736 subjects with normal echocardiography and frontal CXR from a single center were enrolled in this study (study period, 2000 - 2016; mean age 53.7 years; 64.3% of male). Previously validated deep learning-based CB analysis system calculated cardiothoracic ratio (CTR), the width of each CB (right upper/lower, aortic knob, pulmonary artery, left atrial appendage [LAA], left lower, descending aorta), and carinal angle. Reference CB values in each age group and gender were determined. Correlation between CB values and echocardiography-driven measurements was demonstrated. CB values were compared with those of the external datasets (MIMIC-CXR CheXpert)

RESULTS

Normal CTR is 0.44 (<40 years 0.42, >70 years 0.46; external datasets MIMIC-CXR 0.47, ChXpert 0.44). The normal carinal angle was 72 degrees (75 in MIMIC-CXR, 74 in CheXpert). The width (mm) of each CB is as follows: right upper 29.5, right lower 40.3, aortic knob 38.1, pulmonary artery 38.6, LAA 46.2, left lower 84.5, and descending aorta 34.1. The CTR, aortic knob, right upper CB, descending aorta, and left lower CB are increased with age. Ascending aortic diameter on echocardiography was correlated with the width of the right upper CB (r=0.23), aortic knob (r=0.27), descending aorta (r=0.28), and left lower CB (r=0.25).

CONCLUSION

s The normal reference values for CB on frontal chest radiographs were determined using CB analysis software powered by deep learning.

CLINICAL RELEVANCE/APPLICATION

The CB reference values obtained in this study may be used in conjunction with CXR analysis software for the purpose of identifying or classifying cardiovascular disease.

W5A-SPCH-5

Image Quality and Radiation Dose of Contrast-Enhanced Chest CT acquired on a Clinical Photon-Counting Detector CT vs 2nd Generation Dual-Source CT in An Oncologic Cohort

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - CH DPS

Participants
Lukas Walder, Tuebingen, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Our aim was to compare image quality and patient dose of contrast-enhanced oncologic chest CT of 1st generation photon-counting detector (PCD-CT) and 2nd generation dual-source dual-energy CT (DSCT).

METHODS AND MATERIALS

For this reason one hundred oncologic patients (63 male, 65±11 years, BMI: 16-42 kg/m2) were prospectively enrolled. Clinically indicated contrast-enhanced chest CT were obtained with PCD-CT and compared to previously obtained chest DSCT in the same individuals. The median time interval between the scans was three months. The same contrast media protocol was used for both scans. PCD-CT was performed in QuantumPlus mode (obtaining full spectral information) at 120kVp. DSCT was performed using 100 kV for Tube A and 140 kV for Tube B. "T3D" PCD-CT images were evaluated, which emulate conventional 120 keV polychromatic images. For DSCT, the convolution algorithm was set at I31f with class 1 iterative reconstruction, whereas comparable Br40 kernel and iterative reconstruction (Q1 and Q3) were applied for PCD-CT. Two radiologists assessed image quality using a 5-point Likert scale and performed measurements of vessels and lung parenchyma for signal-to-noise ratio (SNR) and contrast-to-noise ratio (CNR) measurements.

RESULTS

PCD-CT CNRvessel was significantly higher than DSCT CNRvessel (all, $p<0.05$). Readers rated image contrast of mediastinum, vessels, and lung parenchyma significantly higher on PCD-CT than DSCT images ($p<0.001$). Q3 PCD-CT CNRlung_parenchyma was significantly higher than DSCT CNRlung_parenchyma and Q1 PCD-CT CNRlung_parenchyma ($p<0.01$). CTDI, DLP, SSDE mean values for PCD-CT and DSCT were 4.17±1.29 mGy vs. 7.21±0.49 mGy, 151.01±48.56 mGy*cm vs. 288.64±31.17 mGy*cm and 4.23±0.97 vs. 7.48±1.09, respectively.

CONCLUSION

s PCD-CT enables oncologic chest CT with a significantly reduced dose while retaining image quality similar to a 2nd generation DSCT for comparable protocol settings.

CLINICAL RELEVANCE/APPLICATION

The mean SSDE for the PCD-CT could be reduced by 43% compared to the previous DSCT examination

W5A-SPCH-6

Lung Cancer Screening Using Clinical Photon-Counting-Detector CT and Energy-Integrating-Detector CT: A Prospective Patient Study

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - CH DPS

Participants
Akitoshi Inoue, MD, PhD, Rochester, MN (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the image quality of photon-counting detector (PCD) CT in patients undergoing lung cancer screening compared with energy-integrating detector (EID) CT in a prospective multi-reader study.

METHODS AND MATERIALS

Patients undergoing clinically-indicated lung cancer screening at EID CT (SOMATOM Force, Siemens Healthineers GmbH) were prospectively recruited to undergo same-day research CT on an FDA-approved PCD-CT system (NAEOTOM Alpha, Siemens Healthineers GmbH) using Qr56 kernel, 0.8 mm slice thickness, 512x 512 matrix. Both systems used matched radiation dose (CTDIvol=0.9 mGy) using automatic exposure control. . Three thoracic radiologists blinded to the image type compared PCD-CT and EID-CT images in a side-by-side fashion, using a 5-point Likert comparison score (-2 [left image is worse] to +2 [left image is better]) for artifact, sharpness, image noise, diagnostic image quality, emphysema visualization, and lung nodule evaluation. A post hoc correction of scores was performed (-2 [PCD-CT image is worse than EID-CT] to +2 [PCD-CT image is better than EID-CT]). A non-reader radiologist measured image noise as the standard deviation of CT number (HU).

RESULTS

Thirty-three patients (66.9 ± 5.6 years, 11 female,) were enrolled. 45% (15/33) patients had BMI over 30. Pulmonary nodules (3 ground-glass nodules; 1 part-solid nodule; 7 solid nodules, median diameter 6 mm [range: 4—11 mm]) were identified in 11 of 33 patients. Comparison scores were significantly higher (positive score = PCD-CT better) in sharpness (0.8 ± 0.6, p<0.001), image noise (0.3 ± 0.8, p<0.001), diagnostic image quality (0.4 ± 0.6, p<0.001), emphysema visualization (0.3 ± 0.6, p<0.001), and lung nodule borders (0.8 ± 0.9 p<0.001), but significantly lower for artifact (-0.4 ± 0.6; P<0.001). PCD-CT had significantly lower objective image noise (74.4 ± 10.5 vs. 80.1 ± 8.6; P=0.048) despite slightly lower dose CTDIvol (0.61 ± 0.21 vs. 0.73 ± 0.22; P<0.001).

CONCLUSION

s PCD-CT demonstrated better image quality in the evaluation of pulmonary emphysema and lung nodules compared to EID-CT in the setting of low-dose lung cancer screening CT.

CLINICAL RELEVANCE/APPLICATION

PCD-CT provides improved image quality in low-dose lung cancer screening to evaluate nodule and emphysema.

W5A-SPCH-7

MRI-derived Ventilation Inhomogeneity from 3D-UTE MRI in Patients with Cystic Fibrosis on Therapy with CFTR Modulators

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - CH DPS

Participants
Julius Heidenreich, MD, Wurzburg, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the image-derived ventilation inhomogeneity of functional 3D UTE MRI compared with lung clearance index in patients under treatment with the new CFTR modulator combination therapy Trikafta.

METHODS AND MATERIALS

3D-UTE MRI imaging of the lungs was performed on a 3T MR-scanner (MAGNETOM Prisma, Siemens Healthcare GmbH, Erlangen, Germany). A prototypical 3D UTE VIBE sequence with a stack of spirals trajectory was used with the following parameters: TE = 0.05 ms; TR = 2.35 ms; flip angle = 4°, non-selective hard pulse duration = 60 µs; FOV = 600 mm x 600 mm; spiral interleaves = 264; readouts per spiral = 265; resolution = 2.3 mm isotrope; number of partitions = 102 ± 10; acquisition time per measurement = 12.3 ± 1.5 s. Sixteen patients with CF underwent MR imaging in 2019 and a follow-up examination in 2021. Images from in- and expiration were co-registered and segmented using a deep-learning approach. Signal intensities were analyzed per voxel. Voxelwise fractional ventilation, expansion rate and interquartile range (IQR) of ventilation as a measurement of ventilation inhomogeneity were obtained. The IQR of MRI ventilation was correlated with the results of pulmonary function tests and lung clearance index (LCI).

RESULTS

8 patients received a new therapy with the triple combination Trikafta (ivacaftor/elexacaftor/tezacaftor) between 2019 and 2021. 8 patients did not receive drug therapy between both examinations. The ventilation inhomogeneity (IQR) correlated almost perfectly with the LCI2.5% in the initial and follow-up examination (Spearman's rho = 0.90, $p < 0.01$). Between initial and follow-up, LCI and MRI-derived ventilation inhomogeneity changed proportionally. MRI-derived ventilation inhomogeneity decreased significantly in patients on therapy (Wilcoxon $p = 0.02$). Color-coded ventilation maps could be used for visual and regional functional assessment as well as evaluation of morphology.

CONCLUSION

s Functional lung imaging with single breath-hold 3D-UTE MRI can be used for calculation of an MRI-derived ventilation inhomogeneity, which correlates almost perfectly with the lung clearance index, a sensitive measure for lung function. Using functional lung MRI, the clinical improvement of patients on therapy with the recently approved drug-combination ivacaftor/elexacaftor/tezacaftor can be evaluated based on image analysis.

CLINICAL RELEVANCE/APPLICATION

For CF patients who need recurrent imaging of the lungs a radiation free approach which can be used for simultaneous morphologic and functional imaging is favourable.

Quantitative CT in Chronic Lung Diseases: A Real-life Study of Changes in Physician's Decision Making

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - CH DPS

Participants
Matheus Zanon, MD, MSc, Porto Alegre, Brazil (*Presenter*) Nothing to Disclose

PURPOSE

To determine how physicians' diagnoses, diagnostic certainty, and management decisions are affected by the results of quantitative computed tomography (QCT) in the real-life management of chronic lung diseases.

METHODS AND MATERIALS

Data was collected prospectively during 12 months from 5 different centers. Physicians were surveyed before and after QCT to determine the possible new diagnosis, diagnostic confidence, and management decisions. The doctors have access to all patients' functional and laboratory tests previously to QCT results. The QCT analysis comprised the following parameters: 1) total lung volume; 2) normal lung density volume; 3) normal lung index; 4) emphysema index; 5) percentage of high-attenuation areas; and 6) air trapping index.

RESULTS

QTC analysis was done in 92 patients (men, 54; mean age 67+/- 21 years), and surveys were completed by 11 doctors (senior pulmonologists). The most common new diagnoses were chronic interstitial lung disease (15.2%) and emphysema (9.7%). Patient management was changed in 11 cases (11.9%) as follows: new specialized care by an ILD multidisciplinary team (n=7, 7.6%) and new targeted treatment of small airway disease (n=4, 4.3%). Pre-CT diagnostic confidence was inversely associated with the likelihood of a diagnostic change (p<.001). Diagnosis confidence increased 52.7% in COPD and 45.1% in ILD (both, p<.001). Median confidence post-QCT was high (75%).

CONCLUSION

s After the QTC analysis, physicians frequently changed the final diagnoses, enhancing the diagnostic confidence. Up to 12% of patients with chronic lung diseases had their management changed due to QTC.

CLINICAL RELEVANCE/APPLICATION

QCT substantially influence key attributes of physician decision making. Physicians performed new diagnoses in one-sixth of patients after QCT results became available. In most cases, physicians reported CT to be helpful in addressing certain diagnoses and rule-out diagnoses of concern.

W5A-SPGI-1 Usefulness of the combination of Fast3D Technique and Deep Learning Based Reconstruction for Magnetic Resonance Cholangiography

Participants
Kaori Shiraishi, Kumamoto, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the usefulness of the Fast3D technique and deep-learning-based reconstruction (DLR) at 3D-MRCP within a single breath-hold (BH).

METHODS AND MATERIALS

This retrospective study included 70 consecutive patients who underwent a respiratory gating MRCP and a single BH-MRCP with Fast3D between August and September 2021. BH images were reconstructed with and without DLR. The signal-to-noise ratio (SNR), contrast, contrast-to-noise ratio (CNR) between the common bile duct (CBD) and periductal tissues, and full width at half maximum (FWHM) of CBD on 3D-MRCP were evaluated quantitatively. Two board-certified radiologists scored image noise, contrast, artifacts, blur, and overall image quality of the three image types using a 4-point scale. Quantitative and qualitative socares were compared with using Friedman test and post hoc Nemenyi test.

RESULTS

This study consisted of 32 patients with biliary and pancreatic disorders (17 men and 15 women; age range, 26-92 years; mean age, 66.1 years) . The SNR and CNR of MRCP were no significant differences between under respiratory gating and under BH without DLR. However, these were significantly higher under BH with DLR than under respiratory gating ($P < 0.05$). The contrast and FWHM of MRCP under BH with and without DLR were lower than under respiratory gating (Contrast: $P<0.01$, FWHM: $P<0.05$). Qualitative scores for noise, blurr and over all image quality were higher under BH with DLR than those under respiratory gating($p < 0.05$). Contrast and Artifact were no significant differences between under BH with DLR and under respiratory gating ($p < 0.05$).

CONCLUSION

s The combination of the Fast3D technique and DLR is a useful technique for MRCP within a single BH without deterioration of image quality.

CLINICAL RELEVANCE/APPLICATION

The combination of the Fast3D technique and DLR is a useful technique forBH MRCP and can offer the comparable image quality with respiratory gating MRCP in a short scan time.

W5A-SPGI-10 Explore the potential of diffusion-relaxation correlation spectroscopic imaging for evaluating response to neoadjuvant chemoradiotherapy in locally advanced rectal cancer

Participants
Xixi Zhao, Guangzhou, China (*Presenter*) Nothing to Disclose

PURPOSE

To determine the diagnostic performance of diffusion-relaxation correlation spectroscopic imaging (DR-CSI) in discriminating the pathological complete response (pCR) to neoadjuvant chemoradiotherapy (nCRT) in locally advanced rectal cancer (LARC).

METHODS AND MATERIALS

Nineteen patients with LARC underwent examination by a 3.0T MRI scanner (uMR780, United Imaging Healthcare, Shanghai, China) after nCRT. DR-CSI data were acquired for each patient using 24 DWI images with 6 b-values (0, 200, 500, 800, 1500, 2000 s/mm2) combining 4 TEs (102, 128, 154, 180 ms). Region of interests (ROI) were decided in rectum on 5 slices. DR-CSI spectra (range: D 0~5×10-3 mm2/s, T2 0~150 ms) were constructed for each voxel, and a total spectrum summating all voxels was given. All spectra were segmented into 4 compartments, A (low D, short T2), B (high D, long T2), C (high D, long T2) and D (low D, long T2). Segmentation boundaries D 3×10-3 mm2/s and T2 60 ms were chosen according to foreknowledge of rectum. Volume fraction Vm for each compartment m was acquired in each voxel by spectral integration, and then averaged in the whole ROI.

RESULTS

Two main peaks, separately with high and low diffusivity, were observed in spectra of all patients. Compared to non-pCR group

Two main peaks, separately with high and low diffusivity, were observed in spectra of all patients. Compared to non-pCR group, pCR group showed decreased average VD (5.6±1.7% vs 7.2±2.0%), although not statistically significant (p=0.118). ROC curve analysis indicated that the VD (AUC 0.756) has good diagnostic performance in distinguishing pCR from non-pCR patients, better than traditional ADC (0.500) and T2 value (0.539).

CONCLUSION

s In-vivo DR-CSI, disentangling tissue diffusivity and relaxometry at sub-voxel level, demonstrates its potential to evaluate response to nCRT in patients with LARC. VD was decreased in pCR group, although not significant, which may be due to small sampling number. The compartment D with slow diffusivity and high T2 should related with water concentration and may correlates with residual tumor, requiring confirmation by further research. Moreover, the V maps may assist recognizing areas of possible residual tumor, demonstrating potential in personalized subsequent treatment.

CLINICAL RELEVANCE/APPLICATION

Although nCRT has become the standard treatment for LARC, current tumor response evaluation is still lack of accuracy. Radiologic indicator containing compositional information is of great value.

W5A-SPGI-2 Liver T2-Weighted Imaging and Diffusion-weighted Imaging: Comparison of Respiratory-Frequency Modulated Continuous Wave Radar-trigger, Respiratory Belt-trigger and Navigator-trigger Acquisition

Participants
Xinyue Liang, Shanghai, China (*Presenter*) Nothing to Disclose

PURPOSE

For abdominal MRI, respiratory motion artifacts could significantly degrade image quality. Respiratory belt-trigger (BT) and navigator-trigger (NT) acquisition have been widely used to mitigate motion artifacts. However, belt required external device and extra patient preparation time. Accuracy of NT depends on the quality and position of the navigator. Additionally, efficiency of NT was limited by the fixed acceptance window. Novel contactless respiratory-frequency modulated continuous wave radar trigger (FT) acquisition was developed recently without any additional setup steps. The aim of this study is to compare the performance of novel FT acquisition with traditional respiratory trigger acquisitions (BT and NT) for T2-weighted imaging (T2WI) and diffusion-weighted Imaging (DWI) of liver.

METHODS AND MATERIALS

Seventeen volunteers were prospectively imaged on a 1.5T MR scanner (uMR 680; United Imaging Healthcare; Shanghai; China) using T2WI and DWI with FT, BT and NT acquisitions. Overall image quality, blurring, motion artifacts, and liver edge delineations were assessed on a 4-point scale by two radiologists. Signal-to-noise ratio (SNR) and apparent diffusion coefficient (ADC) value of liver parenchyma were calculated. Differences between three acquisitions were evaluated using Wilcoxon signed-ranks test. Inter-observer agreements between two radiologists were measured by intraclass correlation coefficients (ICCs).

RESULTS

All acquisitions provided acceptable overall image quality (score > 2.8) in all subjects on T2WI and DWI. There were no significant differences between three respiratory trigger acquisitions in qualitative scores (all $p > 0.05$) on both sequences. The acquisition time of 179.2 sec for NT was significantly longer than that of 141.3 sec for BT and 142.8 sec for FT on T2WI ($p < 0.05$). Quantitative parameters were comparable among FT, BT and NT, with mirror or no significant differences. Agreement between each reviewer was excellent (ICC > 0.9).

CONCLUSION

s This study indicates that the novel FT acquisition provides comparable image quality and simplifies subject preparation steps compared to the use of traditional BT and NT acquisitions.

CLINICAL RELEVANCE/APPLICATION

FT can be used as an effective respiratory trigger acquisition in T2WI and DWI of the liver, with high potential for improving MR workflow efficiency and patient comfort.

W5A-SPGI-3 Image Quality Evolution of Diffusion-weighted imaging Sequences for the Assessment of Rectal Cancer

Participants
Maria El Homsi, MD, New York, NY (*Presenter*) Nothing to Disclose

PURPOSE

To compare and evaluate image quality of 3 different diffusion-weighted imaging (DWI) sequences with low and high b values for the assessment of rectal cancer and to provide quantitative estimates of signal-to-noise ratio (SNR) and contrast-to-noise ratio (CNR).

METHODS AND MATERIALS

This retrospective study included 30 consecutive patients who underwent 3.0 T MRI exams between January and June 2020. DWI was performed in each subject with 1) single-shot echo planar imaging (ssEPI) (b=800 s/mm2), multiplexed sensitivity encoding (MUSE) (b=800 s/mm2), MUSE (b=1500 s/mm2), and FOV optimized and constrained undistorted single-shot (FOCUS) (b=1500 s/mm2). Two radiologists independently subjectively scored the image quality, contour, and lesion conspicuity of the DW images based on a 5-point Likert scale. One radiologist drew ROI on rectal wall on the 4 sequences and ADC map. Inter-reader agreement was assessed by applying the procedure of weighted Cohens' kappa (?). Image scores were evaluated by using the Wilcoxon signed rank test with Bonferroni adjustment. The SNR, CNR, and ADC measurements between sequences were compared using the paired t-test.

RESULTS

Both readers found image quality, contour, and conspicuity to be significantly superior with MUSE (b=800 s/mm2) as compared to

ssEPI. MUSE (b=800 s/mm2) had the highest score for image quality and contour which was statistically significant for both readers as compared to all other acquisitions. Conspicuity was equally superior for both MUSE sequences. One reader had improved lesion conspicuity on MUSE (b=800 s/mm2) as compared to FOCUS. There was no significant difference between MUSE at different b-values for the assessment of conspicuity. There was good to excellent interreader agreement for all qualitative features (?, 0.72-0.88). MUSE (b=800 s/mm2) had the highest SNR, and MUSE (b=1500 s/mm2) had the highest CNR. Significant difference in ADC were observed in comparing ssEPI to the other sequences ($p<0.001$), and between MUSE (b=800 s/mm2) and FOCUS.

CONCLUSION

s MUSE has improved image quality and tumor conspicuity as compared to ssEPI. The choice of b value significantly affects ADC estimates in MUSE.

CLINICAL RELEVANCE/APPLICATION

The use of MUSE can improve image quality and tumor conspicuity compared to the traditional DWI in rectal MRI. This can be in part related to better CNR, SNR, and reduced geometric distortion.

W5A-SPGI-4 Artificial intelligence (AI) augmented reconstruction provides improved image quality and enables shorter breath-holds in contrast-enhanced liver MRI.

Participants
Francesca Castagnoli, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To compare image quality and lesion detection using an AI-augmented contrast enhanced (CE) T1w MRI sequence in the liver [derived from applying a neural network (NN) trained on high-resolution images to conduct interpolation and partial Fourier reconstruction, in addition to iterative denoising (ID)] with a conventional CE T1w sequence.

METHODS AND MATERIALS

50 consecutive patients who underwent clinical liver MRI with Gd-EOB-DTPA on a 1.5T scanner were prospectively enrolled. The protocol included a hepatobiliary phase conventional 17s CE-T1w sequence, a 17s T1w with NN reconstruction and ID and a 12s accelerated T1w with prototypical NN reconstruction and ID. The 3 image sets were analyzed independently by 2 blinded radiologists. Image assessment was made by evaluating the overall image quality, contrast-to-noise ratio (CNR), lesion edge sharpness, vessel edge sharpness and respiratory motion artefacts. Kruskal-Wallis test was used to compare image quality scores. Clinical lesion detection was assessed by identifying and counting focal liver lesions and measuring the diameter of the smallest lesion on the 12s NN+ID acquisition and 17s standard reconstruction. A 4-week break was granted between the reading sessions. Student's t-test was used to compare the number of lesions recorded and the diameter of smallest lesion.

RESULTS

There were significantly higher scores for image quality, CNR, vessel edge sharpness and lesion edge sharpness for the 17s and 12s acquisitions using NN+ID compared with standard reconstruction ($p<0.0001$), but with no significant difference between 17s and 12s NN+ID acquisitions. No significant difference was found for respiratory motion artefacts ($p>0.05$) between all three image sets. For clinical lesion detection, there was no significant difference between the number of lesions and diameter of smallest lesion identified using 12s NN+ID compared with conventional 17s acquisition for either reader ($p>0.05$).

CONCLUSION

s Advanced reconstruction methods using a trained neural network for data interpolation combined with iterative denoising can improve image quality while reducing the duration of breath-hold on T1w CE liver imaging, without compromising clinical lesion detection.

CLINICAL RELEVANCE/APPLICATION

AI augmented T1-weighted imaging can improve image quality, reduce image acquisition time without compromising diagnostic performance. Reduction in breath-hold time can improve patient compliance for MRI liver examinations.

W5A-SPGI-5 Title Usefulness of breath-hold fat-suppressed T2-weighted image (FS-T2WI) with deep learning-based reconstruction compared to free-breathing turbo spin echo FS-T2WI

Participants
Fumihito Ichinohe, (*Presenter*) Nothing to Disclose

PURPOSE

To show the usefulness of fat-suppressed T2-weighted images (FS-T2WI) with deep learning (DL)-based reconstruction by comparing acquisition time and image quality between respiratory-gated turbo spin echo (RG-TSE), breath-hold TSE with DL (BH-DL-TSE), and half Fourier single shot turbo spin echo with DL (BH-DL-HASTE).

METHODS AND MATERIALS

Sixty-two consecutive patients who were suspected of having liver disease and underwent 3 T MRI were enrolled in this study. Forty-eight focal liver lesions > 10 mm were also enrolled. Three sets of FS-T2WI were acquired using RG-TSE, prototypical BH-DL-TSE, and prototypical BH-DL-HASTE, respectively. In the qualitative analysis, two radiologists independently evaluated the images quality (liver parenchyma, edge sharpness of the left and right lobes of the liver, intra-hepatic vessels clarity, and lesion conspicuity) using a five-point scale, and consensus was reached. In the quantitative analysis, we calculated the signal intensity ratio of the lesion and the liver (LLR) and the lesion and the muscle (LMR). Differences of each variable between the three groups were statistically analyzed using Friedman test and Dunn's multiple comparisons test.

RESULTS

The mean acquisition time was 279 (95%CI 258-300) s in RG-TSE, 20 s × 2 in BH-DL-TSE, 20 s in BH-DL-HASTE. In the qualitative analysis, the score for intrahepatic vessels clarity was significantly higher in RG-TSE and BH-DL-TSE than in BH-DL-HASTE ($P < 0.001$). The score for edge sharpness of the left lobe was the highest in BH-DL-HASTE ($P < 0.001$), and it was significantly higher in BH-DL-TSE than in RG-TSE ($P = 0.004$). There was no significant difference in the score for liver parenchyma, edge sharpness of

the right lobe, and lesion conspicuity (P = 0.191, 0.570, 0.330, respectively). In the quantitative analysis, there was no statistically significant difference in LLR (P = 0.174). LMR was significantly higher in BH-DL-TSE than in BH-DL-HASTE (P < 0.001).

CONCLUSION

s RG-TSE could be replaced by BH-DL-TSE in acquiring FS-T2WI, because BH-DL-TSE has comparable or better performance compared with RG-TSE. However, BH-DL-HASTE should be used complementarily with BH-DL-TSE, because BH-DL-HASTE has an advantage of motion resistant and disadvantage of vessel clarity over BH-DL-TSE.

CLINICAL RELEVANCE/APPLICATION

Although RG-TSE is often used as a routine protocol for acquiring liver T2WI, BH-DL-TSE can be an alternative to it and may improve the image quality and efficiency of MRI of the liver.

W5A-SPGI-6 Amide Proton Transfer Imaging of Rectal Cancer: Baseline values and Feasibility for Predicting neoadjuvant CRT-resistant

Participants
Lan Zhang, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

To determine whether APTw imaging is repeatable in rectal cancer and whether APTw imaging can predict neoadjuvant CRT-resistant for LARC.

METHODS AND MATERIALS

Twenty-three patients with histological diagnostic rectal cancer and clinical T3-4 or N+ were prospectively recruited into this institutional review board-approved study. All participants were scanned at 3.0T using standard rectal protocols (T1WI, T2WI, DWI, contrast-enhanced) and APTw-imaging (acquired with 3D turbo-spin-echo sequence). Total mesorectal excision was performed on 21 patients (2 patient refusing operation after neoadjuvant CRT were finally excluded) and the relevant pathological features were evaluated. APT values were measured by two radiologists independently drawing ROIs on a commercially available post-processing workstation. Polygonal ROIs were placed in the solid component of a tumor on the T2WI image, avoiding cystic, large necrotic, or hemorrhagic components, and copied onto the APTw image by each radiologist. The size of ROIs were draw =260 mm2 (=80 pixels) and as large as possible. Pathological features including tumor grade and Tumor regression stage(TRG) were evaluated. Inter-observer agreement on APT values was analyzed using intraclass correlation coefficient (ICC). APT values were compared between the two groups classified by pathological grade using independent sample t-test, while the correlation between APT values and TRG was evaluated using Pearson correlation analysis.

RESULTS

APT value of all tumors was 3.55±1.78(%, range from1.09 to7.80). The ICC of APT values was 0.963($p<0.05$) between the 2 radiologists. 13 rectal tumors TRG graded as 0 or 1 were classified in CRT-response group, while 8 rectal tumors graded as 2 or 3 were classified in CRT-resistant group. APT values between the group of TRG0-1 and TRG2-3 were significantly different($p<0.05$). The TRG was significantly associated with APT value ($R=0.796, p<0.05$).

CONCLUSION

s Rectal cancer is usually very proliferative and possesses high considerable potential in long-distance metastases, which likely lead to an abundant pool of mobile cellular proteins and peptides. We have established a baseline for the APT values in rectal cancer, which was shown significantly correlated with TRG after neoadjuvant CRT.We speculate that APT value may be a useful biomarker for assessing rectal pathological characteristics and predicting neoadjuvant CRT-resistant.

CLINICAL RELEVANCE/APPLICATION

APTw imaging has a potential impact on the clinical therapeutic strategies for patients, and this needs to be validated in a further study with larger sample size.

W5A-SPGI-7 3D Single Breath-Hold MRE for the Simultaneous Assessment of Liver Fibrosis and Inflammation.

Participants
Omar Darwish, BEng, London, United Kingdom (*Presenter*) Nothing to Disclose

PURPOSE

3D MRE compared to 2D MRE sequences have the advantage of measuring both liver inflammation and fibrosis, however, require several 16-20 sec breath-holds with associated slice position misregistration. The purpose is to develop and validate a 3D multi-slice SMS accelerated GRE-MRE acquisition (Intenso MRE) done in a single 17 sec breath-hold.

METHODS AND MATERIALS

A total of 19 subjects were included in this prospective study, 10 were healthy subject and 9 were patients with steatohepatitis. All subjects were imaged using Intenso MRE at 60Hz mechanical excitation. For the healthy subjects, a 3D multi breath-hold acquisition (eXpresso MRE) was performed for comparison. Patients had a single breath-hold 2D SE-EPI acquisition and liver biopsies (ISHAK scores) for validation.The viscoelastic parameters were measured for all subjects to include the magnitude of the shear modulus |G*| [kPa], and Intenso MRE measured additionally the shear wave speed Cs [m/s] and the loss modulus G" [kPa].

RESULTS

The average age and BMI for all subjects were 38.5 ± 14.7 years , and 28.0 ± 6.6 kg/m2. A Bland-Altman plot of |G*| (Figure 1 (A)) for all healthy subjects shows a bias of 0.035 kPa in Intenso relative to eXpresso and a maximum difference of 0.42 kPa, demonstrating excellent agreement between the two methods. There was a statistically significant linear relationship ($R2=0.97$ and $p < 0.001$) for the estimated |G*| in patients between Intenso and the 2D SE-EPI sequence (Figure 1(B)). A clear differentiation between the different ISHAK fibrosis scores in patients is visible using Cs (Figure 1 (C)). A generic power-law model is fitted to Cs versus ISHAK fibrosis score, i.e., Cs(F) ? Fd, with d = 0.88 ± 0.12 which suggests a nearly linear increase of Cs with respect to the ISHAK fibrosis score ($R2=0.96$ and $p < 0.001$) Furthermore, G" increases with the ISHAK inflammation scores (Figure 1 (D)), allowing Intenso to quantify hepatic inflammation. A generic power-law is fitted to G" versus ISHAK inflammation score, i.e., G"(I) ? Id, with

d = 0.29 ± 0.08 (R2=0.74 and p < 0.001)

CONCLUSION

s Intenso MRE is effective in measuring both liver fibrosis and inflammation simultaneously within a single breath-hold.

CLINICAL RELEVANCE/APPLICATION

Multi-slice single breath-hold 3D MRE is a patient friendly method measuring both liver fibrosis and inflammation without the slice misregistration encountered in multi breath-hold 3D MRE techniques.

W5A-SPGI-8 Comparison of Abdominal MRI at 0.55 T and 1.5 T: Initial evaluation in healthy subjects

Participants
Anupama Ramachandran, MD, (*Presenter*) Siemens AG

PURPOSE

To compare the quality of abdominal MRI images acquired at 0.55T with images acquired at 1.5T in the same cohort of healthy subjects.

METHODS AND MATERIALS

In this prospective IRB approved study, unenhanced MR imaging of the upper abdomen was performed in 12 healthy subjects on both 0.55T (Magnetom Free.Max) and a 1.5T (Magnetom Sola) MR system (Siemens Healthineers, Erlangen, Germany). The protocol comprised the following sequences: single-shot T2w TSE, fat sat T2w BLADE, DWI, 2D IP-OP dual-echo GRE, 3D FS T1w GRE, and respiratory triggered coronal 3D T2w TSE MRCP. The images were rated by 2 radiologists with 22 and 17 years' experience in body MRI on a 4-point scale (1: extremely poor, 2: poor, 3: good, 4: excellent) for the following features: signal-to-noise ratio, edge definition of organs (liver, spleen, pancreas, adrenals, kidneys), delineation of hepatic veins, artifacts, and overall image quality. MRCP images were rated for delineation of biliary and pancreatic ducts, and overall image quality. The Mann-Whitney U test was used to determine any statistically significant difference in image quality between the different field strengths for all sequences, where a p-value <0.05 was considered to be statistically significant

RESULTS

Abdominal MRI with acceptable image quality (overall image quality score =3) was achieved in all 12 cases at 0.55Tat an average acquisition time of 22 ± 4 min. 3D MRCPs acquired at 0.55T had higher overall image quality scores than 1.5T (p = 0.04 by reader 1). The overall image quality scores were significantly higher at 1.5T for coronal and axial single shot T2w TSE by both readers (reader 1: p=0.02 and p=0.01 , reader 2: p=0.003 and p=0.0001, respectively). SNR scores were higher at 1.5T images for all sequences except DWI b50, for which the score was equal to (reader 1) or less than (reader2) that at 0.55T. The SNR ratings of coronal and axial single shot T2w TSE and were significantly higher at 1.5 T by both readers (reader 1: p=0.04 and p=0.04, reader 2: p=0.0022 and p=0.00008, respectively).

CONCLUSION

s Diagnostically acceptable quality abdominal MR images can be obtained at 0.55T. While the image quality in some sequences including coronal and axial single shot T2w TSE and DWI at 0.55T may be improved, some sequences such as 3D MRCPs were rated higher at 0.55T than at 1.5T. Further work is needed to assess ratings from multiple radiologists, reader experience, and effect of various sequence settings on diagnostic accuracy.

CLINICAL RELEVANCE/APPLICATION

A commercial 0.55T MRI system has the potential to provide acceptable quality abdominal MR images collected in healthy subjects. Further studies are needed to assess continued protocol and sequence refinement, as well as clinical performance.

W5A-SPGI-9 Arterial Enhancement Fraction in Evaluating the Therapeutic Effect and Survival for Hepatocellular Carcinoma Patients Treated with DEB-TACE

Participants
Bin Chai, (*Presenter*) Nothing to Disclose

PURPOSE

To retrospectively investigate relationships between arterial enhancement fraction (AEF) and treatment response and survival in hepatocellular carcinoma (HCC) patients treated with drug-eluting bead (DEB) TACE.

METHODS AND MATERIALS

AEF of the primary HCC lesion (AEFpre) and residual tumor (AEFpost) were obtained from triphasic liver CT scans before and after DEB-TACE in 158 HCC patients. Wilcoxon-signed rank test was used to compare the AEFpre and AEFpost for different response groups. Cox regression analyses were used to determine the association between AEF and overall survival.

RESULTS

There was no correlation between AEFpre and treatment response. The AEFpost was significantly lower than AEFpre in the partial response group (38.9% vs. 52.7%, p < 0.001) and stable disease group (49.3% vs. 52.1%, p = 0.029). In patients with disease progression, AEFpost was numerically higher than AEFpre (55.5% vs. 53.0%, p = 0.604). Cox regression analyses showed that risk of death increased in patients with AEFpre > 57.95% (HR = 1.66, p = 0.019) and with AEFpost > 54.85% (HR = 2.47, p < 0.001), and the risk reduced in patients with decrease ratio > -0.102 (HR = 0.32, p < 0.001).

CONCLUSION

s No prediction of response was possible before DEB-TACE based on AEF. The change in AEF of viable tumor is correlated with the response of HCC to DEB-TACE. In addition, the AEF could be a helpful predictor in future prospective studies on the embolization treatment for HCC.

CLINICAL RELEVANCE/APPLICATION

Computed tomography perfusion imaging (CTPI), providing information about the hemodynamics properties of tissue at a microscopic level, has shown promising results for monitoring HCC and assessing treatment response more accurately than traditional morphologic imaging. However, Liver CTPI typically involves scanning the liver at numerous (>20) time points after IV contrast injection, thus requiring dedicated scanning protocols and the large radiation dose. Arterial enhancement fraction (AEF) derived from routine triphasic liver CT examinations is an ideal surrogate biomarker to estimate the perfusion information without extra exposure concern. Our findings showed that AEF could be an easily accessible parameters for monitoring the response of HCC to DEB-TACE, and be a useful prognostic factor for survival.

W5A-SPGI-1

Usefulness of the combination of Fast3D Technique and Deep Learning Based Reconstruction for Magnetic Resonance Cholangiography

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - GI DPS

Participants
Kaori Shiraishi, Kumamoto, Japan (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the usefulness of the Fast3D technique and deep-learning-based reconstruction (DLR) at 3D-MRCP within a single breath-hold (BH).

METHODS AND MATERIALS

This retrospective study included 70 consecutive patients who underwent a respiratory gating MRCP and a single BH-MRCP with Fast3D between August and September 2021. BH images were reconstructed with and without DLR. The signal-to-noise ratio (SNR), contrast, contrast-to-noise ratio (CNR) between the common bile duct (CBD) and periductal tissues, and full width at half maximum (FWHM) of CBD on 3D-MRCP were evaluated quantitatively. Two board-certified radiologists scored image noise, contrast, artifacts, blur, and overall image quality of the three image types using a 4-point scale. Quantitative and qualitative socares were compared with using Friedman test and post hoc Nemenyi test.

RESULTS

This study consisted of 32 patients with biliary and pancreatic disorders (17 men and 15 women; age range, 26-92 years; mean age, 66.1 years) . The SNR and CNR of MRCP were no significant differences between under respiratory gating and under BH without DLR. However, these were significantly higher under BH with DLR than under respiratory gating ($P < 0.05$). The contrast and FWHM of MRCP under BH with and without DLR were lower than under respiratory gating (Contrast: $P<0.01$, FWHM: $P<0.05$). Qualitative scores for noise, blurr and over all image quality were higher under BH with DLR than those under respiratory gating($p < 0.05$). Contrast and Artifact were no significant differences between under BH with DLR and under respiratory gating ($p < 0.05$).

CONCLUSION

s The combination of the Fast3D technique and DLR is a useful technique for MRCP within a single BH without deterioration of image quality.

CLINICAL RELEVANCE/APPLICATION

The combination of the Fast3D technique and DLR is a useful technique forBH MRCP and can offer the comparable image quality with respiratory gating MRCP in a short scan time.

W5A-SPGI-10

Explore the potential of diffusion-relaxation correlation spectroscopic imaging for evaluating response to neoadjuvant chemoradiotherapy in locally advanced rectal cancer

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - GI DPS

Participants
Xixi Zhao, Guangzhou, China (*Presenter*) Nothing to Disclose

PURPOSE

To determine the diagnostic performance of diffusion-relaxation correlation spectroscopic imaging (DR-CSI) in discriminating the pathological complete response (pCR) to neoadjuvant chemoradiotherapy (nCRT) in locally advanced rectal cancer (LARC).

METHODS AND MATERIALS

Nineteen patients with LARC underwent examination by a 3.0T MRI scanner (uMR780, United Imaging Healthcare, Shanghai, China) after nCRT. DR-CSI data were acquired for each patient using 24 DWI images with 6 b-values (0, 200, 500, 800, 1500, 2000 s/mm2) combining 4 TEs (102, 128, 154, 180 ms). Region of interests (ROI) were decided in rectum on 5 slices. DR-CSI spectra (range: D 0~5×10-3 mm2/s, T2 0~150 ms) were constructed for each voxel, and a total spectrum summating all voxels was given. All spectra were segmented into 4 compartments, A (low D, short T2), B (high D, long T2), C (high D, long T2) and D (low D, long T2). Segmentation boundaries D 3×10-3 mm2/s and T2 60 ms were chosen according to foreknowledge of rectum. Volume fraction Vm for each compartment m was acquired in each voxel by spectral integration, and then averaged in the whole ROI.

RESULTS

Two main peaks, separately with high and low diffusivity, were observed in spectra of all patients. Compared to non-pCR group, pCR group showed decreased average VD (5.6±1.7% vs 7.2±2.0%), although not statistically significant (p=0.118). ROC curve analysis indicated that the VD (AUC 0.756) has good diagnostic performance in distinguishing pCR from non-pCR patients, better than traditional ADC (0.500) and T2 value (0.539).

CONCLUSION

s In-vivo DR-CSI, disentangling tissue diffusivity and relaxometry at sub-voxel level, demonstrates its potential to evaluate response to nCRT in patients with LARC. VD was decreased in pCR group, although not significant, which may be due to small sampling number. The compartment D with slow diffusivity and high T2 should related with water concentration and may correlates with residual tumor, requiring confirmation by further research. Moreover, the V maps may assist recognizing areas of possible residual tumor, demonstrating potential in personalized subsequent treatment.

CLINICAL RELEVANCE/APPLICATION

Although nCRT has become the standard treatment for LARC, current tumor response evaluation is still lack of accuracy. Radiologic indicator containing compositional information is of great value.

W5A-SPGI-2

Liver T2-Weighted Imaging and Diffusion-weighted Imaging: Comparison of Respiratory-Frequency Modulated Continuous Wave Radar-trigger, Respiratory Belt-trigger and Navigator-trigger Acquisition

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - GI DPS

Participants
Xinyue Liang, Shanghai, China (*Presenter*) Nothing to Disclose

PURPOSE

For abdominal MRI, respiratory motion artifacts could significantly degrade image quality. Respiratory belt-trigger (BT) and navigator-trigger (NT) acquisition have been widely used to mitigate motion artifacts. However, belt required external device and extra patient preparation time. Accuracy of NT depends on the quality and position of the navigator. Additionally, efficiency of NT was limited by the fixed acceptance window. Novel contactless respiratory-frequency modulated continuous wave radar trigger (FT) acquisition was developed recently without any additional setup steps. The aim of this study is to compare the performance of novel FT acquisition with traditional respiratory trigger acquisitions (BT and NT) for T2-weighted imaging (T2WI) and diffusion-weighted Imaging (DWI) of liver.

METHODS AND MATERIALS

Seventeen volunteers were prospectively imaged on a 1.5T MR scanner (uMR 680; United Imaging Healthcare; Shanghai; China) using T2WI and DWI with FT, BT and NT acquisitions. Overall image quality, blurring, motion artifacts, and liver edge delineations were assessed on a 4-point scale by two radiologists. Signal-to-noise ratio (SNR) and apparent diffusion coefficient (ADC) value of liver parenchyma were calculated. Differences between three acquisitions were evaluated using Wilcoxon signed-ranks test. Inter-observer agreements between two radiologists were measured by intraclass correlation coefficients (ICCs).

RESULTS

All acquisitions provided acceptable overall image quality (score > 2.8) in all subjects on T2WI and DWI. There were no significant differences between three respiratory trigger acquisitions in qualitative scores (all $p > 0.05$) on both sequences. The acquisition time of 179.2 sec for NT was significantly longer than that of 141.3 sec for BT and 142.8 sec for FT on T2WI ($p < 0.05$). Quantitative parameters were comparable among FT, BT and NT, with mirror or no significant differences. Agreement between each reviewer was excellent (ICC > 0.9).

CONCLUSION

s This study indicates that the novel FT acquisition provides comparable image quality and simplifies subject preparation steps compared to the use of traditional BT and NT acquisitions.

CLINICAL RELEVANCE/APPLICATION

FT can be used as an effective respiratory trigger acquisition in T2WI and DWI of the liver, with high potential for improving MR workflow efficiency and patient comfort.

Image Quality Evolution of Diffusion-weighted imaging Sequences for the Assessment of Rectal Cancer

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - GI DPS

Participants
Maria El Homsi, MD, New York, NY (*Presenter*) Nothing to Disclose

PURPOSE

To compare and evaluate image quality of 3 different diffusion-weighted imaging (DWI) sequences with low and high b values for the assessment of rectal cancer and to provide quantitative estimates of signal-to-noise ratio (SNR) and contrast-to-noise ratio (CNR).

METHODS AND MATERIALS

This retrospective study included 30 consecutive patients who underwent 3.0 T MRI exams between January and June 2020. DWI was performed in each subject with 1) single-shot echo planar imaging (ssEPI) (b=800 s/mm2), multiplexed sensitivity encoding (MUSE) (b=800 s/mm2), MUSE (b=1500 s/mm2), and FOV optimized and constrained undistorted single-shot (FOCUS) (b=1500 s/mm2). Two radiologists independently subjectively scored the image quality, contour, and lesion conspicuity of the DW images based on a 5-point Likert scale. One radiologist drew ROI on rectal wall on the 4 sequences and ADC map. Inter-reader agreement was assessed by applying the procedure of weighted Cohens' kappa (?). Image scores were evaluated by using the Wilcoxon signed rank test with Bonferroni adjustment. The SNR, CNR, and ADC measurements between sequences were compared using the paired t-test.

RESULTS

Both readers found image quality, contour, and conspicuity to be significantly superior with MUSE (b=800 s/mm2) as compared to ssEPI. MUSE (b=800 s/mm2) had the highest score for image quality and contour which was statistically significant for both readers as compared to all other acquisitions. Conspicuity was equally superior for both MUSE sequences. One reader had improved lesion conspicuity on MUSE (b=800 s/mm2) as compared to FOCUS. There was no significant difference between MUSE at different b-values for the assessment of conspicuity. There was good to excellent interreader agreement for all qualitative features (?, 0.72-0.88). MUSE (b=800 s/mm2) had the highest SNR, and MUSE (b=1500 s/mm2) had the highest CNR. Significant difference in ADC were observed in comparing ssEPI to the other sequences ($p<0.001$), and between MUSE (b=800 s/mm2) and FOCUS.

CONCLUSION

s MUSE has improved image quality and tumor conspicuity as compared to ssEPI. The choice of b value significantly affects ADC estimates in MUSE.

CLINICAL RELEVANCE/APPLICATION

The use of MUSE can improve image quality and tumor conspicuity compared to the traditional DWI in rectal MRI. This can be in part related to better CNR, SNR, and reduced geometric distortion.

W5A-SPGI-4

Artificial intelligence (AI) augmented reconstruction provides improved image quality and enables shorter breath-holds in contrast-enhanced liver MRI.

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - GI DPS

Participants
Francesca Castagnoli, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To compare image quality and lesion detection using an AI-augmented contrast enhanced (CE) T1w MRI sequence in the liver [derived from applying a neural network (NN) trained on high-resolution images to conduct interpolation and partial Fourier reconstruction, in addition to iterative denoising (ID)] with a conventional CE T1w sequence.

METHODS AND MATERIALS

50 consecutive patients who underwent clinical liver MRI with Gd-EOB-DTPA on a 1.5T scanner were prospectively enrolled. The protocol included a hepatobiliary phase conventional 17s CE-T1w sequence, a 17s T1w with NN reconstruction and ID and a 12s accelerated T1w with prototypical NN reconstruction and ID. The 3 image sets were analyzed independently by 2 blinded radiologists. Image assessment was made by evaluating the overall image quality, contrast-to-noise ratio (CNR), lesion edge sharpness, vessel edge sharpness and respiratory motion artefacts. Kruskal-Wallis test was used to compare image quality scores. Clinical lesion detection was assessed by identifying and counting focal liver lesions and measuring the diameter of the smallest lesion on the 12s NN+ID acquisition and 17s standard reconstruction. A 4-week break was granted between the reading sessions. Student's t-test was used to compare the number of lesions recorded and the diameter of smallest lesion.

RESULTS

There were significantly higher scores for image quality, CNR, vessel edge sharpness and lesion edge sharpness for the 17s and 12s acquisitions using NN+ID compared with standard reconstruction ($p<0.0001$), but with no significant difference between 17s and 12s NN+ID acquisitions. No significant difference was found for respiratory motion artefacts ($p>0.05$) between all three image sets. For clinical lesion detection, there was no significant difference between the number of lesions and diameter of smallest lesion identified using 12s NN+ID compared with conventional 17s acquisition for either reader ($p>0.05$).

CONCLUSION

s Advanced reconstruction methods using a trained neural network for data interpolation combined with iterative denoising can improve image quality while reducing the duration of breath-hold on T1w CE liver imaging, without compromising clinical lesion detection.

CLINICAL RELEVANCE/APPLICATION

AI augmented T1-weighted imaging can improve image quality, reduce image acquisition time without compromising diagnostic performance. Reduction in breath-hold time can improve patient compliance for MRI liver examinations.

Title Usefulness of breath-hold fat-suppressed T2-weighted image (FS-T2WI) with deep learning-based reconstruction compared to free-breathing turbo spin echo FS-T2WI

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - GI DPS

Participants
Fumihito Ichinohe, (*Presenter*) Nothing to Disclose

PURPOSE

To show the usefulness of fat-suppressed T2-weighted images (FS-T2WI) with deep learning (DL)-based reconstruction by comparing acquisition time and image quality between respiratory-gated turbo spin echo (RG-TSE), breath-hold TSE with DL (BH-DL-TSE), and half Fourier single shot turbo spin echo with DL (BH-DL-HASTE).

METHODS AND MATERIALS

Sixty-two consecutive patients who were suspected of having liver disease and underwent 3 T MRI were enrolled in this study. Forty-eight focal liver lesions > 10 mm were also enrolled. Three sets of FS-T2WI were acquired using RG-TSE, prototypical BH-DL-TSE, and prototypical BH-DL-HASTE, respectively. In the qualitative analysis, two radiologists independently evaluated the images quality (liver parenchyma, edge sharpness of the left and right lobes of the liver, intra-hepatic vessels clarity, and lesion conspicuity) using a five-point scale, and consensus was reached. In the quantitative analysis, we calculated the signal intensity ratio of the lesion and the liver (LLR) and the lesion and the muscle (LMR). Differences of each variable between the three groups were statistically analyzed using Friedman test and Dunn's multiple comparisons test.

RESULTS

The mean acquisition time was 279 (95%CI 258-300) s in RG-TSE, 20 s × 2 in BH-DL-TSE, 20 s in BH-DL-HASTE. In the qualitative analysis, the score for intrahepatic vessels clarity was significantly higher in RG-TSE and BH-DL-TSE than in BH-DL-HASTE ($P < 0.001$). The score for edge sharpness of the left lobe was the highest in BH-DL-HASTE ($P < 0.001$), and it was significantly higher in BH-DL-TSE than in RG-TSE ($P = 0.004$). There was no significant difference in the score for liver parenchyma, edge sharpness of the right lobe, and lesion conspicuity ($P = 0.191$, 0.570, 0.330, respectively). In the quantitative analysis, there was no statistically significant difference in LLR ($P = 0.174$). LMR was significantly higher in BH-DL-TSE than in BH-DL-HASTE ($P < 0.001$).

CONCLUSION

s RG-TSE could be replaced by BH-DL-TSE in acquiring FS-T2WI, because BH-DL-TSE has comparable or better performance compared with RG-TSE. However, BH-DL-HASTE should be used complementarily with BH-DL-TSE, because BH-DL-HASTE has an advantage of motion resistant and disadvantage of vessel clarity over BH-DL-TSE.

CLINICAL RELEVANCE/APPLICATION

Although RG-TSE is often used as a routine protocol for acquiring liver T2WI, BH-DL-TSE can be an alternative to it and may improve the image quality and efficiency of MRI of the liver.

Amide Proton Transfer Imaging of Rectal Cancer: Baseline values and Feasibility for Predicting neoadjuvant CRT-resistant

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - GI DPS

Participants
Lan Zhang, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

To determine whether APTw imaging is repeatable in rectal cancer and whether APTw imaging can predict neoadjuvant CRT-resistant for LARC.

METHODS AND MATERIALS

Twenty-three patients with histological diagnostic rectal cancer and clinical T3-4 or N+ were prospectively recruited into this institutional review board-approved study. All participants were scanned at 3.0T using standard rectal protocols (T1WI, T2WI, DWI, contrast-enhanced) and APTw-imaging (acquired with 3D turbo-spin-echo sequence). Total mesorectal excision was performed on 21 patients (2 patient refusing operation after neoadjuvant CRT were finally excluded) and the relevant pathological features were evaluated. APT values were measured by two radiologists independently drawing ROIs on a commercially available post-processing workstation. Polygonal ROIs were placed in the solid component of a tumor on the T2WI image, avoiding cystic, large necrotic, or hemorrhagic components, and copied onto the APTw image by each radiologist. The size of ROIs were draw =260 mm2 (=80 pixels) and as large as possible. Pathological features including tumor grade and Tumor regression stage(TRG) were evaluated. Inter-observer agreement on APT values was analyzed using intraclass correlation coefficient (ICC). APT values were compared between the two groups classified by pathological grade using independent sample t-test, while the correlation between APT values and TRG was evaluated using Pearson correlation analysis.

RESULTS

APT value of all tumors was 3.55±1.78(%, range from1.09 to7.80). The ICC of APT values was 0.963($p<0.05$) between the 2 radiologists. 13 rectal tumors TRG graded as 0 or 1 were classified in CRT-response group, while 8 rectal tumors graded as 2 or 3 were classified in CRT-resistant group. APT values between the group of TRG0-1 and TRG2-3 were significantly different($p<0.05$). The TRG was significantly associated with APT value ($R=0.796, p<0.05$).

CONCLUSION

s Rectal cancer is usually very proliferative and possesses high considerable potential in long-distance metastases, which likely lead to an abundant pool of mobile cellular proteins and peptides. We have established a baseline for the APT values in rectal cancer, which was shown significantly correlated with TRG after neoadjuvant CRT.We speculate that APT value may be a useful biomarker for assessing rectal pathological characteristics and predicting neoadjuvant CRT-resistant.

CLINICAL RELEVANCE/APPLICATION

APTw imaging has a potential impact on the clinical therapeutic strategies for patients, and this needs to be validated in a further study with larger sample size.

W5A-SPGI-7

3D Single Breath-Hold MRE for the Simultaneous Assessment of Liver Fibrosis and Inflammation.

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - GI DPS

Participants
Omar Darwish, BEng, London, United Kingdom (*Presenter*) Nothing to Disclose

PURPOSE

3D MRE compared to 2D MRE sequences have the advantage of measuring both liver inflammation and fibrosis, however, require several 16-20 sec breath-holds with associated slice position misregistration. The purpose is to develop and validate a 3D multi-slice SMS accelerated GRE-MRE acquisition (Intenso MRE) done in a single 17 sec breath-hold.

METHODS AND MATERIALS

A total of 19 subjects were included in this prospective study, 10 were healthy subject and 9 were patients with steatohepatitis. All subjects were imaged using Intenso MRE at 60Hz mechanical excitation. For the healthy subjects, a 3D multi breath-hold acquisition (eXpresso MRE) was performed for comparison. Patients had a single breath-hold 2D SE-EPI acquisition and liver biopsies (ISHAK scores) for validation.The viscoelastic parameters were measured for all subjects to include the magnitude of the shear modulus |G*| [kPa], and Intenso MRE measured additionally the shear wave speed Cs [m/s] and the loss modulus G" [kPa].

RESULTS

The average age and BMI for all subjects were 38.5 ± 14.7 years , and 28.0 ± 6.6 kg/m2. A Bland-Altman plot of |G*| (Figure 1 (A)) for all healthy subjects shows a bias of 0.035 kPa in Intenso relative to eXpresso and a maximum difference of 0.42 kPa, demonstrating excellent agreement between the two methods. There was a statistically significant linear relationship ($R2=0.97$ and $p < 0.001$) for the estimated |G*| in patients between Intenso and the 2D SE-EPI sequence (Figure 1(B)). A clear differentiation between the different ISHAK fibrosis scores in patients is visible using Cs (Figure 1 (C)). A generic power-law model is fitted to Cs versus ISHAK fibrosis score, i.e., $Cs(F) ? Fd$, with $d = 0.88 \pm 0.12$ which suggests a nearly linear increase of Cs with respect to the ISHAK fibrosis score ($R2=0.96$ and $p < 0.001$) Furthermore, G" increases with the ISHAK inflammation scores (Figure 1 (D)), allowing Intenso to quantify hepatic inflammation. A generic power-law is fitted to G" versus ISHAK inflammation score, i.e., $G"(I) ? Id$, with $d = 0.29 \pm 0.08$ ($R2=0.74$ and $p < 0.001$)

CONCLUSION

s Intenso MRE is effective in measuring both liver fibrosis and inflammation simultaneously within a single breath-hold.

CLINICAL RELEVANCE/APPLICATION

Multi-slice single breath-hold 3D MRE is a patient friendly method measuring both liver fibrosis and inflammation without the slice misregistration encountered in multi breath-hold 3D MRE techniques.

W5A-SPGI-8

Comparison of Abdominal MRI at 0.55 T and 1.5 T: Initial evaluation in healthy subjects

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - GI DPS

Participants
Anupama Ramachandran, MD, (*Presenter*) Siemens AG

PURPOSE

To compare the quality of abdominal MRI images acquired at 0.55T with images acquired at 1.5T in the same cohort of healthy subjects.

METHODS AND MATERIALS

In this prospective IRB approved study, unenhanced MR imaging of the upper abdomen was performed in 12 healthy subjects on both 0.55T (Magnetom Free.Max) and a 1.5T (Magnetom Sola) MR system (Siemens Healthineers, Erlangen, Germany). The protocol comprised the following sequences: single-shot T2w TSE, fat sat T2w BLADE, DWI, 2D IP-OP dual-echo GRE, 3D FS T1w GRE, and respiratory triggered coronal 3D T2w TSE MRCP. The images were rated by 2 radiologists with 22 and 17 years' experience in body MRI on a 4-point scale (1: extremely poor, 2: poor, 3: good, 4: excellent) for the following features: signal-to-noise ratio, edge definition of organs (liver, spleen, pancreas, adrenals, kidneys), delineation of hepatic veins, artifacts, and overall image quality. MRCP images were rated for delineation of biliary and pancreatic ducts, and overall image quality. The Mann-Whitney U test was used to determine any statistically significant difference in image quality between the different field strengths for all sequences, where a p-value <0.05 was considered to be statistically significant

RESULTS

Abdominal MRI with acceptable image quality (overall image quality score =3) was achieved in all 12 cases at 0.55Tat an average acquisition time of 22 ± 4 min. 3D MRCPs acquired at 0.55T had higher overall image quality scores than 1.5T (p = 0.04 by reader 1). The overall image quality scores were significantly higher at 1.5T for coronal and axial single shot T2w TSE by both readers (reader 1: p=0.02 and p=0.01 , reader 2: p=0.003 and p=0.0001, respectively). SNR scores were higher at 1.5T images for all sequences except DWI b50, for which the score was equal to (reader 1) or less than (reader2) that at 0.55T. The SNR ratings of coronal and axial single shot T2w TSE and were significantly higher at 1.5 T by both readers (reader 1: p=0.04 and p=0.04, reader 2: p=0.0022 and p=0.00008, respectively).

CONCLUSION

s Diagnostically acceptable quality abdominal MR images can be obtained at 0.55T. While the image quality in some sequences including coronal and axial single shot T2w TSE and DWI at 0.55T may be improved, some sequences such as 3D MRCPs were rated higher at 0.55T than at 1.5T. Further work is needed to assess ratings from multiple radiologists, reader experience, and effect of various sequence settings on diagnostic accuracy.

CLINICAL RELEVANCE/APPLICATION

A commercial 0.55T MRI system has the potential to provide acceptable quality abdominal MR images collected in healthy subjects. Further studies are needed to assess continued protocol and sequence refinement, as well as clinical performance.

W5A-SPGI-9

Arterial Enhancement Fraction in Evaluating the Therapeutic Effect and Survival for Hepatocellular Carcinoma Patients Treated with DEB-TACE

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - GI DPS

Participants
Bin Chai, (*Presenter*) Nothing to Disclose

PURPOSE

To retrospectively investigate relationships between arterial enhancement fraction (AEF) and treatment response and survival in hepatocellular carcinoma (HCC) patients treated with drug-eluting bead (DEB) TACE.

METHODS AND MATERIALS

AEF of the primary HCC lesion (AEFpre) and residual tumor (AEFpost) were obtained from triphasic liver CT scans before and after DEB-TACE in 158 HCC patients. Wilcoxon-signed rank test was used to compare the AEFpre and AEFpost for different response groups. Cox regression analyses were used to determine the association between AEF and overall survival.

RESULTS

There was no correlation between AEFpre and treatment response. The AEFpost was significantly lower than AEFpre in the partial response group (38.9% vs. 52.7%, $p < 0.001$) and stable disease group (49.3% vs. 52.1%, $p = 0.029$). In patients with disease progression, AEFpost was numerically higher than AEFpre (55.5% vs. 53.0%, $p = 0.604$). Cox regression analyses showed that risk of death increased in patients with AEFpre > 57.95% (HR = 1.66, $p = 0.019$) and with AEFpost > 54.85% (HR = 2.47, $p < 0.001$), and the risk reduced in patients with decrease ratio > -0.102 (HR = 0.32, $p < 0.001$).

CONCLUSION

s No prediction of response was possible before DEB-TACE based on AEF. The change in AEF of viable tumor is correlated with the response of HCC to DEB-TACE. In addition, the AEF could be a helpful predictor in future prospective studies on the embolization treatment for HCC.

CLINICAL RELEVANCE/APPLICATION

Computed tomography perfusion imaging (CTPI), providing information about the hemodynamics properties of tissue at a microscopic level, has shown promising results for monitoring HCC and assessing treatment response more accurately than traditional morphologic imaging. However, Liver CTPI typically involves scanning the liver at numerous (>20) time points after IV contrast injection, thus requiring dedicated scanning protocols and the large radiation dose. Arterial enhancement fraction (AEF) derived from routine triphasic liver CT examinations is an ideal surrogate biomarker to estimate the perfusion information without extra exposure concern. Our findings showed that AEF could be an easily accessible parameters for monitoring the response of HCC to DEB-TACE, and be a useful prognostic factor for survival.

W5A-SPGU-2 Challenging early contrast-enhancement of malignant renal tumor after cryoablation therapy

Participants
Sylvain Bodard, (*Presenter*) Nothing to Disclose

PURPOSE

Most of the early contrast enhancement (CE) of renal tumor following cryoablation therapy described in literature are related to residual tumor due to incomplete treatment. However, we've experienced an uncommon precocious benign contrast enhancement of the cryoablation zone during post-therapeutic follow-up. The aim of our study was to assess the inital follow-up contrast enhancement on MRI that could be challenging to distinguish from a persistent residual lesion.

METHODS AND MATERIALS

In this retrospective study, patients who underwent percutaneous cryotherapy for malignant renal tumors from January 2013 to December 2017 and exhibit early contrast enhancement of the ablation zone on MRI were included. A minimum 3-year follow-up in MRI was necessary for inclusion. Exclusion criteria were the diagnostic of benign renal tumor or with insufficient follow-up after cryoablation. The characteristics of the CE were systematically assessed by two independent investigators.

RESULTS

82 patients were included. Median age was 70 years ± 8 (range 20- 89 years). Tumor type included 76 RCC (93%), 2 chromophobe renal carcinomas (2%) and 2 clear cell tubulopapillary renal cell carcinomas (2%). All of the first follow-up MRI were performed at 24 hours.8 patients had incomplete treatment, all of them showing CE in the ablation zone, the growing size of the CE at next follow-up. Residual tumor CE pattern include either early arterial wash-in at the endorenal side of the peripheric ablation zone, 5/9 were nodular shaped, with a mean size of 18mm (range: 12-27mm,).8 All were located on the peripheric endorenal side of the ablation zone. 7 of 8 (88%) incomplete treatment CE featured a significant wash-out (WO). Benign CE were spotted in 74 patients, all presenting a wash-in at the arterial phase, with a predominant non-nodular shape (51/74), a median length of 13mm (range 2-30mm). They were located either in the central zone (5/74),covering the whole ablation zone (4/74), peripheric on the endorenal side (30/74) or exorenal side (24/74). Every each of those CE regressed completely at the 6 weeks control MRI. Moreover, the majority of the benign findings presented a significant increase of the signal size (69/74) and intensity of the CE throughout the time, and a reverse WO (69/74).

CONCLUSION

s We described in our study an early benign contrast enhancement of the cryoablation zone that is very similar to a residual tumoral lesion except for a significant increase of the signal size, a reverse WO the absence of wash-out and the spontaneous and complete regression at 1 month after treatment.

CLINICAL RELEVANCE/APPLICATION

These features can help differentiate between tumor remnant and physiological contrast uptake when a retreatment decision is necessary.

W5A-SPGU-3 Evaluation of a T2-weighted Adrenal MRI Calculator to Differentiate Adrenal Pheochromocytoma from Lipid Poor Adrenal Adenoma

Participants
Rosalind Gerson, MD, MSc, Cumberland, ON (*Presenter*) Nothing to Disclose

PURPOSE

To assess the sensitivity, specificity, and diagnostic accuracy of a quantitative and quantitative T2 MRI calculator in differentiating pheochromocytomas from lipid-poor adenomas.

METHODS AND MATERIALS

In this retrospective case-control study, three blinded radiologists assessed T2 weighted (T2W) MRI of 29 pathology confirmed pheochromocytomas and 23 lipid-poor adrenal adenomas. Nodule heterogeneity and signal intensity relative to renal cortex were subjectively rated on 5 point Likert scales. T2W signal intensity ratio (SIR) was calculated relative to ipsilateral skeletal muscle and entropy was calculated using histogram analysis following manual segmentation. Values were entered into qualitative and quantitative MR calculators previously developed using logistic regression models. Sensitivity, specificity, and diagnostic accuracy were determined using 2x2 table analysis.

RESULTS

For all three readers, subjective ratings for T2W SI and heterogeneity, as well as quantitative T2W SI ratio and entropy were significantly higher in pheochromocytoma compared to adenoma. Inter-observer agreement was fair to moderate (k=0.37-0.46) for subjective T2W SI and fair (k=0.24-0.32) for subjective heterogeneity.Sensitivity, specificity, and accuracy for pheochromocytoma diagnosis using the qualitative MR calculator ranged from 45-59%, 100%, and 72-79% respectively.Sensitivity, specificity, and accuracy for pheochromocytoma diagnosis using the quantitative MR calculator ranged from 93-100%, 87-96%, and 94-96% respectively.

CONCLUSION

s A quantitative MR calculator using T2W SIR and entropy can differentiate pheochromocytoma from lipid-poor adenoma with high sensitivity, specificity, and accuracy, and demonstrated higher sensitivity and accuracy than a qualitative MR calculator.

CLINICAL RELEVANCE/APPLICATION

Lipid-poor adrenal adenomas and pheochromocytomas have overlapping imaging features, but are differentiated with a high degree of sensitivity and specificity using a quantitative T2 MRI calculator.

W5A-SPHN-1 Radiologic Depth of Invasion and Its Correlation with Pathologic Depth of Invasion in Tongue Squamous Cell Carcinoma: A Systematic Review and Meta-Analysis

Participants
Min Kyoung Lee, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To comprehensively assess the radiologic depth of invasion (rDOI) and its correlation with pathologic depth of invasion (pDOI) in tongue squamous cell carcinoma (SqCC) via a systematic review and meta-analysis.

METHODS AND MATERIALS

PubMed and EMBASE databases were searched to find pertinent original studies reporting rDOI of tongue SqCC published up until September 17, 2021. Studies that evaluated the correlations and mean differences (MD) between the rDOI and pDOI were included. We defined rDOI as the measurement based on any of the radiologic imaging modalities including US, CT, and MRI. The correlation coefficients and MD between rDOI and pDOI were meta-analytically pooled using a random-effects model. Subgroup analyses were performed according to the imaging modality. Pooled sensitivity and specificity were calculated using the bivariate model for studies investigating prediction of cervical lymph node (LN) metastasis based on rDOI. Between-study heterogeneity was assessed via Higgin's inconsistency index (I2). The quality assessment was based on the Newcastle-Ottawa scale for cohort and case-control studies.

RESULTS

Twenty-three studies including 1946 patients were eligible for analysis. All studies received good (n=9) to very good (n=14) quality ratings. The overall pooled correlation coefficient was 0.86 (95% CI, 0.82-0.90) and the pooled MD was 1.84 mm (95% CI, 1.02-2.67 mm). There were moderate to substantial heterogeneities among studies for MD (I2=68.6 %) and correlations (I2=88.6 %). Among the four studies predicting cervical LN, the pooled AUC, sensitivity, and specificity were 0.84 (95% CI, 0.80-0.87), 79% (95% CI, 58-91%) and 75% (95% CI, 44-92%), respectively. In subgroup analysis, MRI showed the largest MD (n=11; 2.62 mm, 95% CI, 2.02-3.22 mm) followed by US (n=2; -0.41 mm, 95% CI, -1.30-0.46 mm) and CT (n=2; 0.12 mm, 95% CI, -2.18-2.41 mm). The correlation coefficient was the highest in US (n=3; 0.91, 95% CI, 0.85-0.97) followed by MRI (n=12; 0.85, 95% CI, 0.81-0.90) and CT (n=2; 0.84, 95% CI, 0.61-1.07).

CONCLUSION

s The rDOI measured by the three imaging modalities (US, CT, and MRI) demonstrated excellent correlations with pDOI. The rDOI was also useful in predicting cervical LN metastasis.

CLINICAL RELEVANCE/APPLICATION

The recent AJCC 8th edition included the depth of invasion (DOI) into T-classification of oral cavity cancers. Since pathologic DOI can only be acquired after surgical resection, preoperative non-invasive assessment of radiologic DOI would help clinicians in early assessment of patients' prognosis.

W5A-SPHN-3 Radiomics Nomogram for the Preoperative Differential Diagnosis of Benign and Malignant Tumors in the Parotid Gland

Awards
Trainee Research Prize - Medical Student

Participants
Sijing Feng, MBChB, BMedSc, Mosgiel, New Zealand (*Presenter*) Nothing to Disclose

PURPOSE

We aimed to develop and validate radiomic nomograms to allow preoperative differentiation between benign- and malignant parotid gland tumors (BPGT and MPGT, respectively), as well as between pleomorphic adenomas (PAs) and Warthin tumors (WTs).

METHODS AND MATERIALS

This retrospective study enrolled 183 parotid gland tumors (68 PAs, 62 WTs, and 53 MPGTs) and divided them into training (n = 128) and testing (n = 55) cohorts. In total, 2553 radiomics features were extracted from fat-saturated T2-weighted images, apparent diffusion coefficient maps, and contrast-enhanced T1-weighted images to construct single-, double-, and multi-sequence combined radiomics models, respectively. The radiomics score (Rad-score) was calculated using the best radiomics model and clinical features to develop the radiomics nomogram. The receiver operating characteristic curve and area under the curve (AUC)

were used to assess these models, and their performances were compared using DeLong’s test. Calibration curves and decision curve analysis were used to assess the clinical usefulness of these models.

RESULTS

The multi-sequence combined radiomics model exhibited better differentiation performance (BPGT vs. MPGT, AUC=0.863; PA vs. MPGT, AUC=0.929; WT vs. MPGT, AUC=0.825; PA vs. WT, AUC=0.927) than the single- and double sequence radiomic models. Nomogram based on the multi-sequence combined radiomics model and clinical features attained an improved classification performance (BPGT vs. MPGT, AUC=0.907; PA vs. MPGT, AUC=0.961; WT vs. MPGT, AUC=0.879; PA vs. WT, AUC=0.967).

CONCLUSION

s Radiomics nomogram yielded excellent diagnostic performance in distinguishing BPGT from MPGT, PA from MPGT, and PA from WT, respectively.

CLINICAL RELEVANCE/APPLICATION

Preoperative diagnosis of parotid gland tumors is of great significance, since in comparison to BPGT, MPGT often require much more aggressive approach, such as total parotidectomy with or without radiotherapy. MRI has the characteristics of noninvasive and high soft-tissue resolution, which is important when evaluating parotid gland tumors, but it is often subject to the subjective influence of the radiologist. In this study, we extracted 2553 radiomics features from FS-T2WI, ADC maps, and CE-T1WI to construct single-, double-, and multi-sequence combined radiomics models, respectively, and compared the diagnostic performance of these models. Then the Rad-score was calculated using the best radiomics model and incorporate clinical features to develop the radiomics nomogram to further improve differential diagnostic performance for parotid gland tumors.

Radiologic Depth of Invasion and Its Correlation with Pathologic Depth of Invasion in Tongue Squamous Cell Carcinoma: A Systematic Review and Meta-Analysis

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - HN DPS

Participants
Min Kyoung Lee, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To comprehensively assess the radiologic depth of invasion (rDOI) and its correlation with pathologic depth of invasion (pDOI) in tongue squamous cell carcinoma (SqCC) via a systematic review and meta-analysis.

METHODS AND MATERIALS

PubMed and EMBASE databases were searched to find pertinent original studies reporting rDOI of tongue SqCC published up until September 17, 2021. Studies that evaluated the correlations and mean differences (MD) between the rDOI and pDOI were included. We defined rDOI as the measurement based on any of the radiologic imaging modalities including US, CT, and MRI. The correlation coefficients and MD between rDOI and pDOI were meta-analytically pooled using a random-effects model. Subgroup analyses were performed according to the imaging modality. Pooled sensitivity and specificity were calculated using the bivariate model for studies investigating prediction of cervical lymph node (LN) metastasis based on rDOI. Between-study heterogeneity was assessed via Higgin's inconsistency index (I2). The quality assessment was based on the Newcastle-Ottawa scale for cohort and case-control studies.

RESULTS

Twenty-three studies including 1946 patients were eligible for analysis. All studies received good (n=9) to very good (n=14) quality ratings. The overall pooled correlation coefficient was 0.86 (95% CI, 0.82-0.90) and the pooled MD was 1.84 mm (95% CI, 1.02-2.67 mm). There were moderate to substantial heterogeneities among studies for MD (I2=68.6 %) and correlations (I2=88.6 %). Among the four studies predicting cervical LN, the pooled AUC, sensitivity, and specificity were 0.84 (95% CI, 0.80-0.87), 79% (95% CI, 58-91%) and 75% (95% CI, 44-92%), respectively. In subgroup analysis, MRI showed the largest MD (n=11; 2.62 mm, 95% CI, 2.02-3.22 mm) followed by US (n=2; -0.41 mm, 95% CI, -1.30-0.46 mm) and CT (n=2; 0.12 mm, 95% CI, -2.18-2.41 mm). The correlation coefficient was the highest in US (n=3; 0.91, 95% CI, 0.85-0.97) followed by MRI (n=12; 0.85, 95% CI, 0.81-0.90) and CT (n=2; 0.84, 95% CI, 0.61-1.07).

CONCLUSION

s The rDOI measured by the three imaging modalities (US, CT, and MRI) demonstrated excellent correlations with pDOI. The rDOI was also useful in predicting cervical LN metastasis.

CLINICAL RELEVANCE/APPLICATION

The recent AJCC 8th edition included the depth of invasion (DOI) into T-classification of oral cavity cancers. Since pathologic DOI can only be acquired after surgical resection, preoperative non-invasive assessment of radiologic DOI would help clinicians in early assessment of patients' prognosis.

Sub-Events

W5A-SPIN-1 Deep Learning Image Reconstruction of Diffusion Weighted Imaging in Pelvic MRI at 1.5 Tesla

Participants
Sebastian Gassenmaier, MD, Tuebingen, Germany (*Presenter*) Nothing to Disclose

PURPOSE

The aim of this study was to investigate the impact of a novel deep learning image reconstruction algorithm for diffusion weighted imaging (DWI) including acquisition time reduction in 1.5T pelvic MRI on image quality parameters and diagnostic confidence.

METHODS AND MATERIALS

Thirty patients who were examined in February and March 2022 were retrospectively included in this monocentric study. All patients underwent a clinically indicated 1.5T pelvic MRI including DWI with two different b-values (b=50 s/mm2 and b=800 s/mm2). Apparent diffusion coefficient maps were calculated. Afterwards, the raw data of standard DWI (DWISD) was processed using a novel deep learning image reconstruction algorithm resulting in datasets of DWIDL. This algorithm simulated a reduced acquisition time via reduction of averages in the high b-value. Standard acquisition applied one average for b=50 s/mm2 and 12 averages for b=800 s/mm2 resulting in an acquisition time of 2:58 min. DWIDL applied also one average for b=50 s/mm2 but omitted 6 averages for b=800 s/mm2 of the original data resulting in a reduced acquisition time of 1:42 min. Both datasets were independently evaluated by two radiologists in a blinded random order reading using a Likert scale ranging from 1 - 4 with 4 being the best. The following criteria were assessed: noise levels, extent of artifacts, sharpness, contrast, lesion detectability, overall image quality, and diagnostic confidence.

RESULTS

Mean patient age was 57 ± 15 years. Noise levels as well as the image contrast was evaluated to be significantly superior in DWIDL with a median of 4 in comparison to a median of 3 in DWISD ($p<0.001$ for both readers). The sharpness of images was also assessed to be better in DWIDL with a median of 4 versus a median of 4 in DWISD ($p=0.020$ for reader 1 and $p=0.011$ for reader 2). No significant differences were found regarding extent of artifacts, lesion detectability, overall image quality, and diagnostic confidence ($p>0.05$ for both readers).

CONCLUSION

s Deep learning image reconstruction of DWI in pelvic MRI provides the opportunity of acquisition time reduction without loss of image quality.

CLINICAL RELEVANCE/APPLICATION

Deep learning image reconstruction offers a great opportunity for further acquisition time reduction of time-consuming DWI in combination with diagnostic image quality. These results demonstrate the potential of novel deep learning image reconstruction algorithms.

W5A-SPIN-2 A multi-view Deep Learning-based Architecture for Thyroid Nodules Detection and Characterization

Participants
Sanaz Vahdati, MD, Rochester, MN (*Presenter*) Nothing to Disclose

PURPOSE

Thyroid cancer is regarded as one of the most rapidly growing malignancies in the general population, with an incidence rate of 14.6 per 100,000 in the United States. Thyroid Ultrasound (US) is the primary method to screen thyroid nodules and determine whether a nodule requires Fine Needle Aspiration (FNA). While the US is a safe and cheap method, FNA is an invasive and costly procedure for evaluating thyroid nodules. In recent years, deep learning (DL) has played a significant role in detecting and classifying different types of malignancies. Likewise, we propose a DL-based pipeline to detect and classify thyroid nodules into benign or malignant groups relying on two views of US imaging.

METHODS AND MATERIALS

Transverse and longitudinal views from B-mode US images of single thyroid nodules from 1003 patients were collected retrospectively. A total of 101 cases were held out as a testing set, and the rest of the data was used in five-fold cross-validation (CV). Two You Look Only Once (YOLO) v5 models, one for each view, were trained to detect nodules and classify them as benign or malignant. For each view, five models developed during the CV, one for each fold, were ensembled by using non-max suppression (NMS) to boost their collective generalizability. Finally, an extreme gradient boosting machine (XGBoost) model was trained on outputs of the ensembled models for both transverse and longitudinal views to yield a final prediction of malignancy for a single nodule. Mean average precision at 50% overlap (mAP0.5) was used to evaluate the YOLO models. The whole pipeline's performance

was evaluated using Area under receiving operating curve (AUROC). All the metrics were reported on the holdout test set.

RESULTS

The total number of malignant nodules was 518 (of 1003 nodules: 51%), with 50 malignant nodules in the test set. The averaged mAP0.5 of the five cross-validation folds for transverse, and longitudinal YOLO models were 0.70 (SD: 0.033) and 0.72 (SD: 0.039), respectively. The ensembled models for each view achieved a mAP0.5 of 0.797 (for the transverse view) and 0.716 (for the longitudinal view). The whole pipeline, created by the XGBoost ensemble, reached an AUROC of 0.84 (CI 95%: 0.75-0.91) with sensitivity and specificity of 0.84 and 0.627, respectively. The negative predictive value of the pipeline was 0.799, with F1 score of 0.756.

CONCLUSION

s We demonstrate the robustness of an ensemble of DL models receiving multiple views of thyroid US images to detect and characterize thyroid nodules.

CLINICAL RELEVANCE/APPLICATION

This study proposes a DL-based pipeline to assist radiologists with diagnosing malignant thyroid nodules from multiple views of US images, which can eventually reduce unnecessary FNA for cases that are highly suggestive of being benign.

W5A-SPIN-4 Automated Triage System to Screen No Change Follow-up Chest Radiographs Using Multi-task Deep Learning With Vision Transformer

Participants
Jeeyoung Kim, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To propose a novel method to classify change/no-change in follow-up chest radiographs (CXRs) using multi-task learning which performs three tasks at once including classifying normal/abnormal, matching similar regions, and classifying change/no-change.

METHODS AND MATERIALS

A total of 404K baseline and follow-up CXR pairs were acquired from a tertiary hospital in South Korea, which contained 174K change and 230K no-change pairs. All CXRs were labeled based on radiologic reports with in-house natural language processing. Visual validation of labels was conducted by an expert thoracic radiologist with more than 20 years' experience, which showed approximately 80% accuracy in sampled dataset. For internal validation dataset, 1620 change/no-change pairs were enrolled. For two external datasets, one is 533 pairs collected from the same center, and the other is 430 pairs from the CheXpert dataset. All validation datasets were labeled with 100% accuracy by the radiologist. To overcome patient's posture, breath-hold level, aging, and other changes not related to disease progression, our network consists of four parts including Siamese network architecture, pretrained A DenseNet backbone U-Net with strong labels of diseases, Attend-and-Compare Module (ACM), a self-attention method to match the similar anatomical structure, and multi-task learning containing three loss functions to classify normal/abnormal, match each pair, and classify change/no-change. The baseline model is ResNet-152 and the full model contains CMT with all of the above mentioned. The AUC, accuracy, sensitivity, and specificity were evaluated in internal and external validations. In addition, saliency maps acquired by using Grad-CAM were used to compare the qualitative results. Hanley McNeil test is used for the statistical analysis.

RESULTS

In internal validation, AUC, accuracy, sensitivity, and specificity of the full model were 0.77, 0.70, 0.57, and 0.83, respectively. In external validation dataset from same center, those were 0.85, 0.71, 0.51, and 0.91, and in CheXpert dataset, those were 0.76, 0.64, 0.34, and 0.93, respectively. Those of the baseline model were 0.72, 0.67, 0.56, and 0.78 for a same center validation dataset, and 0.66, 0.60, 0.40, and 0.71 for CheXpert dataset. For external validation dataset, all ROCs of full model show significantly better than those of the baseline model. (P-values < 0.01)

CONCLUSION

s Our multi-task learning model can assist classifying change/no-change in follow-up CXRs which is one of the main tasks of radiologists.

CLINICAL RELEVANCE/APPLICATION

This model could be used to develop fully automated triage system to screen no change follow-up CXRs in acutal clinical practice which could reduce heavy burden of radiologists' reading.

W5A-SPIN-5 Detection of Active Inflammatory Changes and Structural Damage to Sacroiliac Joints in Patients with Axial Spondyloarthritis Using Deep Learning

Participants
Keno Bressem, MD, Berlin, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Develop an artificial neural network for detecting axial spondyloarthritis (axSpA)-induced inflammatory or structural changes of sacroiliac joints in MRI.

METHODS AND MATERIALS

This multicenter retrospective study included MRI examinations from five cohorts of patients in whom axSpA was clinically suspected. The examinations were collected between 01/2006 and 09/2020 at university and community hospitals. Four of the cohorts were used for artificial neural network development and training, and one cohort was withheld for testing.Six experts in the field of rheumatologic imaging specializing in axSpA evaluated the MRIs of the training group for the presence of inflammatory changes or structural lesions. Seven additional experts evaluated the MRIs of the test cohort. Majority consensus among the experts was chosen as the final diagnosis. In case of a tie, another expert was consulted as a tiebreaker.To enable the training of a classification network, a homogenization of the data had to be performed first. This could be achieved by applying a U-Net autoencoder. Subsequently, a ResNet101-3d was trained for the detection of inflammatory and structural lesions. Area under the

receiver operating characteristic curve (AUC), sensitivity, and specificity were used to evaluate the performance of the classification network. A p-value of <.05 was considered significant.

RESULTS

The five cohorts included 593 patients (302 women) with a mean age of 37 ± 11 years. 477 patients were assigned to the training cohort and 116 patients to the test cohort.The prevalence of inflammatory changes in the exercise group was 41% and the prevalence of structural changes was 51%. In the test group, the prevalence of changes was significantly lower, with 21.6% inflammatory and 22.4 structural changes.On the test data set, the classification network achieved an AUC of 0.94 (95% CI 0.84-0.97) for the detection of inflammatory changes, 0.88 (0.80-0.95) for inflammatory changes meeting the ASAS definition, and 0.89 (0.81-0.96) for the detection of structural changes.

CONCLUSION

s Artificial neural networks can detect inflammatory or structural changes in sacroiliac joints even in heterogeneous multicenter MRI data.

CLINICAL RELEVANCE/APPLICATION

The developed neural networks could help clinicians detect signs of axSpA in MRI earlier and thus help direct patients to appropriate treatment. In addition, it could serve as decision support tool in clinical trials.

W5A-SPIN-6 Age Is More Than a Number: Estimating Biologic Age from Chest X-rays

Participants
Kaesha Thomas, MBBS, (*Presenter*) Nothing to Disclose

PURPOSE

Chronological age, the time elapsed since birth, is the defacto measure of aging in clinical pathways such as medical formulas and screening guidelines. However, given the impact of biological and socioenvironmental factors on disease trajectory, chronological age may be an imprecise measure of the effects of aging versus biological age. Given the ability of AI to detect patterns not obvious to the human eye, we explore if AI can be used to determine biological age. We hypothesize that CXR-Age is a better predictor of observed, all-cause mortality than chronological age.

METHODS AND MATERIALS

CXR-Age is an open-source, convolutional neural network (CNN) model trained using CXRs from 116,035 individuals from the Prostate, Lung, Colorectal and Ovarian Cancer National Lung Screening trials. Using a CXR dataset from Emory University Healthcare, we validated the performance of this CNN on 30,806 unique patient CXR images with an output of biological age (CXR-age). CXR-Age, chronological age and risk factors were compared to observed mortality. Gradient-weighted Class Activation Mapping (Grad-CAM) localized areas contributing to the highest probability for the prediction. Data analyses were conducted in Python and OpenAI. A p-value < 0.05 was statistically significant.

RESULTS

Our cohort of 30,806 patients had a mean age of 64.5 (5.8) years and was 49% male. Most had a CXR-Age within 5 years their chronological age (57.4%, [17,694 of 30,806]). For patients with observed mortality (n=2,774), the AUC for CXR-Age was significantly greater than chronological age (0.523 and 0.595, respectively; p < 0.05). Observed mortality in chronological age strata was found to be statistically different among CXR-Age strata (p <0.01). Patients with a CXR-Age =70 years had the highest mortality among the strata ([569 of 4,156], 13.7%). Patients with a CXR-Age greater than 5 years their original age had higher risk of observed mortality than those with a CXR-Age within 5 years their original age (RR=1.4, p<0.01). No significant association was found for those with a CXR-Age at least five years younger than their original age likely due to a lack of observed death within this stratum (RR=1.1, p=0.1). The upper and lower mediastinum were common activation areas that contributed to the CXR-Age age estimate.

CONCLUSION

s In this cohort, patients with a CXR-Age more than 5 years their original age were at increased risk of observed morality. Determining biological age from medical images like CXR may improve risk stratification of patients.

CLINICAL RELEVANCE/APPLICATION

Chronological age is an imperfect measure of aging. In contrast, biological age extracted from chest radiographs using using deep learning can improve risk stratification of patients and clinical assessment.

Deep Learning Image Reconstruction of Diffusion Weighted Imaging in Pelvic MRI at 1.5 Tesla

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - IN DPS

Participants
Sebastian Gassenmaier, MD, Tuebingen, Germany (*Presenter*) Nothing to Disclose

PURPOSE

The aim of this study was to investigate the impact of a novel deep learning image reconstruction algorithm for diffusion weighted imaging (DWI) including acquisition time reduction in 1.5T pelvic MRI on image quality parameters and diagnostic confidence.

METHODS AND MATERIALS

Thirty patients who were examined in February and March 2022 were retrospectively included in this monocentric study. All patients underwent a clinically indicated 1.5T pelvic MRI including DWI with two different b-values (b=50 s/mm2 and b=800 s/mm2). Apparent diffusion coefficient maps were calculated. Afterwards, the raw data of standard DWI (DWISD) was processed using a novel deep learning image reconstruction algorithm resulting in datasets of DWIDL. This algorithm simulated a reduced acquisition time via reduction of averages in the high b-value. Standard acquisition applied one average for b=50 s/mm2 and 12 averages for b=800 s/mm2 resulting in an acquisition time of 2:58 min. DWIDL applied also one average for b=50 s/mm2 but omitted 6 averages for b=800 s/mm2 of the original data resulting in a reduced acquisition time of 1:42 min. Both datasets were independently evaluated by two radiologists in a blinded random order reading using a Likert scale ranging from 1 - 4 with 4 being the best. The following criteria were assessed: noise levels, extent of artifacts, sharpness, contrast, lesion detectability, overall image quality, and diagnostic confidence.

RESULTS

Mean patient age was 57 ± 15 years. Noise levels as well as the image contrast was evaluated to be significantly superior in DWIDL with a median of 4 in comparison to a median of 3 in DWISD ($p<0.001$ for both readers). The sharpness of images was also assessed to be better in DWIDL with a median of 4 versus a median of 4 in DWISD ($p=0.020$ for reader 1 and $p=0.011$ for reader 2). No significant differences were found regarding extent of artifacts, lesion detectability, overall image quality, and diagnostic confidence ($p>0.05$ for both readers).

CONCLUSION

s Deep learning image reconstruction of DWI in pelvic MRI provides the opportunity of acquisition time reduction without loss of image quality.

CLINICAL RELEVANCE/APPLICATION

Deep learning image reconstruction offers a great opportunity for further acquisition time reduction of time-consuming DWI in combination with diagnostic image quality. These results demonstrate the potential of novel deep learning image reconstruction algorithms.

Automated Triage System to Screen No Change Follow-up Chest Radiographs Using Multi-task Deep Learning With Vision Transformer

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - IN DPS

Participants
Jeeyoung Kim, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To propose a novel method to classify change/no-change in follow-up chest radiographs (CXRs) using multi-task learning which performs three tasks at once including classifying normal/abnormal, matching similar regions, and classifying change/no-change.

METHODS AND MATERIALS

A total of 404K baseline and follow-up CXR pairs were acquired from a tertiary hospital in South Korea, which contained 174K change and 230K no-change pairs. All CXRs were labeled based on radiologic reports with in-house natural language processing. Visual validation of labels was conducted by an expert thoracic radiologist with more than 20 years' experience, which showed approximately 80% accuracy in sampled dataset. For internal validation dataset, 1620 change/no-change pairs were enrolled. For two external datasets, one is 533 pairs collected from the same center, and the other is 430 pairs from the CheXpert dataset. All validation datasets were labeled with 100% accuracy by the radiologist. To overcome patient's posture, breath-hold level, aging, and other changes not related to disease progression, our network consists of four parts including Siamese network architecture, pretrained A DenseNet backbone U-Net with strong labels of diseases, Attend-and-Compare Module (ACM), a self-attention method to match the similar anatomical structure, and multi-task learning containing three loss functions to classify normal/abnormal, match each pair, and classify change/no-change. The baseline model is ResNet-152 and the full model contains CMT with all of the above mentioned. The AUC, accuracy, sensitivity, and specificity were evaluated in internal and external validations. In addition, saliency maps acquired by using Grad-CAM were used to compare the qualitative results. Hanley McNeil test is used for the statistical analysis.

RESULTS

In internal validation, AUC, accuracy, sensitivity, and specificity of the full model were 0.77, 0.70, 0.57, and 0.83, respectively. In external validation dataset from same center, those were 0.85, 0.71, 0.51, and 0.91, and in CheXpert dataset, those were 0.76, 0.64, 0.34, and 0.93, respectively. Those of the baseline model were 0.72, 0.67, 0.56, and 0.78 for a same center validation dataset, and 0.66, 0.60, 0.40, and 0.71 for CheXpert dataset. For external validation dataset, all ROCs of full model show significantly better than those of the baseline model. (P-values < 0.01)

CONCLUSION

s Our multi-task learning model can assist classifying change/no-change in follow-up CXRs which is one of the main tasks of radiologists.

CLINICAL RELEVANCE/APPLICATION

This model could be used to develop fully automated triage system to screen no change follow-up CXRs in acutal clinical practice which could reduce heavy burden of radiologists' reading.

W5A-SPIN-5

Detection of Active Inflammatory Changes and Structural Damage to Sacroiliac Joints in Patients with Axial Spondyloarthritis Using Deep Learning

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - IN DPS

Participants
Keno Bressem, MD, Berlin, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Develop an artificial neural network for detecting axial spondyloarthritis (axSpA)-induced inflammatory or structural changes of sacroiliac joints in MRI.

METHODS AND MATERIALS

This multicenter retrospective study included MRI examinations from five cohorts of patients in whom axSpA was clinically suspected. The examinations were collected between 01/2006 and 09/2020 at university and community hospitals. Four of the cohorts were used for artificial neural network development and training, and one cohort was withheld for testing.Six experts in the field of rheumatologic imaging specializing in axSpA evaluated the MRIs of the training group for the presence of inflammatory changes or structural lesions. Seven additional experts evaluated the MRIs of the test cohort. Majority consensus among the experts was chosen as the final diagnosis. In case of a tie, another expert was consulted as a tiebreaker.To enable the training of a classification network, a homogenization of the data had to be performed first. This could be achieved by applying a U-Net autoencoder. Subsequently, a ResNet101-3d was trained for the detection of inflammatory and structural lesions. Area under the receiver operating characteristic curve (AUC), sensitivity, and specificity were used to evaluate the performance of the classification network. A p-value of <.05 was considered significant.

RESULTS

The five cohorts included 593 patients (302 women) with a mean age of 37 ± 11 years. 477 patients were assigned to the training cohort and 116 patients to the test cohort.The prevalence of inflammatory changes in the exercise group was 41% and the prevalence of structural changes was 51%. In the test group, the prevalence of changes was significantly lower, with 21.6% inflammatory and 22.4 structural changes.On the test data set, the classification network achieved an AUC of 0.94 (95% CI 0.84-0.97) for the detection of inflammatory changes, 0.88 (0.80-0.95) for inflammatory changes meeting the ASAS definition, and 0.89 (0.81-0.96) for the detection of structural changes.

CONCLUSION

s Artificial neural networks can detect inflammatory or structural changes in sacroiliac joints even in heterogeneous multicenter MRI data.

CLINICAL RELEVANCE/APPLICATION

The developed neural networks could help clinicians detect signs of axSpA in MRI earlier and thus help direct patients to appropriate treatment. In addition, it could serve as decision support tool in clinical trials.

Age Is More Than a Number: Estimating Biologic Age from Chest X-rays

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - IN DPS

Participants
Kaesha Thomas, MBBS, (*Presenter*) Nothing to Disclose

PURPOSE

Chronological age, the time elapsed since birth, is the defacto measure of aging in clinical pathways such as medical formulas and screening guidelines. However, given the impact of biological and socioenvironmental factors on disease trajectory, chronological age may be an imprecise measure of the effects of aging versus biological age. Given the ability of AI to detect patterns not obvious to the human eye, we explore if AI can be used to determine biological age. We hypothesize that CXR-Age is a better predictor of observed, all-cause mortality than chronological age.

METHODS AND MATERIALS

CXR-Age is an open-source, convolutional neural network (CNN) model trained using CXRs from 116,035 individuals from the Prostate, Lung, Colorectal and Ovarian Cancer National Lung Screening trials. Using a CXR dataset from Emory University Healthcare, we validated the performance of this CNN on 30,806 unique patient CXR images with an output of biological age (CXR-age). CXR-Age, chronological age and risk factors were compared to observed mortality. Gradient-weighted Class Activation Mapping (Grad-CAM) localized areas contributing to the highest probability for the prediction. Data analyses were conducted in Python and OpenAI. A p-value < 0.05 was statistically significant.

RESULTS

Our cohort of 30,806 patients had a mean age of 64.5 (5.8) years and was 49% male. Most had a CXR-Age within 5 years their chronological age (57.4%, [17,694 of 30,806]). For patients with observed mortality (n=2,774), the AUC for CXR-Age was significantly greater than chronological age (0.523 and 0.595, respectively; $p < 0.05$). Observed mortality in chronological age strata was found to be statistically different among CXR-Age strata ($p < 0.01$). Patients with a CXR-Age =70 years had the highest mortality among the strata ([569 of 4,156], 13.7%). Patients with a CXR-Age greater than 5 years their original age had higher risk of observed mortality than those with a CXR-Age within 5 years their original age (RR=1.4, $p<0.01$). No significant association was found for those with a CXR-Age at least five years younger than their original age likely due to a lack of observed death within this stratum (RR=1.1, p=0.1). The upper and lower mediastinum were common activation areas that contributed to the CXR-Age age estimate.

CONCLUSION

s In this cohort, patients with a CXR-Age more than 5 years their original age were at increased risk of observed morality. Determining biological age from medical images like CXR may improve risk stratification of patients.

CLINICAL RELEVANCE/APPLICATION

Chronological age is an imperfect measure of aging. In contrast, biological age extracted from chest radiographs using using deep learning can improve risk stratification of patients and clinical assessment.

Interventional Wednesday Poster Discussions - A

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - IR DPS

Sub-Events

W5A-SPIR-1 Feasibility, Safety and Outcomes of Thermal Ablation of Kidney Cancer in the Elderly

Participants
Wenhui Zhou, MD,PhD, Menlo Park, CA (*Presenter*) Nothing to Disclose

PURPOSE

When renal cell carcinoma is diagnosed in patients of advanced age, patient co-morbidities may limit treatment options active surveillance only. This study assessed the technical results, procedural complications and survival outcome of thermal ablation in patients greater than 80 years of age diagnosed with stage T1 RCC.

METHODS AND MATERIALS

A retrospective analysis was performed of 113 patients greater than 80 years of age who underwent computed tomography-guided thermal ablations for 126 biopsy-proven T1N0M0 renal cell carcinoma (mean size = 3.2 cm, size SD = 1.3 cm) between October 2008 and March 2020. The rates of technical success, peri- and post-procedural complications, residual disease and local recurrence were examined. The Kaplan-Meier method was used to compute overall and cancer-specific survival.

RESULTS

Of the 103 elderly patients treated, the median age = 85 yrs, (range = 80 to 95 yrs) were treated and mean Charlson comorbidity index score was 3.8 (SD = 1.3). Technical success was achieved in all of the patients. Asymptomatic perinephric hematoma (Clavien-Dindo Grade I) was the most common complication, occurring in 23% of patients. Ureteral stricture requiring stent placement was the only major complication, and occurred in 2% of patients. Primary technique efficacy was achieved in 89% of cases. At 1, 3 and 5 years post-ablation, the overall survival rates were 98%, 85%, and 80%, RCC-specific survival rates were 100%, 100% and 98%, and local progression-free survival rates were 100%, 95%, and 92%, respectively.

CONCLUSION

s Renal ablation appears technically feasible, well-tolerated and effective in treating stage T1 renal cell carcinoma in elderly patients. Small asymptomatic perinephric hematomas are a common complication following this procedure in this population.

CLINICAL RELEVANCE/APPLICATION

Thermal ablation may be an effective non-surgical alternative to nephrectomy or active surveillance for elderly patients diagnosed with renal cell carcinomas. For elderly patients motivated to pursue minimally invasive treatment for renal cell carcinoma, thermal ablation should be considered.

W5A-SPIR-3 Ablation Margin and Tumor Morphology Metrics from a Randomized Controlled Drug + Device Trial in 3-7 cm Hepatocellular Carcinoma

Participants
Katerina Lee, BS, Cedar Park, TX (*Presenter*) Nothing to Disclose

PURPOSE

We studied the factors associated with differences in local recurrence and survival in a clinical trial of patients with hepatocellular carcinoma (HCC) who underwent radiofrequency ablation (RFA).

METHODS AND MATERIALS

550 patients from the OPTIMA Trial (with solitary HCC lesions =3 but =7cm, randomized to RFA or RFA+LTLD) were screened for well-defined tumor imaging on pre-RFA CT. 242 pre-ablation tumors and 338 post-ablation (28 days) de-vascularized volumes were manually segmented (3D Slicer). 187 pairs of corresponding pre-ablation and post-ablation CT scans were registered with General Registration (Elastix), and structural similarity was calculated in MatLab to assess registration quality (average 99.3% similarity) (Fig 1). Dice similarity metrics were recorded from the Radiotherapy Segment Comparison module. Segmented tumor and ablation zone overlap were used to define undertreated tumor and treated tumor (percent and absolute volume) (Fig 2). Multiple tumor morphology metrics were determined (3DSlicer MatLab). Relationships between these variables were analyzed using R. “Disease progression classes” were initially: complete response/no evidence of disease progression, distant hepatic recurrence, extrahepatic recurrence, incomplete response, local recurrence. These were further split into 2 final classes: Local recurrence (Yes or No). Survival data was analyzed for 122.

RESULTS

Univariate multinomial logistic regression showed significance between “local recurrence” and volume (p=.004) and surface area

(p=.002). Multivariate analysis revealed a significant relationship between “local recurrence” and age (p=0.0478). Univariate analysis had significance with age (p=0.01) and absolute overlap volume (p=0.02). For survival (deceased vs alive at end of trial), there was a significant trend/relationship with age (p=0.0098), percent overlap (p=.05), and absolute undertreated volume (p=0.055) from univariate logistic regression.

CONCLUSION

s The correlations between tumor-ablation zone overlap and survival/local recurrence support the use of pre- and post-ablation image registration to verify coverage or predict recurrence.

CLINICAL RELEVANCE/APPLICATION

Image assessment and registration with ablation may support standardization, quality control, and outcome prediction. Understanding the factors contributing to outcome would help tailor treatment approaches.

W5A-SPIR-4 Percutaneous CT/MRI-US Fusion System Guided Radiofrequency Ablation of Hepatocellular Carcinoma in Difficult Locations: The Feasibility Rate and Mid-term Outcome

Participants
Jae Hyun Kim, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the feasibility rate and the mid-term outcomes of CT/MRI-US fusion system guided radiofrequency ablation (RFA) of hepatocellular carcinomas (HCCs) in difficult locations and to compare the results with non-difficult HCCs.

METHODS AND MATERIALS

For this single-center retrospective study, from April 2019 to April 2020, a total of 533 patients with 572 HCCs were referred for CT/MRI-US fusion system guided RFA. The radiologic reports of 533 RFA planning US were reviewed in terms of the feasibility rate. The difficult locations were defined as follows: tumors located 1) = 5 mm from major vessels or bile ducts; 2) = 5 mm from diaphragm, colon, stomach, or right kidney; 3) = 1cm from pericardium. We calculated cumulative incidences of local tumor progression (LTP) by using Kaplan-Meier method between patients with HCCs in difficult locations and patients with non-difficult HCCs. LTP rates between two groups were compared by the chi-squared test. The patients with less than three months follow-up were excluded from these analyses.

RESULTS

In 499 of 533 (93.6%) RFA planning US, percutaneous RFA of HCC was feasible. Among 499 HCC patients (mean tumor size=15.8 mm ± 0.60) who were feasible for RFA, 261 patients (52.3%) had at least one HCC with difficult location. Of the 499 patients, 10 patients had less than three months follow-up. During the median follow-up period of 28.5 months (range, 3.7-37.3 months), there was no significant difference in LTP rates between patients with difficult HCCs (n=251) and patients with non-difficult HCCs (n=238) (6.0% [15/251] vs. 6.3% [15/238]; P=0.881). The 1- and 2-year estimated cumulative incidences of LTP were 3.7% and 5.9% in patients with difficult HCCs; and 2.6% and 5.9% in patients with non-difficult HCCs.

CONCLUSION

s HCCs in difficult locations for RFA could be treated effectively with CT/MRI-US fusion system guided RFA, and there was no significant difference in LTP rates between patients with difficult HCCs and patients with non-difficult HCCs.

CLINICAL RELEVANCE/APPLICATION

CT/MRI-US fusion system guided RFA could increase the feasibility rate and clinical outcomes of HCCs in difficult locations.

W5A-SPIR-5 Percutaneous Cryoablation for Extra-Abdominal Desmoid Tumors: A Systematic Review

Participants
Tushar Garg, MD, Baltimore, MD (*Presenter*) Conference Travel, Siemens Healthineers

PURPOSE

To systematically review the literature published on percutaneous cryoablation for the treatment of extra-abdominal desmoid (EAD) tumor and assess its safety and efficacy.

METHODS AND MATERIALS

Using three databases, a systematic review was performed following Preferred Reporting Items for Systematic Reviews and Meta-analyses (PRISMA) guidelines. The search strategy used was "cryo*"[All Fields] AND ("fibromatosis, aggressive"[MeSH Terms] OR ("fibromatosis"[All Fields] AND "aggressive"[All Fields]) OR "aggressive fibromatosis"[All Fields] OR "desmoid"[All Fields] OR "desmoids" [All Fields]). From all the articles the type of study, mean age of patients, number of patients, number of EAD tumor, EAD tumor size before cryoablation, follow-up characteristics, treatment results, and complications were recorded in Microsoft Excel and analyzed using IBM SPSS software (Armonk, NY).

RESULTS

A total of ten studies with eight retrospective chart reviews and two prospective studies were included in the final analysis. A total of 219 patients were enrolled between ten studies and included 247 EAD tumors. The mean age of patients in the studies ranged from 24.2 to 41 years and the tumour volume ranged from 38.6 cm3 to 258.6 cm3. A total of 284 procedures were performed with 79 (36.07%) patients undergoing cryoablation as the primary procedure. The mean imaging follow-up ranged from 11.3 to 53.7 months and was done with either CT or MRI. Complete response was seen in 74 (35.9%) tumors, partial response in 60 (32.25%) tumors, and disease progression or recurrence in 47 (21.86%) tumors. 91.3% (138) patients had symptoms prior to cryoablation due to EAD tumor and 88.4% (122) patients showed improvement in symptoms after the procedure. Only 17.82% of procedures were associated with complications with an even lower incidence of serious complications.

CONCLUSION

s Current data from the studies show that cryoablation is safe and well-tolerated in select patients with EAD tumors. Combining

open surgery with an image-guided approach can reduce adverse events, but further evaluation of the effect of this approach on treatment outcomes is needed. .

CLINICAL RELEVANCE/APPLICATION

Prospective investigations with long-term follow-up are required to further clarify the efficacy and safety profile of cryoablation and further establish its place in the treatment of EAD tumors

W5A-SPIR-7 An Investigation on Clinical Usefulness of Motion Compensation of Cone-beam Computed Tomography for Trans-arterial Chemoembolization

Participants
JANG SOON HWANG, (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the effect of a motion artifact correction algorithm (MACA) on C-arm computed tomography (CT) during transarterial chemoembolization (TACE) for hepatic malignancies.

METHODS AND MATERIALS

Among 769 patients who underwent TACE in a dedicated angioroom from June 2020 to March 2021, 42 patients with identifiable motion artifacts on their single C-arm CT scans were retrospectively evaluated. The image qualities of the native and motion-corrected data were compared using both qualitative and quantitative methods. The maximum intensity, sharpness, and diameter of the five segmental hepatic arteries were measured quantitatively using software. The overall quality of maximum intensity projection (MIP) images and conspicuity of tumor-supplying arteries were qualitatively graded by two independent readers. Paired t-tests and Wilcoxon signed-rank tests were used to compare the quantitative and qualitative parameters of native and motion corrected image sets. Inter-reader agreements of the qualitative measurements were addressed using a quadratic weighted kappa test.

RESULTS

The mean maximum intensity and sharpness of the hepatic arteries increased from 2792.01 ± 451.36 HU to 3148.40 ± 594.46 HU and from 0.31 ± 0.02 /mm to 0.34 ± 0.02 /mm, respectively, using MACA ($p < 0.001$ and $p < 0.001$, respectively). In the same line, MACA decreased the mean diameter from 2.02 ± 0.27 mm to 1.78 ± 0.26 mm ($p < 0.001$), suggesting improved vessel conspicuity with less blurred contours by motion compensation. With a regard to the qualitative analyses, inter-reader agreement was substantially beyond chance in both MIP images (weighted ?, 0.818; 95% confidence interval, 0.771-0.866) and tumor-supplying artery (weighted ?, .810; 95% confidence interval, 0.759 - 0.861) evaluation. The overall quality of the MIP images and conspicuity of the tumor-supplying artery were enhanced from 2.5-point to 3.0-point and the from 3.0-point to 4.0-point by MACA ($p < 0.001$ and $p < 0.001$, respectively).

CONCLUSION

s MACA significantly improved both quantitative and qualitative image quality in patients with hepatic malignancies treated with TACE.

CLINICAL RELEVANCE/APPLICATION

A motion artifact correction algorithm can improve the quality of C-arm CT images degraded by motion artifact in patients treated with TACE, suggesting potential improvement of procedural outcomes.

W5A-SPIR-8 Efficacy and Safety of DEB-TACE Plus Idarubicin Versus Epirubicin for Unresectable Hepatocellular Carcinoma

Participants
Jiaping Li, Guangzhou, China (*Presenter*) Nothing to Disclose

PURPOSE

Drug-eluting beads transarterial chemoembolization (DEB-TACE) is one of the standard treatments for unresectable hepatocellular carcinoma (HCC), while the efficacy of epirubicin-loaded DEB-TACE remains unsatisfactory. Recent studies indicated idarubicin's remarkable effect on HCC. This study aimed to compare effectiveness and safety between idarubicin and epirubicin as the chemotherapeutic agent in DEB-TACE for unresectable HCC.

METHODS AND MATERIALS

This study included patients with unresectable HCC from January 2019 to May 2020 who received idarubicin-loaded DEB-TACE (IT group, n=111) or epirubicin-loaded DEB-TACE (ET group, n=117). Overall survival (OS), progression-free survival (PFS), local response and adverse events (AEs) were compared between the two groups.

RESULTS

Altogether 228 (55±12 years old, 203 men) consecutive cases were recruited. OS rates at 6 months were 91.6% and 60.8% in IT and ET groups; at 12 months, 68.4% and 42.8%. Median PFS rates were 7.9 and 2.6 months in IT and ET groups ($P<0.001$). Platelet count (OS: HR=0.45, PFS: HR=0.60), portal vein tumor thrombus (OS: HR=1.68, PFS: HR=1.91), and idarubicin treatment (OS: HR=3.60, PFS: HR=2.66) were independent predictors of OS and PFS (all $P<0.05$). Subgroup analysis suggested that ET group was superior to IT group in the subgroup with tumor size >10 cm (OS: HR=5.33, P=0.002; PFS: HR=2.60, P=0.004). AEs were consistent in both groups, and there were no Grade 3 or 4 adverse events.

CONCLUSION

s Idarubicin is a more effective and safer chemotherapeutic agent in DEB-TACE for the treatment of unresectable HCC.

CLINICAL RELEVANCE/APPLICATION

1.Idarubicin-loaded DEB-TACE is well-tolerated and safe for unresectable HCC.2.Idarubicin-loaded DEB-TACE is superior to doxorubicin-loaded DEB-TACE in survival improvement.3.Idarubicin-loaded DEB-TACE might be a new therapeutic option for

unresectable HCC.

Percutaneous CT/MRI-US Fusion System Guided Radiofrequency Ablation of Hepatocellular Carcinoma in Difficult Locations: The Feasibility Rate and Mid-term Outcome

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - IR DPS

Participants
Jae Hyun Kim, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the feasibility rate and the mid-term outcomes of CT/MRI-US fusion system guided radiofrequency ablation (RFA) of hepatocellular carcinomas (HCCs) in difficult locations and to compare the results with non-difficult HCCs.

METHODS AND MATERIALS

For this single-center retrospective study, from April 2019 to April 2020, a total of 533 patients with 572 HCCs were referred for CT/MRI-US fusion system guided RFA. The radiologic reports of 533 RFA planning US were reviewed in terms of the feasibility rate. The difficult locations were defined as follows: tumors located 1) = 5 mm from major vessels or bile ducts; 2) = 5 mm from diaphragm, colon, stomach, or right kidney; 3) = 1cm from pericardium. We calculated cumulative incidences of local tumor progression (LTP) by using Kaplan-Meier method between patients with HCCs in difficult locations and patients with non-difficult HCCs. LTP rates between two groups were compared by the chi-squared test. The patients with less than three months follow-up were excluded from these analyses.

RESULTS

In 499 of 533 (93.6%) RFA planning US, percutaneous RFA of HCC was feasible. Among 499 HCC patients (mean tumor size=15.8 mm ± 0.60) who were feasible for RFA, 261 patients (52.3%) had at least one HCC with difficult location. Of the 499 patients, 10 patients had less than three months follow-up. During the median follow-up period of 28.5 months (range, 3.7-37.3 months), there was no significant difference in LTP rates between patients with difficult HCCs (n=251) and patients with non-difficult HCCs (n=238) (6.0% [15/251] vs. 6.3% [15/238]; P=0.881). The 1- and 2-year estimated cumulative incidences of LTP were 3.7% and 5.9% in patients with difficult HCCs; and 2.6% and 5.9% in patients with non-difficult HCCs.

CONCLUSION

s HCCs in difficult locations for RFA could be treated effectively with CT/MRI-US fusion system guided RFA, and there was no significant difference in LTP rates between patients with difficult HCCs and patients with non-difficult HCCs.

CLINICAL RELEVANCE/APPLICATION

CT/MRI-US fusion system guided RFA could increase the feasibility rate and clinical outcomes of HCCs in difficult locations.

Percutaneous Cryoablation for Extra-Abdominal Desmoid Tumors: A Systematic Review

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - IR DPS

Participants
Tushar Garg, MD, Baltimore, MD (*Presenter*) Conference Travel, Siemens Healthineers

PURPOSE

To systematically review the literature published on percutaneous cryoablation for the treatment of extra-abdominal desmoid (EAD) tumor and assess its safety and efficacy.

METHODS AND MATERIALS

Using three databases, a systematic review was performed following Preferred Reporting Items for Systematic Reviews and Meta-analyses (PRISMA) guidelines. The search strategy used was "cryo*"[All Fields] AND ("fibromatosis, aggressive"[MeSH Terms] OR ("fibromatosis"[All Fields] AND "aggressive"[All Fields]) OR "aggressive fibromatosis"[All Fields] OR "desmoid"[All Fields] OR "desmoids"[All Fields]). From all the articles the type of study, mean age of patients, number of patients, number of EAD tumor, EAD tumor size before cryoablation, follow-up characteristics, treatment results, and complications were recorded in Microsoft Excel and analyzed using IBM SPSS software (Armonk, NY).

RESULTS

A total of ten studies with eight retrospective chart reviews and two prospective studies were included in the final analysis. A total of 219 patients were enrolled between ten studies and included 247 EAD tumors. The mean age of patients in the studies ranged from 24.2 to 41 years and the tumour volume ranged from 38.6 cm3 to 258.6 cm3. A total of 284 procedures were performed with 79 (36.07%) patients undergoing cryoablation as the primary procedure. The mean imaging follow-up ranged from 11.3 to 53.7 months and was done with either CT or MRI. Complete response was seen in 74 (35.9%) tumors, partial response in 60 (32.25%) tumors, and disease progression or recurrence in 47 (21.86%) tumors. 91.3% (138) patients had symptoms prior to cryoablation due to EAD tumor and 88.4% (122) patients showed improvement in symptoms after the procedure. Only 17.82% of procedures were associated with complications with an even lower incidence of serious complications.

CONCLUSION

s Current data from the studies show that cryoablation is safe and well-tolerated in select patients with EAD tumors. Combining open surgery with an image-guided approach can reduce adverse events, but further evaluation of the effect of this approach on treatment outcomes is needed. .

CLINICAL RELEVANCE/APPLICATION

Prospective investigations with long-term follow-up are required to further clarify the efficacy and safety profile of cryoablation and further establish its place in the treatment of EAD tumors

An Investigation on Clinical Usefulness of Motion Compensation of Cone-beam Computed Tomography for Trans-arterial Chemoembolization

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - IR DPS

Participants
JANG SOON HWANG, (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the effect of a motion artifact correction algorithm (MACA) on C-arm computed tomography (CT) during transarterial chemoembolization (TACE) for hepatic malignancies.

METHODS AND MATERIALS

Among 769 patients who underwent TACE in a dedicated angioroom from June 2020 to March 2021, 42 patients with identifiable motion artifacts on their single C-arm CT scans were retrospectively evaluated. The image qualities of the native and motion-corrected data were compared using both qualitative and quantitative methods. The maximum intensity, sharpness, and diameter of the five segmental hepatic arteries were measured quantitatively using software. The overall quality of maximum intensity projection (MIP) images and conspicuity of tumor-supplying arteries were qualitatively graded by two independent readers. Paired t-tests and Wilcoxon signed-rank tests were used to compare the quantitative and qualitative parameters of native and motion corrected image sets. Inter-reader agreements of the qualitative measurements were addressed using a quadratic weighted kappa test.

RESULTS

The mean maximum intensity and sharpness of the hepatic arteries increased from 2792.01 ± 451.36 HU to 3148.40 ± 594.46 HU and from 0.31 ± 0.02 /mm to 0.34 ± 0.02 /mm, respectively, using MACA ($p < 0.001$ and $p < 0.001$, respectively). In the same line, MACA decreased the mean diameter from 2.02 ± 0.27 mm to 1.78 ± 0.26 mm ($p < 0.001$), suggesting improved vessel conspicuity with less blurred contours by motion compensation. With a regard to the qualitative analyses, inter-reader agreement was substantially beyond chance in both MIP images (weighted ?, 0.818; 95% confidence interval, 0.771-0.866) and tumor-supplying artery (weighted ?, .810; 95% confidence interval, 0.759 - 0.861) evaluation. The overall quality of the MIP images and conspicuity of the tumor-supplying artery were enhanced from 2.5-point to 3.0-point and the from 3.0-point to 4.0-point by MACA ($p < 0.001$ and $p < 0.001$, respectively).

CONCLUSION

s MACA significantly improved both quantitative and qualitative image quality in patients with hepatic malignancies treated with TACE.

CLINICAL RELEVANCE/APPLICATION

A motion artifact correction algorithm can improve the quality of C-arm CT images degraded by motion artifact in patients treated with TACE, suggesting potential improvement of procedural outcomes.

Efficacy and Safety of DEB-TACE Plus Idarubicin Versus Epirubicin for Unresectable Hepatocellular Carcinoma

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - IR DPS

Participants
Jiaping Li, Guangzhou, China (*Presenter*) Nothing to Disclose

PURPOSE

Drug-eluting beads transarterial chemoembolization (DEB-TACE) is one of the standard treatments for unresectable hepatocellular carcinoma (HCC), while the efficacy of epirubicin-loaded DEB-TACE remains unsatisfactory. Recent studies indicated idarubicin's remarkable effect on HCC. This study aimed to compare effectiveness and safety between idarubicin and epirubicin as the chemotherapeutic agent in DEB-TACE for unresectable HCC.

METHODS AND MATERIALS

This study included patients with unresectable HCC from January 2019 to May 2020 who received idarubicin-loaded DEB-TACE (IT group, n=111) or epirubicin-loaded DEB-TACE (ET group, n=117). Overall survival (OS), progression-free survival (PFS), local response and adverse events (AEs) were compared between the two groups.

RESULTS

Altogether 228 (55±12 years old, 203 men) consecutive cases were recruited. OS rates at 6 months were 91.6% and 60.8% in IT and ET groups; at 12 months, 68.4% and 42.8%. Median PFS rates were 7.9 and 2.6 months in IT and ET groups (P<0.001). Platelet count (OS: HR=0.45, PFS: HR=0.60), portal vein tumor thrombus (OS: HR=1.68, PFS: HR=1.91), and idarubicin treatment (OS: HR=3.60, PFS: HR=2.66) were independent predictors of OS and PFS (all P<0.05). Subgroup analysis suggested that ET group was superior to IT group in the subgroup with tumor size >10 cm (OS: HR=5.33, P=0.002; PFS: HR=2.60, P=0.004). AEs were consistent in both groups, and there were no Grade 3 or 4 adverse events.

CONCLUSION

s Idarubicin is a more effective and safer chemotherapeutic agent in DEB-TACE for the treatment of unresectable HCC.

CLINICAL RELEVANCE/APPLICATION

1.Idarubicin-loaded DEB-TACE is well-tolerated and safe for unresectable HCC.2.Idarubicin-loaded DEB-TACE is superior to doxorubicin-loaded DEB-TACE in survival improvement.3.Idarubicin-loaded DEB-TACE might be a new therapeutic option for unresectable HCC.

Musculoskeletal Wednesday Poster Discussions - A

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - MK DPS

Sub-Events

W5A-SPMK-1 Natural History of Progression of Gluteal Tendon Tears Using MRI

Participants
Zachary Pryor, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To identify imaging features predictive of progression of gluteal tendinopathy to guide clinicians on optimal period of intervention.

METHODS AND MATERIALS

Noncontrast MRI hip/bony pelvis exams at 1.5T were retrospectively reviewed between 2003-2021 on patients >40 years old. Patients meeting inclusion criteria had two MRIs performed >6 months and <10 years apart. Patients were excluded for prior surgery, trauma, osteonecrosis, malignancy, or complete gluteal tear on initial imaging. Axial T2 FS and coronal T1 and STIR sequences were used to grade gluteus medius pathology as follows: tendinosis, low-grade partial thickness (PT) tear, high-grade PT tear, complete tear. Greater trochanteric bursitis was graded as none, mild, moderate, severe. Muscle atrophy on coronal T1 weighted sequence was categorized by Goutallier classification. Tensor fasciae latae angle (TFLA) was calculated between the anterior superior iliac spine, greater trochanter and TFL. Progression of tendon pathology on subsequent exam was assessed and statistical analysis performed.

RESULTS

45 hips met inclusion criteria for the study, 27% of which were male and with a mean age of 67.8 ± 10.8. The mean interval between the two MRI exams was 32.3 ± 20.7 months. 19/45 patients presented with low-grade PT tears, of which 10 progressed to high-grade on subsequent exam. The proportion of progression in patients presenting with low-grade PT tearing was greater than those with either tendinosis or high-grade tearing (p=0.02). Degree of bursitis on initial MRI was associated with tendinopathy progression (p=0.036). Patients with TFLA <162o had higher rate of tendinopathy progression (p=0.0224).

CONCLUSION

s Gluteus medius tendinopathy is more likely to progress when initially present with concomitant greater trochanteric bursitis and narrowed TFLA, which may contribute to extrinsic compressive force.

CLINICAL RELEVANCE/APPLICATION

Special attention recommended to the presence of low-grade PT tears and hips experiencing greater extrinsic compressive forces as these were more likely to progress on subsequent exam.

W5A-SPMK-3 Impact of Photon-counting-detector CT on Radiation Dose Reduction for Femoroacetabular Impingement Evaluation

Participants
Dennis Adaaquah, MD, Rochester, MN (*Presenter*) Nothing to Disclose

PURPOSE

To demonstrate feasibility of ultra-high-resolution (UHR) low-dose photon-counting detector (PCD) CT imaging of the pelvis for radiologic evaluation and surgical planning for femoroacetabular impingement (FAI).

METHODS AND MATERIALS

Patients who underwent a standard dose energy-integrating detector (EID) CT (SOMATOM Edge or Force, Siemens Healthcare) of the pelvis for FAI evaluation were recruited to undergo the same exam on a PCD-CT system (NAEOTOM Alpha, Siemens) in UHR mode. PCD-CT exams were acquired at either the same dose as the EID-CT or 50% dose. Simulated 50% dose EID-CT images were generated with noise insertion algorithms, for a total of 3 image sets per patient. Matched multiplanar reconstructions (Br62/64, 1 mm thickness) were generated for both the EID-CT and the PCD-CT exams. Two fellowship-trained musculoskeletal radiologists independently evaluated randomized EID-CT and PCD-CT images, blinded to CT system and radiation dose. Alpha angle and acetabular version measurements were computed for each image. Radiologist perception of image quality based on image noise, artifacts, and bone cortex visualization as well as confidence in non-FAI pathology was rated on 4-point scale (3 = adequate for diagnostic task). Preference tests of (1) PCD-CT at standard dose, (2) PCD-CT at 50% dose, and (3) EID-CT at 50% dose relative to standard dose EID-CT were performed using Wilcoxon Rank test.

RESULTS

20 patients underwent pelvis CTs (mean CTDIvol = 4.5 mGy (standard dose EID-CT, N=20); 4.0 mGy (standard dose PCD-CT,

N=10); and 2.6 mGy (half-dose PCD-CT, N=10)). Three patients had bilateral exams that were independently reviewed, for a total of 69 unique image sets. Standard dose EID-CT images were consistently scored as adequate for diagnostic task in all categories (range 2.8-2.9). Simulated half-dose EID-CT images received significantly lower average scores in all categories (range 1.8-2.3, $p<0.001$). Conversely, PCD-CT images at standard dose were scored significantly higher than the reference EID-CT (range 3.4-4, $p<0.05$). Finally, half-dose PCD-CT images were scored significantly higher than the standard EID-CT for noise and cortex visualization ($p<0.05$), and equivalent for artifact and visualization of non-FAI pathology ($p>0.05$).

CONCLUSION

s UHR-PCD-CT at matched radiation dose is superior to EID-CT for FAI evaluation. PCD-CT enables 50% radiation dose reduction compared to EID while still being diagnostically adequate for FAI evaluation.

CLINICAL RELEVANCE/APPLICATION

Evaluation of FAI tends to involve young patients. The lower noise intrinsic of UHR-PCD-CT compared to EID-CT can be leveraged for 50% radiation dose reduction for FAI imaging, without compromising image quality and diagnostic certainty.

W5A-SPMS

Multisystem Wednesday Poster Discussion - A

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - MS DPS

Sub-Events

W5A-SPMS-1 Development and Validation of CTbased Radiomics Model of PET-negative Residual CT Masses for The Prediction of Relapsefree Survival in Lymphoma Patients Showing Complete Metabolic Response

Participants
Hyun Jin Kim, MD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

PET-negative residual CT masses (PnRCMs) are usually dismissed as nonviable post-treatment lesions in lymphoma patients showing complete metabolic response (CMR). We aimed to develop and validate CT-based radiomics score of PnRCM for predicting relapse-free survival (RFS) in lymphoma patients showing CMR after first line chemotherapy.

METHODS AND MATERIALS

A total 247 patients who showed CMR after completion of first line chemotherapy for PET-avid lymphomas were recruited for model development. Patients with PnRCM were selected in accordance with the Lugano criteria, and 3-D segmentation was done on contrast-enhanced CT. Radiomics features for masses were extracted and radiomics scores were constructed using the Least absolute shrinkage and selection operator analysis. Cox regression analysis was performed with radiomics and clinical parameters (IPI score, age, aggressiveness of lymphoma, and treatment including rituximab). The efficiency of the model was evaluated using area under the curve (AUC). For validation of the model, 154 patients with PnRCM from an outside hospital were recruited and analyzed in the same way.

RESULTS

Among the included patients, 76 patients (30.1%) had PnRCM in the development cohort. Kaplan-Meier analysis showed that patients with PnRCM had significantly shorter RFS (p=0.009) than those without PnRCM. In Kaplan-Meier analysis using the cutoff value generated by maximally selected rank statistics, high radiomics score group showed significantly shorter RFS (p=0.0016). Multivariate Cox regression analysis also showed that IPI score (hazard ratio [HR]=0.249; p=0.006), treatment including rituximab (HR=3.517, 5.193; p= 0.007, 0.006) and radiomics score (HR=3.047; p=0.002) were related factors for RFS. In estimating RFS, the radiomics model and combined model showed an AUC of 0.74 and 0.80, respectively. In the validation cohort, the radiomics model and the combined model showed an AUC of 0.73 and 0.82 respectively.

CONCLUSION

s The combined model that incorporated both clinical parameters and CT based radiomics score showed good performance in predicting recurrence in lymphoma patients with PnRCM.

CLINICAL RELEVANCE/APPLICATION

If the CT-based radiomics model can sensitively detect PnRCM with a high probability of relapse, it will be helpful in determining a patient's treatment strategy.

W5A-SPNMMI-1 Application of Machine Learning Approach Using Clinical and 18F-FDG-PET-based Radiomic Features to Predict Prognosis in Patients with Laryngeal Cancer

Participants
Masatoyo Nakajo, MD, PhD, Kagoshima, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Laryngeal cancer is one of the most common head and neck cancer. Even with careful treatment, advanced stage disease (T-stage 3-4 tumors) has a significantly worse survival with 3-yr disease specific survival around 50%. Thus, accurate diagnostic methods to predict tumor aggressiveness are needed for pretreatment risk stratification. The purpose of this study was to examine whether the machine learning (ML) approach using 18F-FDG-PET-based radiomic features is useful for predicting prognosis in patients with laryngeal cancer.

METHODS AND MATERIALS

This retrospective study included 49 patients with laryngeal cancer who underwent 18F-FDG-PET/CT before treatment. Seven clinical (age, sex, T-stage, N-stage, M-stage, UICC stage, and treatment) and 40 PET-based radiomic features were used to predict disease progression using six different ML algorithms (random forest, neural network, k-nearest neighbors, naïve Bayes, logistic regression, and support vector machine) with a ten-fold cross-validation and stratified sampling method. Each ML algorithm calculated the probability for disease progression. The AUCs were calculated to compare the predictive performances between the conventional SUV-related parameters (SUVmax, MTV, TLG) and the ML algorithms. Survival curves were drawn using the Kaplan-Meier method, and the significance of difference between survival curves was tested using the log-rank test.

RESULTS

Of 49 patients, 17 had disease progression. On the ROC analysis for conventional SUV-related parameters, the AUC for predicting progression was 0.64 for SUVmax, 0.65 for MTV and 0.72 for TLG, respectively. Among 6 ML algorithms, the naïve Bayes model was the best performing classifier with highest AUC of 0.83. The AUC of this naive Bayes model was significantly higher than that of each conventional SUV-related parameter ($p<0.05$, each). In the naive Bayes model, 5-year PFS was significantly higher in predicted non-progression than predicted progression (83.7% vs. 33.5%, $p < 0.001$).

CONCLUSION

s The ML approach using clinical and pretreatment 18F-FDG-PET-based radiomic features may be useful for predicting tumor progression in patients with laryngeal cancer.

CLINICAL RELEVANCE/APPLICATION

The ML approach using clinical and 18F-FDG-PET-based radiomic features may be more useful than SUV-related parameters for predicting tumor progression in patients with laryngeal cancer.

W5A-SPNMMI-2 Fibrin-Targeting Molecular MRI in Inflammatory CNS Disorders

Participants
Johannes Lohmeier, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Fibrin deposition is a fundamental pathophysiological event in the inflammatory component of various CNS disorders, such as multiple sclerosis (MS) or Alzheimer's disease. Beyond its traditional role in coagulation, fibrin elicits immunoinflammatory changes with oxidative-stress response and activation of CNS-resident/peripheral immune-cells contributing to CNS injury. To investigate if CNS-fibrin deposition can be determined using molecular MRI.

METHODS AND MATERIALS

Specificity and efficacy of a peptide-conjugated Gd-based molecular MRI probe (EP2104-R) to visualise and quantify CNS-fibrin deposition were evaluated. Probe efficacy to specifically target CNS-fibrin deposition in murine adoptive-transfer experimental autoimmune encephalomyelitis (EAE), a preclinical model for MS (n = 12), was assessed. Findings were validated using IHC and LA-

ICP MS. Deposition of fibrin in neuroinflammatory conditions was investigated and its diagnostic capacity for disease staging and monitoring as well as quantification of immunoinflammatory response was determined. Results were compared using t-tests (two groups) or one-way ANOVA with multiple comparisons test. Linear regression was used to model the relationship between variables.

RESULTS

For the first time (to our knowledge), CNS-fibrin deposition was visualised and quantified in vivo using molecular imaging. Signal enhancement was apparent in EAE lesions even 12 h after administration of EP2104-R due to targeted binding (M ± SD, 1.07 ± 0.10 (baseline) vs. 0.73 ± 0.09 (EP2104-R), $p = .008$), which could be inhibited with an MRI-silent analogue (M ± SD, 0.60 ± 0.14 (EP2104-R) vs. 0.96 ± 0.13 (EP2104-La), $p = .006$). CNS fibrin deposition corresponded to immunoinflammatory activity ($R2 = 0.85$, $p < .001$) and disability ($R2 = 0.81$, $p < .001$) in a model for MS, which suggests a clinical role for staging and monitoring. Additionally, EP2104-R showed substantially higher SNR (M ± SD, 6.6 ± 1 (EP2104-R) vs. 2.7 ± 0.4 (gadobutrol), $p = .004$) than clinically used contrast media, which increases sensitivity for lesion detection.

CONCLUSION

s Molecular imaging of CNS-fibrin deposition provides an imaging biomarker for inflammatory CNS pathology, which corresponds to pathophysiological ECM remodelling and disease activity, and yields high signal-to-noise ratio, which can improve diagnostic neuroimaging across several neurological diseases with variable degrees of barrier impairment.

CLINICAL RELEVANCE/APPLICATION

We proposed CNS-fibrin deposition as a non-invasive imaging biomarker for CNS pathology, which is sensitive to disease activity and acts as a surrogate for neuroinflammation and barrier impairment.

Application of Machine Learning Approach Using Clinical and 18F-FDG-PET-based Radiomic Features to Predict Prognosis in Patients with Laryngeal Cancer

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - NMMI DPS

Participants
Masatoyo Nakajo, MD, PhD, Kagoshima, Japan (*Presenter*) Nothing to Disclose

PURPOSE

Laryngeal cancer is one of the most common head and neck cancer. Even with careful treatment, advanced stage disease (T-stage 3-4 tumors) has a significantly worse survival with 3-yr disease specific survival around 50%. Thus, accurate diagnostic methods to predict tumor aggressiveness are needed for pretreatment risk stratification. The purpose of this study was to examine whether the machine learning (ML) approach using 18F-FDG-PET-based radiomic features is useful for predicting prognosis in patients with laryngeal cancer.

METHODS AND MATERIALS

This retrospective study included 49 patients with laryngeal cancer who underwent 18F-FDG-PET/CT before treatment. Seven clinical (age, sex, T-stage, N-stage, M-stage, UICC stage, and treatment) and 40 PET-based radiomic features were used to predict disease progression using six different ML algorithms (random forest, neural network, k-nearest neighbors, naïve Bayes, logistic regression, and support vector machine) with a ten-fold cross-validation and stratified sampling method. Each ML algorithm calculated the probability for disease progression. The AUCs were calculated to compare the predictive performances between the conventional SUV-related parameters (SUVmax, MTV, TLG) and the ML algorithms. Survival curves were drawn using the Kaplan-Meier method, and the significance of difference between survival curves was tested using the log-rank test.

RESULTS

Of 49 patients, 17 had disease progression. On the ROC analysis for conventional SUV-related parameters, the AUC for predicting progression was 0.64 for SUVmax, 0.65 for MTV and 0.72 for TLG, respectively. Among 6 ML algorithms, the naïve Bayes model was the best performing classifier with highest AUC of 0.83. The AUC of this naive Bayes model was significantly higher than that of each conventional SUV-related parameter ($p<0.05$, each). In the naive Bayes model, 5-year PFS was significantly higher in predicted non-progression than predicted progression (83.7% vs. 33.5%, $p < 0.001$).

CONCLUSION

s The ML approach using clinical and pretreatment 18F-FDG-PET-based radiomic features may be useful for predicting tumor progression in patients with laryngeal cancer.

CLINICAL RELEVANCE/APPLICATION

The ML approach using clinical and 18F-FDG-PET-based radiomic features may be more useful than SUV-related parameters for predicting tumor progression in patients with laryngeal cancer.

Fibrin-Targeting Molecular MRI in Inflammatory CNS Disorders

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - NMMI DPS

Participants
Johannes Lohmeier, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Fibrin deposition is a fundamental pathophysiological event in the inflammatory component of various CNS disorders, such as multiple sclerosis (MS) or Alzheimer's disease. Beyond its traditional role in coagulation, fibrin elicits immunoinflammatory changes with oxidative-stress response and activation of CNS-resident/peripheral immune-cells contributing to CNS injury. To investigate if CNS-fibrin deposition can be determined using molecular MRI.

METHODS AND MATERIALS

Specificity and efficacy of a peptide-conjugated Gd-based molecular MRI probe (EP2104-R) to visualise and quantify CNS-fibrin deposition were evaluated. Probe efficacy to specifically target CNS-fibrin deposition in murine adoptive-transfer experimental autoimmune encephalomyelitis (EAE), a preclinical model for MS (n = 12), was assessed. Findings were validated using IHC and LA-ICP MS. Deposition of fibrin in neuroinflammatory conditions was investigated and its diagnostic capacity for disease staging and monitoring as well as quantification of immunoinflammatory response was determined. Results were compared using t-tests (two groups) or one-way ANOVA with multiple comparisons test. Linear regression was used to model the relationship between variables.

RESULTS

For the first time (to our knowledge), CNS-fibrin deposition was visualised and quantified in vivo using molecular imaging. Signal enhancement was apparent in EAE lesions even 12 h after administration of EP2104-R due to targeted binding (M ± SD, 1.07 ± 0.10 (baseline) vs. 0.73 ± 0.09 (EP2104-R), p = .008), which could be inhibited with an MRI-silent analogue (M ± SD, 0.60 ± 0.14 (EP2104-R) vs. 0.96 ± 0.13 (EP2104-La), p = .006). CNS fibrin deposition corresponded to immunoinflammatory activity (R^2 = 0.85, p < .001) and disability (R^2 = 0.81, p < .001) in a model for MS, which suggests a clinical role for staging and monitoring. Additionally, EP2104-R showed substantially higher SNR (M ± SD, 6.6 ± 1 (EP2104-R) vs. 2.7 ± 0.4 (gadobutrol), p = .004) than clinically used contrast media, which increases sensitivity for lesion detection.

CONCLUSION

s Molecular imaging of CNS-fibrin deposition provides an imaging biomarker for inflammatory CNS pathology, which corresponds to pathophysiological ECM remodelling and disease activity, and yields high signal-to-noise ratio, which can improve diagnostic neuroimaging across several neurological diseases with variable degrees of barrier impairment.

CLINICAL RELEVANCE/APPLICATION

We proposed CNS-fibrin deposition as a non-invasive imaging biomarker for CNS pathology, which is sensitive to disease activity and acts as a surrogate for neuroinflammation and barrier impairment.

W5A-SPNPM-2 Impact of COVID-19 Pandemic on Imaging Workload in Radiology; A Case Study of MRI Service in an UK District General Hospital Trust With 1200 Bed Capacity

Participants
Chao Jin Ho, MBBCh, BSc, (*Presenter*) Nothing to Disclose

PURPOSE

The 2019 coronavirus disease (COVID-19) pandemic has been a global health issue with vast social-economical and human mortality impact. The first UK national lockdown was implemented in 23 March 2020 to curb the spread of COVID-19. This study aims to evaluate the impact of the COVID-19 pandemic on MRI volumes and reporting time by comparing MRI imaging volumes and reporting time before and during the COVID-19 pandemic.

METHODS AND MATERIALS

The scan volumes and reporting time of MRI scans performed in four different MRI sites in the Durham and Darlington hospital trust were retrospectively reviewed at three different time periods:1) pre-pandemic (March to June 2019 or P1)2) start of the COVID-19 pandemic (March to June 2020 or P2)3) second year of the COVID-19 pandemic (March to June 2021 or P3)Statistical differences in average monthly MRI scans and average MRI reporting time were compared with t test.

RESULTS

In P1, total MRI scans= 5628, average monthly scans= 1407, average reporting time= 4.56 days.In P2, total MRI scans= 4484, average monthly scans= 1121, average reporting time= 3.22 days.In P3, total MRI scans= 8412, average monthly scans= 2103, average reporting time= 3.69 days.MRI scans in P2 is 20.3% lower ($p<0.05$) than P1 and 46.7% lower ($p<0.01$) than P3. The average reporting time in P2 is 29.4% lower ($p<0.01$) than P1 and 12.7% lower ($p<0.02$) than P3.

CONCLUSION

s The COVID-19 Pandemic accounted for 20.3% decrease in MRI volumes and 29.4% decrease in MRI reporting time. MRI volumes in P3 has recovered with MRI scans 149% of the pre-pandemic volumes. Analysing MRI referral locations found 40.4% and 40.9% of P3 scans are from primary care and outpatients respectively.

CLINICAL RELEVANCE/APPLICATION

The trend in MRI volumes during the COVID-19 pandemic may be a reflection across radiology sites within and possibly outside of UK. The staggering increase in MRI referrals and imaging workload may have been a result of virtual clinical consultations, putting emphasis on imaging, accelerating throughput in Radiology. As 40.4% of MRI volumes in March to June 2021 were generated in primary care, we recommend educating primary care physicians to request appropriate imaging for sustainable delivery of high-quality imaging services. As the pandemic settles, it is important to monitor imaging workload and reporting time so as to plan and optimise future imaging services in Radiology.

W5A-SPNPM-3 Fallout and Benefits of the 21ST Century Cures Act: A Survey of Referring Providers

Participants
Shravan Sridhar, MD, MS, (*Presenter*) Nothing to Disclose

PURPOSE

The 21st Century Cures Act prohibits information blocking practices and mandates the timely release of radiology reports to patients. This study aims to investigate the impact of these practices on patients, clinicians, and clinical workflows.

METHODS AND MATERIALS

A prospective single-center quality improvement survey was administered by email to 313 providers from October 26, 2021 to November 17, 2021. Respondents who spend at least 20% clinical time at our healthcare system and 10% time on outpatient services were given the opportunity to complete an additional survey encompassing positive and negative effects of prohibition of information blocking practices following implementation. The survey questions were vetted by leadership with experience in survey design. Descriptive statistics were calculated.

RESULTS

Of 313 people offered the survey, 290 responded (93% response rate) across 40 different specialties and subspecialties. Following

implementation of the Cures Act, 172 respondents (59%) reported spending somewhat more or significantly more time discussing results with patients overall while only 7 respondents (2%) reported spending somewhat less or significantly less time. 232 (80%) of respondents reported somewhat more or significantly more time spent discussing results with patients outside of clinic visits but during regular work hours, and 227 (78%) reported spending more time outside of regular work hours. As a result of patients having access to radiology reports before meeting with their medical provider, 108 (42%), 121 (46%), 136 (52%), and 135 (52%) providers reported patients were sometimes or often better emotionally prepared to discuss results, more knowledgeable about their medical condition, better at asking questions, and better engaged in their medical decision making, respectively. 233 (86%), 239 (88%), 189 (72%), 89 (37%), and 16 (7%) providers indicated patients sometimes or often experienced anxiety, confusion, online research with incorrect interpretations, disruption to other life activities, and physical injury, respectively.

CONCLUSION

s The immediate release of radiology reports directly to patients has both positive and negative effects on patients and increases the time clinicians spend discussing results with patients outside regular working hours.

CLINICAL RELEVANCE/APPLICATION

Providers agree the release of radiology reports benefits patient knowledge and engagement during their clinical appointments. However, optimized institutional policies and processes/communication pathways are needed to emotionally support patients accessing their results immediately and providers who are subjected to increased patient communications beyond regular work hours.

W5A-SPNR-1 Enhancing Segmentation of Infarct and Penumbra Tissue on CT Perfusion Using Deep Learning

Participants
Mohammad Mahdi Shiraz Bhurwani, PhD, (*Presenter*) Stockholder, qas.ai

PURPOSE

An important imaging component used to triage patients with acute ischemic stroke (AIS) is the size and location of infarct and penumbra tissue. CT perfusion (CTP) software is typically employed and uses contralateral hemisphere relative thresholding to determine infarct and penumbra. This approach is not robust and is widely contested by the scientific community. Providing a more accurate segmentation of infarct and penumbra tissue would allow neuroradiologists to make the best decision regarding optimal clinical workflow. In this study we investigate if the use of a deep learning-based algorithm can improve the segmentation of infarct and penumbra tissue on CTP hemodynamic maps when compared with commercially available software.

METHODS AND MATERIALS

CTP and follow-up diffusion weighted imaging (DWI) scans were retrospectively collected for patients presenting with AIS. Patients in the infarct only sub-study received successful mechanical thrombectomy (mTICI 2b,2c,3) and the DWI within 48 hours of treatment to ensure halting of conversion of penumbra to infarct from time of CTP to DWI imaging. Patients in the infarct and penumbra sub-study received no treatment and the DWI imaging more than 48 hours after presentation to ensure conversion of all penumbra to infarct from time of CTP to DWI imaging. This resulted in 1920 and 1888 axial CTP map slices in the infarct, and infarct and penumbra sub-studies. Commercial CTP software (Olea Sphere 3.0 SP28) was used to generate cerebral blood flow, cerebral blood volume, mean transit time, time to peak, and delay time maps for each case. Deep learning-based algorithms were trained to segment infarct or infarct and penumbra using preprocessed CTP maps. Segmentation performance was evaluated using Dice coefficients (DC), and mean absolute volume errors (ml) (MAVE).

RESULTS

The trained algorithm segmented infarct tissue with a DC of 0.64 ± 0.03 (0.63,0.65), and MAVE of 4.91 ± 0.94 (4.5,5.32) ml. In comparison, the commercial software predicted infarct with a DC of 0.31 ± 0.17 (0.26,0.36) and MAVE of 9.77 ± 8.35 (7.12,12.42) ml. The algorithm was able to segment infarct and penumbra with a DC of 0.61 ± 0.04 (0.6,0.63), and MAVE of 6.51 ± 1.37 (5.91,7.11) ml. In comparison, the commercial software predicted infarct and penumbra with a DC of 0.3 ± 0.19 (0.25,0.35) and MAVE of 9.18 ± 7.55 (7.25,11.11) ml.

CONCLUSION

s Use of deep learning algorithms to segment infarct and penumbra volume is proven to be accurate and outperforms current contralateral hemisphere relative threshold methods. Such an algorithm can enhance the treatment selection for AIS patients.

CLINICAL RELEVANCE/APPLICATION

The enhanced identification of infarct and penumbra tissue would improve triaging of patients with AIS and could thus enhance patient outcome.

W5A-SPNR-10 Deep Learning-Based Differentiation of Atypical Parkinsonian Syndromes Using Susceptibility Weighted Images

Participants
Wonjune Choi, Pusan, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Atypical parkinsonian syndromes (APSs) such as progressive supranuclear palsy (PSP) and a parkinsonian variant of multiple system atrophy (MSA-P) show similar symptoms and signs as Parkinson's disease (PD), but additional symptoms with different rates of functional deterioration. Each parkinsonian syndrome has unique topographic pattern of iron accumulation, and susceptibility weighted imaging (SWI) is widely used to detect these specific patterns of localized iron concentration in the deep brain nuclei regions. In this work, therefore, we propose a novel framework for differentiating APS from PD in SWI using a deep learning (DL)-based approach with explainable AI.

METHODS AND MATERIALS

We obtained the T1-weighted (T1w) and SWI MRI scans of 33 MSA-P, 21 PSP, and 66 PD patients using protocols approved by the

IRB. First, bias-field correction and intensity normalization were applied. Second, the SWI volume was registered in the MNI space using the hybrid contrast (HC) images generated as a linear combination of T1w and SWI. To select the deep brain nuclei regions, we extracted 15 slices from 70 to 85 of the MNI space axial axis, and cropped each slice to the size of 120x100 with the center of the slice. Then, we used the pretrained ResNet152 model to classify each image into subtypes of APS. The model was implemented by minimizing the Binary-Cross-Entropy loss using Adam optimizer for a learning rate of 1e-4. Convergence was achieved using batch size of 16 for each 100 epochs. The model was evaluated with a 5-fold cross validation test by measuring the balanced accuracy (bAcc), sensitivity (Sen) and specificity (Spe). We also compared with the conventional machine learning (ML) methods such as quadratic discriminant analysis (QDA) and support vector machine (SVM). Finally, we used Gradient-weighted Class Activation Mapping (Grad-CAM) to highlight important regions (heatmap) used for differentiation of APS.

RESULTS

The proposed DL-based method achieved the performance with bACC of 0.9399, Sen of 0.9360 and Spe of 0.9439 for differentiation of MSA-P and PD; while QDA (SVM) achieved 0.8804 (0.8981), 0.8501 (0.9046), 0.9107 (0.8917). For MSA-P vs. PSP, the DL-based method achieved bAcc of 0.8522, Sen of 0.8483 and Spe of 0.8562 than QDA (SVM): 0.8380 (0.7862), 0.8561 (0.8802) and 0.8201 (0.6922). Heatmap from Grad-CAM shows that the prediction of the DL model was highly influenced by the putamen and globus pallidus regions.

CONCLUSION

s The proposed DL-based method differentiates APSs significantly better than the ML-based methods, and also holds promise for identifying regions impacted by APSs.

CLINICAL RELEVANCE/APPLICATION

The high classification accuracy of our explainable DL model may contribute to a reliable clinical diagnosis of PD and APS.

W5A-SPNR-11 Effect of different pre ASiR-V on image quality and radiation dose of energy spectrum CT: A Phantom Study

Participants
Yaoxing Ma, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the impact of different pre adaptative statistical iterative reconstruction - Veo (ASiR-V) level on image quality and radiation dose of spectral CT.

METHODS AND MATERIALS

A polypropylene cylindrical phantom(QSP Phantom dimension) with nine tubes containing different concentrations of iodine (0, 2.5, 5, 10, 20 mgI/ml) was scanned in gemstone spectral imaging (GSI) mode using fast kV switch (80/140 kV) ,the tube current is 485mA, the layer thickness is 1.25mm, the collimation width is 80mm, ,noise index (NI)5HU,pitch 0.992:1,dual energy CT (Revolution CT, GE Healthcare) . Three groups of pre-ASiR-V weight (30%,40%,50% increments) was used for spectral CT scanning. Eleven groups of images were selected from the scan center and five layers above and below. The area of ROI was 1 / 2-1 / 3 of the cross-sectional area of the phantom tube, and the CT value and SD value of 20% and 10% iodine and water membrane tube were measured. The CT dose index (CTDI) of ASiR-V spectral scan with different weights was recorded. The dose length product (DLP), CT value and noise (SD) of the tube were recorded. The DLP across three groups were analyzed by simple linear regression analysis CT value and noise (SD) , across three groups were analyzed by one-way ANOVA.

RESULTS

With the increase of pre-selected ASiR-V level, noise (SD) showed the SD value remains unchanged. There was significant difference in DLP among groups (7.95mSv, 6.87mSv,4.73mSv for 30%,40%,50%pre-ASiR-V, respectively. $P<0.05$). There were no significant differences in SD among groups (9.92±0.55(I20),10.51±0.56(I10),9.80±0.61(H2O), for 30% pre-ASiR-V ,10.04±0.44(I20),10.04±0.44(I10),10.01±0.37(H2O)40% pre-ASiR-V ,10.52±0.64(I20),10.12±0.34(I10),10.52±0.50(H2O),50% pre-ASiR-V , $F=2.130$, $p > 0.05$).

CONCLUSION

s Conclusion: ASiR-V does not affect the image quality of energy spectrum scanning (SD), and can significantly reduce the radiation dose (CTDI) while maintaining the image quality of energy spectrum scanning (SD).

CLINICAL RELEVANCE/APPLICATION

ASiR-V does not affect the image quality (SD) of energy spectrum scanning, and can significantly reduce the radiation dose (CTDI) while keeping the image quality (SD) of energy spectrum scanning unchanged. Correlation of clinical application: through the basic research of phantom, spectral CT scanning can provide the same image quality, increase the proportion of ASiR-V iterative algorithm and reduce the radiation dose. This study has guiding significance for the application of spectral CT scanning in different clinical scenes.

W5A-SPNR-12 Brain MRI volumetric machine learning model: A potential tool to differentiate Progressive Supranuclear Palsy from Parkinson's disease patients and healthy subjects.

Participants
Francisco Mendoza, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To develop a machine learning model to differentiate Progressive Supranuclear Palsy (PSP) from Parkinson's disease (PD) and healthy subjects (HS) using an automated volumetry of brain MRI, validate its performance, and determine the most relevant Volumes of Interest (VOIs).

METHODS AND MATERIALS

We retrospectively assessed a total of 141 patients with a clinical diagnosis of Parkinsonism paired by age and sex and with a group of HS (PSP n = 47, PD n = 68, HS=26) between January 2003 and April 2021 and analyzed their brain MRI. Patients without T1 high

resolution sequences (T1-MPRAGE) were excluded, leaving 83 patients (PSP n = 29, PD n = 54, HS n=26). We included different clinical subtypes of PSP: PSP-RS (n= 19), PSP-P (n= 5), PSP-PGF (n= 4), and PSP-F (n= 1). Using automatized SyngoviaBrainMorphometry software (Siemens), we obtained 109 VOIs for each subject, including absolute and normalized values. We developed a machine learning model based on multivariate feature selection and an extreme gradient boosting (XGB) vs. univariate feature selection and random forest (RF) to differentiate PSP from PD and HS. All subjects were randomly divided into training (85%) and validation (15%) data sets with the same proportions for each clinical group. The most relevant VOIs were obtained from the model, order by importance score (F-score; where 1.0 represents perfect precision and recall). Additionally, we assessed the diagnostic accuracy of each VOI using ROC curves.

RESULTS

The global diagnostic performance of the model to differentiate between the three groups was 70.6%. The diagnostic accuracy of the model to differentiate each group from the other was: PSP (88.2%), PD (70.6%), and HS (76.5%). The VOIs that presented higher importance scores were the mesencephalic normalized volume (0.068), frontal right white matter volume normalized and absolute (0.053), left hippocampus absolute volume (0.040), left globus pallidum absolute volume (0.036), right hippocampus normalized volume (0.035), right thalamus absolute volume (0.032), frontal right gray matter normalized volume (0.032), left deep white matter normalized volume (0.030) and right hippocampus absolute volume (0.028). The AUC to differentiate PSP from PD and/or HS was: for the mesencephalic normalized volume =0.87, the left globus pallidum absolute volume =0.72, for the left hippocampus absolute volume = 0.59, and the right hippocampus normalized volume= 0.57.

CONCLUSION

s The developed machine learning model using an automated volumetry of brain MRI showed accurate discrimination between PSP, PD, and HS.

CLINICAL RELEVANCE/APPLICATION

Automatized volumetric assessment of brain MRI is a helpful tool for differentiating Progressive Supranuclear Palsy from Parkinson's disease.

W5A-SPNR-13 Multimodal Brain Tumor Segmentation using Deep Convolutional Neural Networks

Participants
Rimjhim Agrawal, PhD, Bangalore, India (*Presenter*) Nothing to Disclose

PURPOSE

Brain tumours are one of the leading causes of death worldwide. As a result, it is critical to discover it as soon as possible. Numerous ways have been developed to forecast and segment the tumour. They do, however, have a number of drawbacks, including the requirement for specialised assistance, the lengthy run-time, and the selection of an appropriate feature extractor. To overcome these difficulties, we suggest a convolutional neural network-based technique for concurrently predicting and segmenting a cerebral tumour using multimodal structural magnetic resonance images (T1w, FLAIR and Post contrast T1w).

METHODS AND MATERIALS

We used mpMRI Brain Tumor Segmentation (BRATS 2021) dataset. For each scan annotation consists of 3 classes - Enhancing Tumor (ET) , Peritumoral Edematous Tissue (ED) and necrotic tumour core (NCR). Our Method was developed by training deep neural networks (DNN) using only 3 Modalities - T1w, FLAIR and Post contrast T1w for generating tumour segmentation masks.

RESULTS

In this study, training and validation was performed on 1251 mpMRI scans and we were able to achieve a mean dice score coefficient (DSC) of 0.89. Also, validation was performed for 50 scans with annotations obtained from an expert radiologist achieving a mean DSC of 0.86 and tumor core DSC of 0.89.

CONCLUSION

s The fully automated brain tumor segmentation method developed on a well-established benchmark (BraTS 2021) dataset demonstrated that it can provide both efficient and robust segmentation compared to manually obtained ground truth. Additionally, our method with only three modalities as input can achieve comparable results to the state-of-the-art methods with four modalities. The proposed method enables objective assessment for clinical tasks such as surgery pre-planning, tumor grade detection and post surgery monitoring.

CLINICAL RELEVANCE/APPLICATION

This research suggests accurate and quick segmentation using deep convolutional neural networks of different subregions of a tumour, and has crucial clinical implications in brain tumour diagnosis, prognosis, treatment and presurgical planning.

W5A-SPNR-16 A light-weight deep learning web app for rapid identification of poor-quality structural MRI scans: A multi-institutional study

Participants
Thomas Desilvio, Cleveland, OH (*Presenter*) Nothing to Disclose

PURPOSE

Screening and diagnosis of neurological disorders largely relies on T1-weighted (T1w) MRI. Presence of one or more artifacts can degrade MR image quality to the extent they are unusable for disease diagnosis, whether by machines or radiologists. Visual inspection and quality assessment of MRI scans to identify cases requiring exclusion or rescanning is often time-consuming and laborious. We present multi-institutional validation of a scalable, light-weight deep learning-based (DL) web-app for rapid identification of poor quality T1w brain MRI scans.

METHODS AND MATERIALS

We utilized publicly available cohorts from ABIDE-I (17 institutes, 1102 T1w MRIs, including 3 expert-reader quality ratings) and TCGA-GBM (5 institutes, 152 T1-POST MRIs). TCGA-GBM was internally evaluated by 3 radiologists to assign quality labels similar to ABIDE-I. Training cohort was curated from ABIDE-I (n=454, 15 institutions), where every scan was assigned "good quality

(GQ)/poor quality (PQ)" based on rating agreement between 2+ readers. Remaining ABIDE-I datasets were split into internal validation (V1, n=400) and external validation (V2, n=248, 2 institutions). TCGA-GBM was additionally used for external validation (V3). For V1-V3, "ground truth" labeling of scans as GQ/PQ was based on mean opinion score of raters. A mid-brain 3D sub-volume (with foreground identification) from each scan used as input to a 3D ResNet18 model, optimized to predict PQ scans via training cohort. Additionally, 64 quality measurements (QMs) from the publicly available MRIQC tool (quantifying SNR, intensity contrast, motion, entropy artifacts) were used to train a random forest classifier for identifying PQ scans. Hold-out evaluation of ResNet and QM models was performed in terms of accuracy of identifying PQ scans on V1-V3.

RESULTS

The ResNet DL model achieved accuracies of 0.89, 0.83, and 0.89 in V1, V2, and V3, respectively for identifying PQ scans. MRIQC-based QM models performed significantly worse with accuracies of 0.77 (V1; $p<0.001$), 0.75 (V2; $p<0.001$), and 0.76 (V3; $p<0.001$) in identifying PQ scans. The DL web-app took <1 min/MRI volume for classifying each scan as PQ or GQ.

CONCLUSION

s Our light-weight deep learning based web interface can enable rapid identification of poor-quality brain MRI scans, and offers improved performance compared to standard image quality measures.

CLINICAL RELEVANCE/APPLICATION

Rapid automated identification of poor-quality MRI scans could have significant implications for downstream machine learning analysis as well as radiology interpretation and disease diagnosis.

W5A-SPNR-18 Post-processing to improve accuracy of Deep Learning Algorithm for Intracranial Hemorrhage Detection: Our experience of introducing an analytical approach simulating Radiologist Reasoning

Participants
Anjali Agrawal, MD, Delhi, PA (*Presenter*) Nothing to Disclose

PURPOSE

Deep learning tools are being increasingly used to optimize radiologist efficiency in the emergency setting, however, overprediction and false positive (FP) results may be counterproductive. We investigated the value of additional post-processing refinements into the deep learning algorithm developed in our lab for the detection of intracranial hemorrhage (ICH) with the intention of introducing specific reasoning and logic similar to that applied by radiologists.

METHODS AND MATERIALS

A deep learning algorithm for ICH detection was developed using a fully convolutional neural network, U-NET with image segmentation and hemorrhage classification properties. Upon validation, several recurring FPs at specific locations posed a challenge in increasing overall accuracy to acceptable levels. Various new approaches were then developed to specifically address each type of FP. Deep learning models were used to decrease FPs instance-wise and slice-wise in calcification and artifact models respectively. Image processing and coding logic were used to decrease FPs in the region of basal ganglia, falx, dural sinus, volume averaging from dense calvaria, and FPs due to accentuated appearance of grey-white matter junction in older patients.

RESULTS

We analyzed 4512 studies of which 2036 were negative and 2476 were positive for intracranial hemorrhage sequentially using the ICH detection deep learning model, without and with post-processing algorithms. The results achieved without and with post-processing were sensitivity (recall) of 96.77% and 90.47%, specificity of 41.99% and 90.28%, precision of 66.98, 91.88%, F1 score of 79.17% and 91.17%, and Area Under Curve of 0.694 and 0.904 respectively.

CONCLUSION

s Postprocessing techniques brought about significant improvement in the model performance by reducing the number of false-positive results.

CLINICAL RELEVANCE/APPLICATION

Our research explores ways to improve the analytical capabilities of deep learning tools by using postprocessing techniques with the goal to develop a more optimal triage workflow in the emergency setting.

W5A-SPNR-19 Radiomics Analysis Distinguish Between Primary Central Nervous System Lymphoma, Glioblastoma, and Brain Metastasis

Participants
Murat AK, MD, Pittsburgh, PA (*Presenter*) Nothing to Disclose

PURPOSE

To investigative the diagnostic performance of radiomics-based machine learning in differentiating glioblastoma (GBM), primary central nervous system lymphoma (PCNSL) and brain metastasis (BM).

METHODS AND MATERIALS

We retrospectively identified 1075 patients from three institutions with untreated solitary, pathologically proven cases of PCNSL (133), GBM (433), and breast or lung BM (509). For each tumor, we segmented edema, contrast enhancement, necrosis, and contralateral white matter (cWM) volume of interest (VOI) for T2 FLAIR and T1 post-contrast sequences. A total of 205 texture features were extracted from each sequence's VOI including 10 histogram based first-order features and 195 second-order features using gray-level co-occurrence matrices. After feature normalization using cWM, we divided the 195 second level features by the volumes of each VOI to generate another 195 volume-independent features per VOI and 2,400 features per MRI. We performed feature selection with Least Absolute Shrinkage and Selection Operator (LASSO). We split the cohort into 70% training and 30% testing sets. We used XGBoost (eXtreme Gradient Boosting) algorithm to perform three-way classification and generate the radiomics model. The predictive performance of the models for classifying each tumor type against all others (i.e., BM versus PCNSL and GBM) was estimated using the receiver operating characteristic (ROC) curve, summarized as the area under the curve (AUC).

RESULTS

LASSO identified 216 independent features, of which 20 most relevant used for model building. Our three-classification model robustly differentiated ($p < 0.001$) between PCNSL (AUC 0.95), GBM (AUC 0.97), and BM (AUC 0.96) and achieved 88% accuracy. The model obtained 76.9% sensitivity and 98.2% specificity for PCNS prediction, 86% sensitivity and 94.7% specificity for the GBM prediction and 92.7% sensitivity 86.3% specificity for the BM prediction.

CONCLUSION

s This study presents radiomics-based signature that can successfully differentiate between PCNSL, GBM, and BM. Although further independent validation is warranted the proposed predictive radiomics-based signature is cost-effective, non-invasive and enable better patient stratification, management, and clinical decision-making

CLINICAL RELEVANCE/APPLICATION

A major challenge in the management of brain tumor is distinguishing tumor type as there are currently no reliable non-invasive biomarkers to predict them. Our data suggests that radiomics using MRI is an cost-effective and non-invasive approach to identify brain tumor type.

W5A-SPNR-2 Automated Lumbar Disc Herniation Grading Through AP-Diameter Measurement in MR Imaging

Participants
Li Zhang, PhD, Princeton, NJ (*Presenter*) Employee, Covera Health

PURPOSE

Lumbar disc herniation (LDH) is often diagnosed using MR, and automated AI pipelines are used to reduce variation in grading severity. A fully automated AI-powered pipeline was used to detect, localize, and segment LDH at each Functional Spinal Unit (FSU) level (L1-2 through L5-S1) and use the anterior-posterior diameter (APD) of the segmented LDH to grade severity.

METHODS AND MATERIALS

Sagittal T2 sequences of MR lumbar spine were collected from 589 studies. 2,872 FSU manually segmented voxel-wise as background - 0 (No segmentation), disc - 1, and herniated disc region - 2. The studies were randomly split into train-validation-test sets in a 75:10:15 ratio. A deep reinforcement model was trained to identify the L1-2 through L5-S1 disc centers. Associated FSUs were cropped to 8 x 8 x 5 cm then fed to a convolutional neural network. An Attention U-Net was trained to segment the images on a 2D slice with 2 adjacent slices provided to the left and right of the target slice. The APD was estimated by summing the voxels' resolution at the apex of the estimated LDH region. A severity is assigned based on this measurement (Normal: 0mm; Small: APD = 3mm; Moderate: 3mm < APD = 6mm; Large: 6mm < APD). If an APD measurement error misassigns the severity by 1-degree, we call it 1-degree error, 1-degree error includes misassignment between Normal and Small, Small and Moderate, Moderate and Large. Similarly, 2-degree error is defined as severity misassignment between Normal and Moderate, Small and Large.

RESULTS

The model achieves an RMSE in APD of 1.33 ± 1.33mm and an average ratio of predicted to ground truth APD of 1.14 ± 0.89 for the true positive predictions. The model accuracy is further evaluated by the assigned severities based on APD. The 1-degree misassignment is 34% where 47% of these are between normal and small and 37% are between small and moderate both with an RMSE of 1.8mm. These, however, are in general inconsequential, the clinical significant 2-degree severity classification error is only 4%.

CONCLUSION

s Segmentation of Lumbar MR has the advantage of providing visualization and location and automated measurement of LDH which can assist diagnosis and reduce interobserver variation.

CLINICAL RELEVANCE/APPLICATION

Automated detection, localization and measurement of LDH pipeline can provide precise, reproducible analysis of pathology which can be useful for quality analysis, enhancing efficiency of utilizing experts.

W5A-SPNR-3 Deep learning for classification of Cranial Ultrasound in Preterm Babies

Participants
Tahani Ahmad, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Cranial ultrasound (CUS) is widely used as a screening tool to assess brain injury in preterm infants. Severe abnormalities on CUS are known to be associated with Neurodevelopmental impairment (NDI). This study investigates the feasibility of using deep learning to identify abnormalities in CUS images collected from a preborn preterm cohort that are routinely clinically assessed for NDI. The objective is to train a model that can classify normal vs. abnormal imaging findings and assess its usability for computer-aided diagnosis that can have merit in daily practice as a complementary decision aid.

METHODS AND MATERIALS

This is a retrospective study of a cohort of very preterm infants born between January 2004 and Dec 2016 and admitted to the Neonatal Intensive Care Unit at IWK Health, Canada. The sample size includes images from 619 patients (4180 images) collected during 3-time points (first week, 6th week of age, and a term-equivalent age). At each point, 3 coronal images were selected at specific landmarks. Each image was anonymized. CUS pixels intensities are normalized and resized to a standard 224x224 pixel. Regions outside of the brain were masked and set to pixel intensity zero. A trained radiologist manually labeled each image as either normal or abnormal. The dataset is split into training/test sets (90:10 percent split). Due to the class imbalance in the dataset, the Area Under the Curve (AUC) was chosen as the metric of reference. The abnormal cases where the model very confidently predicted the image as abnormal were selected, then an approach called Gradcam was applied. In this approach, the saliency of each individual pixel is visualized. The original image has a heatmap overlaid on it, the areas with more red are what lead the model to make its prediction.

RESULTS

We tested different CNN architectures. The total number of normal images is 3531/4180, and the total number of images with abnormal findings is 649/4180. Preliminary results indicate an average of 0.794 AUC (0.757-0.83) using 10 bootstraps stratified sampling strategies using DensNet169

CONCLUSION

s This is a preliminary work to provide a tool to assist clinicians during early NDI assessment by classifying CUS into normal scans and scans with abnormal imaging features that can have merit in daily practice as a complimentary decision aid. Although the dataset is currently limited, early results are positive and likely to improve as more images are going to be included.

CLINICAL RELEVANCE/APPLICATION

Cranial ultrasounds to assess neurodevelopmental impairment is a challenging task subject to high variability. Computer-aided diagnosis tool might help reduce false positive and false negative rates.

W5A-SPNR-4 Prediction of Primary Tumor Entity of Brain Metastases Using Machine Learning based on Radiomic Features Derived from Routine MRI

Participants
Quirin Strotzer, MD, Regensburg, Germany (*Presenter*) Nothing to Disclose

PURPOSE

This study aims to determine the primary tumor entity of brain metastases using machine learning based on radiomic features obtained from routine MRI sequences.

METHODS AND MATERIALS

This multicenter project included 251 patients for whom non-standardized routine MRI sequences T1, T1CE, T2, and FLAIR (from various scanners, 1.5T and 3T) and histologic determination of the primary tumor were available. A preprocessing pipeline was set up using Python libraries, including co-registration, normalization, and automated tumor segmentation using a Convolutional Neural Network with U-shaped architecture. Radiomic features were extracted and selected with a LASSO regression. Metastases were grouped into five classes: the four most frequently occurring primary entities (adenocarcinoma of the lung, melanoma, breast cancer, colorectal cancer) and a fifth group including all less common primaries. Using a five-fold cross-validation scheme, machine learning classifiers were tested on the train/validation partition of the dataset (80%) to predict the primary tumor based on the radiomic features. The performance was evaluated using a holdout test set (20%).

RESULTS

A total of 728 brain metastases were individually segmented. For each metastasis, 3852 radiomic features were extracted. The LASSO regression identified 60 variables with the greatest impact on classification. An AdaBoost classifier yielded the best results for this five-class classification task on the holdout test set (accuracy: 0.601; area under the receiver operating characteristic curve: 0.854). A feature importance analysis showed that the most essential variables for the classifier were second-order statistics features derived from the contrast-enhanced T1-weighted sequences.

CONCLUSION

s Primary tumor entity prediction might be feasible via radiomic feature analysis of non-standardized routine MRI sequences. Further relevant read-outs such as oncogenic driver mutations could be within reach.

CLINICAL RELEVANCE/APPLICATION

Predicting the primary tumor of brain metastases using radiomic features derived from non-standardized routine MRI sequences would significantly enhance the diagnostic value of routine MRI scans and reduce morbidity from invasive biopsies.

W5A-SPNR-5 Accelerated Creation of a Glioma Database for Machine Learning Prediction Model Development using PACS-Integrated Tools

Participants
Victor Becerra, MD, Albany, NY (*Presenter*) Nothing to Disclose

PURPOSE

The creation of well-annotated imaging datasets is crucial for the development of accurate and reproducible machine learning (ML) algorithms. Although an increasing number of ML algorithms are being developed in the academic setting, many of them are created in research-specific software incompatible with the routine clinical workflow. Our purpose was to facilitate the creation of a large, annotated glioma database by implementing clinical PACS-integrated tools for image segmentation and radiomic feature extraction.

METHODS AND MATERIALS

Data from our institution's radiation oncology registry from 2012 to 2019 was used. Glioma images from these patients and the BRaTS 2021 challenge were segmented using a home-grown PACS-integrated (Visage Imaging, Inc) U-net algorithm. These were subsequently validated by a board-certified neuroradiologist. A home-grown PACS-integrated PyRadiomics feature extraction tool was then deployed on the annotated dataset.

RESULTS

Over the course of only 5 months, segmentations and annotations were completed in 595 patients (236 females, 359 males, with a mean age of 50.92 years). Grade distribution was as follows: 245 Grade 4, 52 Grade 3; 97 Grade 2; 26 Grade 1; 175 unknown. Molecular subtypes included IDH (87 mutated, 355 wild-type, 153 unknown), 1p/19q (65 deleted or co-deleted, 87 intact, 443 unknown), MGMT promotor (162 methylated, 70 partially methylated, 207 unmethylated, 156 unknown), EGFR (55 amplified, 121 not amplified, 419 unknown), ATRX (28 mutated, 130 retained, 437 unknown), Ki-67 (433 known, 162 unknown) and p53 (395 known, 200 unknown). To generate a geographically distinct validation set, metadata labels were created for imaging acquired outside our institution.

CONCLUSION

s Our PACS-integrated image annotation tools have allowed us to curate a large number of images in an accelerated manner that is

s Our PACS-integrated image annotation tools have allowed us to curate a large number of images in an accelerated manner that is compatible with the clinical workflow. On average, over 100 gliomas were annotated per month, thus establishing that these tools may be game-changing in the development of annotated imaging databases.

CLINICAL RELEVANCE/APPLICATION

The development of clinical PACS-integrated tools for data curation has the potential to facilitate and accelerate the development of large-scale well-annotated imaging datasets which can be used for algorithm development, radiomic feature extraction, among others.

W5A-SPNR-6 Multi-Scale Fusion 3D Convolutional Neural Networks Based on Attention Mechanism for Survival Prediction of Glioma Patients

Participants
Xuan Yu, (*Presenter*) Nothing to Disclose

PURPOSE

Due to the individual differences of different patients with glioma and individualized precision treatment, the survival time performance of different patients is quite different. Constructing a reliable survival prediction model and analyzing the MRIs of patients with glioma, further mining objective features from the images have extremely important clinical value for the prognosis of patients. we develop a multi-scale fusion 3D convolutional neural networks deep learning model based on attention mechanism to predict the survival time of glioma patients.

METHODS AND MATERIALS

MRIs from 270 cases were included, of which 207 from BraTS 2019 datasets and 63 from the private datasets of the hospital. Firstly, MRIs are preprocessed and a saliency-aware method is adopted to enhance the tumor region. Next we present a 3D convolutional structure to refine multiple scale characteristics of enhanced T1 Weighted imaging. Two crucial designs are shown in the model, one of which is fusing multi-scale features to explore level information in MRIs, and another is the attention gate make the model automatically focus on the crucial area in the images. Finally through the full connection layer to achieve the survival time analysis. The model includes prediction of short, medium, and long-term survival risk classification.

RESULTS

The cases were divided into low-risk group(SD>=450), medium-risk group(300>=SD>=450) and high-risk group(SD<=300) according to the Survival Days(SD). The ROC results show low-risk group AUC is always higher than medium-and high-risk group AUC in training, verification and test sets, which indicates low-risk group is easier to classify. The classification performance of medium-risk group and high-risk group are close. And the medium or high survival risk of patients is relative difficult to study due to the survival time is affected by more complex factors including the degree of tumor necrosis, the individual differences, whether has other disease and so on. By comparing with the popular 3D Unet model, sensitivity, specificity and AUC in our model displays relatively better performance.

CONCLUSION

s Our research demonstrates that appropriate MRIs data preprocessing and saliency-aware enhancement could better show the lesion characteristics of images. 3D convolutional structure preserves the important spatial features. Fusing different scale features is helpful to achieve higher classification accuracy, and the attention gate focuses more on the key areas in the MRIs. Our method is effective to mine MRIs deep features thus to achieve the goal of glioma patients' survival time prediction.

CLINICAL RELEVANCE/APPLICATION

This work provides some support for the operation, treatment and survival evaluation of patients with gliomas.

W5A-SPNR-7 Deep Learning of Dynamic Susceptibility Contrast Perfusion-weighted Imaging to Predict the Local Recurrence in Glioblastoma Patients

Participants
Roh-Eul Yoo, MD, PhD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To develop a deep learning model based on multiparametric MR imaging including dynamic susceptibility contrast perfusion-weighted imaging (DSC-PWI) that predict the local recurrence in patients with glioblastoma (GBM).

METHODS AND MATERIALS

This retrospective study included 213 consecutive GBM patients who underwent standard treatment between May 2010 and April 2021 and had both preoperative MR including DSC-PWI and 1 year follow-up 3T MRI. Patients were divided into the training set (172 patients [58 ± 14 years; 90 men] from 2010 to 2019) and test set (41 patients [56 ± 14 years; 23 men] from 2020 to 2021). Each patient was categorized as local recurrence or non-recurrence group with respect to the presence of local recurrence at 1 year after the diagnosis. Using the follow-up contrast-enhanced T1-weighted image (CE-T1WI) as the reference standard, the sites of local recurrence were annotated in a non-enhancing T2 hyperintense lesion on preoperative T2 FLAIR images. A deep learning model based on conventional MR and DSC-PWI was developed using nnU-Net. The deep learning model performance was validated on the test set. Diagnostic performance of the two models were compared using the McNemar test.

RESULTS

Training set and test set included 73 and 17 recurrence cases, respectively. In the test set, the multiparametric deep learning model using the combination of conventional MR and DSC-PWI showed a significantly higher sensitivity than the model based on conventional MRI alone in predicting the risk of recurrence (71% [12 of 17] vs. 29% [5 of 17], P = .031). The specificity of the model based on the combination of conventional MR and DSC-PWI did not significantly differ from that based on the conventional MRI alone (42% [10 of 24] vs. 58% [14 of 24], P = .34).

CONCLUSION

s A deep learning model based on multiparametric MR imaging including DSC-PWI can be used to predict the risk of local recurrence

in GBM patients.

CLINICAL RELEVANCE/APPLICATION

A deep learning model based on the combination of conventional and DSC-MRI could be used to stratify the risk of local recurrence in GBM patients and potentially to guide radiation treatment planning.

W5A-SPNR-8 From Accuracy to Consensus: Towards a New Paradigm for Assessing Model Performance

Participants
Simas Glinskis, Ithaca, NY (*Presenter*) Employee, Covera Health, Inc

PURPOSE

Machine learning model performance is typically analyzed through accuracy and other statistical measures contingent on consistent ground truth labels. This assumption falls apart with medical applications where considerable inter-reader variability is present due to variation in clinical interpretation. We designed a new statistical mechanism to assess model performance which incorporates multiple sources of truth.

METHODS AND MATERIALS

MRI lumbar spine studies from 207 patients, 1035 functional spine units, were collected and multi-annotated by 10 subspecialty radiologists. The data was partitioned into a ground truth set using labels from the most experienced radiologist available and a secondary set from the remaining experts. Deep learning based models for classification of disc herniation (DH), central canal stenosis (CCS), and nerve root compression (NRC) were used to generate severity predictions. Those predictions were split into two groups, where they agreed with ground truth (agree) and where they did not (disagree). Distributions of label consensus (LC) were generated for both groups by computing the average agreement between ground truth and external annotations for each prediction.

RESULTS

Accuracy of normal, mean agree LC and mean disagree LC are 87%, 97%, and 41% for NRC, 91%, 98% and 37% for CCS, and 74%, 92%, and 47% for DH, respectively. While accuracy is sensitive to the annotation that is selected as the gold standard, LC distributions generate a better measure of model performance which incorporates information from all of the experts. For the disagree set, there is low consensus which unfairly lowers accuracy and for the agree set we see very high consensus which the models are able to capture. Agree LC consistently outperforms accuracy and better represents the predictive power of the model when measured against a group of labels.

CONCLUSION

s We designed label consensus to analyze the performance of machine learning models by incorporating multi-annotated data. When there is inter-reader variability among experts conventional accuracy fails to incorporate information from the corpus of annotators and is sensitive to the choice of gold standard label while consensus is not.

CLINICAL RELEVANCE/APPLICATION

Our proposed label consensus evaluation provides a more effective way of assessing AI model performance in applications with significant inter-reader variability.

W5A-SPNR-1

Enhancing Segmentation of Infarct and Penumbra Tissue on CT Perfusion Using Deep Learning

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Mohammad Mahdi Shiraz Bhurwani, PhD, (*Presenter*) Stockholder, qas.ai

PURPOSE

An important imaging component used to triage patients with acute ischemic stroke (AIS) is the size and location of infarct and penumbra tissue. CT perfusion (CTP) software is typically employed and uses contralateral hemisphere relative thresholding to determine infarct and penumbra. This approach is not robust and is widely contested by the scientific community. Providing a more accurate segmentation of infarct and penumbra tissue would allow neuroradiologists to make the best decision regarding optimal clinical workflow. In this study we investigate if the use of a deep learning-based algorithm can improve the segmentation of infarct and penumbra tissue on CTP hemodynamic maps when compared with commercially available software.

METHODS AND MATERIALS

CTP and follow-up diffusion weighted imaging (DWI) scans were retrospectively collected for patients presenting with AIS. Patients in the infarct only sub-study received successful mechanical thrombectomy (mTICI 2b,2c,3) and the DWI within 48 hours of treatment to ensure halting of conversion of penumbra to infarct from time of CTP to DWI imaging. Patients in the infarct and penumbra sub-study received no treatment and the DWI imaging more than 48 hours after presentation to ensure conversion of all penumbra to infarct from time of CTP to DWI imaging. This resulted in 1920 and 1888 axial CTP map slices in the infarct, and infarct and penumbra sub-studies. Commercial CTP software (Olea Sphere 3.0 SP28) was used to generate cerebral blood flow, cerebral blood volume, mean transit time, time to peak, and delay time maps for each case. Deep learning-based algorithms were trained to segment infarct or infarct and penumbra using preprocessed CTP maps. Segmentation performance was evaluated using Dice coefficients (DC), and mean absolute volume errors (ml) (MAVE).

RESULTS

The trained algorithm segmented infarct tissue with a DC of 0.64 ± 0.03 (0.63,0.65), and MAVE of 4.91 ± 0.94 (4.5,5.32) ml. In comparison, the commercial software predicted infarct with a DC of 0.31 ± 0.17 (0.26,0.36) and MAVE of 9.77 ± 8.35 (7.12,12.42) ml. The algorithm was able to segment infarct and penumbra with a DC of 0.61 ± 0.04 (0.6,0.63), and MAVE of 6.51 ± 1.37 (5.91,7.11) ml. In comparison, the commercial software predicted infarct and penumbra with a DC of 0.3 ± 0.19 (0.25,0.35) and MAVE of 9.18 ± 7.55 (7.25,11.11) ml.

CONCLUSION

s Use of deep learning algorithms to segment infarct and penumbra volume is proven to be accurate and outperforms current contralateral hemisphere relative threshold methods. Such an algorithm can enhance the treatment selection for AIS patients.

CLINICAL RELEVANCE/APPLICATION

The enhanced identification of infarct and penumbra tissue would improve triaging of patients with AIS and could thus enhance patient outcome.

W5A-SPNR-10

Deep Learning-Based Differentiation of Atypical Parkinsonian Syndromes Using Susceptibility Weighted Images

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Wonjune Choi, Pusan, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Atypical parkinsonian syndromes (APSs) such as progressive supranuclear palsy (PSP) and a parkinsonian variant of multiple system atrophy (MSA-P) show similar symptoms and signs as Parkinson's disease (PD), but additional symptoms with different rates of functional deterioration. Each parkinsonian syndrome has unique topographic pattern of iron accumulation, and susceptibility weighted imaging (SWI) is widely used to detect these specific patterns of localized iron concentration in the deep brain nuclei regions. In this work, therefore, we propose a novel framework for differentiating APS from PD in SWI using a deep learning (DL)-based approach with explainable AI.

METHODS AND MATERIALS

We obtained the T1-weighted (T1w) and SWI MRI scans of 33 MSA-P, 21 PSP, and 66 PD patients using protocols approved by the IRB. First, bias-field correction and intensity normalization were applied. Second, the SWI volume was registered in the MNI space using the hybrid contrast (HC) images generated as a linear combination of T1w and SWI. To select the deep brain nuclei regions, we extracted 15 slices from 70 to 85 of the MNI space axial axis, and cropped each slice to the size of 120x100 with the center of the slice. Then, we used the pretrained ResNet152 model to classify each image into subtypes of APS. The model was implemented by minimizing the Binary-Cross-Entropy loss using Adam optimizer for a learning rate of 1e-4. Convergence was achieved using batch size of 16 for each 100 epochs. The model was evaluated with a 5-fold cross validation test by measuring the balanced accuracy (bAcc), sensitivity (Sen) and specificity (Spe). We also compared with the conventional machine learning (ML) methods such as quadratic discriminant analysis (QDA) and support vector machine (SVM). Finally, we used Gradient-weighted Class Activation Mapping (Grad-CAM) to highlight important regions (heatmap) used for differentiation of APS.

RESULTS

The proposed DL-based method achieved the performance with bACC of 0.9399, Sen of 0.9360 and Spe of 0.9439 for differentiation of MSA-P and PD; while QDA (SVM) achieved 0.8804 (0.8981), 0.8501 (0.9046), 0.9107 (0.8917). For MSA-P vs. PSP, the DL-based method achieved bAcc of 0.8522, Sen of 0.8483 and Spe of 0.8562 than QDA (SVM): 0.8380 (0.7862), 0.8561 (0.8802) and 0.8201 (0.6922). Heatmap from Grad-CAM shows that the prediction of the DL model was highly influenced by the putamen and globus pallidus regions.

CONCLUSION

s The proposed DL-based method differentiates APSs significantly better than the ML-based methods, and also holds promise for identifying regions impacted by APSs.

CLINICAL RELEVANCE/APPLICATION

The high classification accuracy of our explainable DL model may contribute to a reliable clinical diagnosis of PD and APS.

Effect of different pre ASiR-V on image quality and radiation dose of energy spectrum CT: A Phantom Study

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Yaoxing Ma, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the impact of different pre adaptative statistical iterative reconstruction - Veo (ASiR-V) level on image quality and radiation dose of spectral CT.

METHODS AND MATERIALS

A polypropylene cylindrical phantom(QSP Phantom dimension) with nine tubes containing different concentrations of iodine (0, 2.5, 5, 10, 20 mgI/ml) was scanned in gemstone spectral imaging (GSI) mode using fast kV switch (80/140 kV) ,the tube current is 485mA, the layer thickness is 1.25mm, the collimation width is 80mm, ,noise index (NI)5HU,pitch 0.992:1,dual energy CT (Revolution CT, GE Healthcare) . Three groups of pre-ASiR-V weight (30%,40%,50% increments) was used for spectral CT scanning. Eleven groups of images were selected from the scan center and five layers above and below. The area of ROI was 1 / 2-1 / 3 of the cross-sectional area of the phantom tube, and the CT value and SD value of 20% and 10% iodine and water membrane tube were measured. The CT dose index (CTDI) of ASiR-V spectral scan with different weights was recorded. The dose length product (DLP), CT value and noise (SD) of the tube were recorded. The DLP across three groups were analyzed by simple linear regression analysis CT value and noise (SD) , across three groups were analyzed by one-way ANOVA.

RESULTS

With the increase of pre-selected ASiR-V level, noise (SD) showed the SD value remains unchanged. There was significant difference in DLP among groups (7.95mSv, 6.87mSv,4.73mSv for 30%,40%,50%pre-ASiR-V, respectively. $P<0.05$). There were no significant differences in SD among groups (9.92±0.55(I20),10.51±0.56(I10),9.80±0.61(H2O), for 30% pre-ASiR-V ,10.04±0.44(I20),10.04±0.44(I10),10.01±0.37(H2O)40% pre-ASiR-V ,10.52±0.64(I20),10.12±0.34(I10),10.52±0.50(H2O),50% pre-ASiR-V , $F=2.130$, $p > 0.05$).

CONCLUSION

s Conclusion: ASiR-V does not affect the image quality of energy spectrum scanning (SD), and can significantly reduce the radiation dose (CTDI) while maintaining the image quality of energy spectrum scanning (SD).

CLINICAL RELEVANCE/APPLICATION

ASiR-V does not affect the image quality (SD) of energy spectrum scanning, and can significantly reduce the radiation dose (CTDI) while keeping the image quality (SD) of energy spectrum scanning unchanged. Correlation of clinical application: through the basic research of phantom, spectral CT scanning can provide the same image quality, increase the proportion of ASiR-V iterative algorithm and reduce the radiation dose. This study has guiding significance for the application of spectral CT scanning in different clinical scenes.

Brain MRI volumetric machine learning model: A potential tool to differentiate Progressive Supranuclear Palsy from Parkinson's disease patients and healthy subjects.

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Francisco Mendoza, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To develop a machine learning model to differentiate Progressive Supranuclear Palsy (PSP) from Parkinson's disease (PD) and healthy subjects (HS) using an automated volumetry of brain MRI, validate its performance, and determine the most relevant Volumes of Interest (VOIs).

METHODS AND MATERIALS

We retrospectively assessed a total of 141 patients with a clinical diagnosis of Parkinsonism paired by age and sex and with a group of HS (PSP n = 47, PD n = 68, HS=26) between January 2003 and April 2021 and analyzed their brain MRI. Patients without T1 high resolution sequences (T1-MPRAGE) were excluded, leaving 83 patients (PSP n = 29, PD n = 54, HS n=26). We included different clinical subtypes of PSP: PSP-RS (n= 19), PSP-P (n= 5), PSP-PGF (n= 4), and PSP-F (n= 1). Using automatized SyngoviaBrainMorphometry software (Siemens), we obtained 109 VOIs for each subject, including absolute and normalized values. We developed a machine learning model based on multivariate feature selection and an extreme gradient boosting (XGB) vs. univariate feature selection and random forest (RF) to differentiate PSP from PD and HS. All subjects were randomly divided into training (85%) and validation (15%) data sets with the same proportions for each clinical group. The most relevant VOIs were obtained from the model, order by importance score (F-score; where 1.0 represents perfect precision and recall). Additionally, we assessed the diagnostic accuracy of each VOI using ROC curves.

RESULTS

The global diagnostic performance of the model to differentiate between the three groups was 70.6%. The diagnostic accuracy of the model to differentiate each group from the other was: PSP (88.2%), PD (70.6%), and HS (76.5%). The VOIs that presented higher importance scores were the mesencephalic normalized volume (0.068), frontal right white matter volume normalized and absolute (0.053), left hippocampus absolute volume (0.040), left globus pallidum absolute volume (0.036), right hippocampus normalized volume (0.035), right thalamus absolute volume (0.032), frontal right gray matter normalized volume (0.032), left deep white matter normalized volume (0.030) and right hippocampus absolute volume (0.028). The AUC to differentiate PSP from PD and/or HS was: for the mesencephalic normalized volume =0.87, the left globus pallidum absolute volume =0.72, for the left hippocampus absolute volume = 0.59, and the right hippocampus normalized volume= 0.57.

CONCLUSION

s The developed machine learning model using an automated volumetry of brain MRI showed accurate discrimination between PSP, PD, and HS.

CLINICAL RELEVANCE/APPLICATION

Automatized volumetric assessment of brain MRI is a helpful tool for differentiating Progressive Supranuclear Palsy from Parkinson’s disease.

Multimodal Brain Tumor Segmentation using Deep Convolutional Neural Networks

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Rimjhim Agrawal, PhD, Bangalore, India (*Presenter*) Nothing to Disclose

PURPOSE

Brain tumours are one of the leading causes of death worldwide. As a result, it is critical to discover it as soon as possible. Numerous ways have been developed to forecast and segment the tumour. They do, however, have a number of drawbacks, including the requirement for specialised assistance, the lengthy run-time, and the selection of an appropriate feature extractor. To overcome these difficulties, we suggest a convolutional neural network-based technique for concurrently predicting and segmenting a cerebral tumour using multimodal structural magnetic resonance images (T1w, FLAIR and Post contrast T1w).

METHODS AND MATERIALS

We used mpMRI Brain Tumor Segmentation (BRATS 2021) dataset. For each scan annotation consists of 3 classes - Enhancing Tumor (ET) , Peritumoral Edematous Tissue (ED) and necrotic tumour core (NCR). Our Method was developed by training deep neural networks (DNN) using only 3 Modalities - T1w, FLAIR and Post contrast T1w for generating tumour segmentation masks.

RESULTS

In this study, training and validation was performed on 1251 mpMRI scans and we were able to achieve a mean dice score coefficient (DSC) of 0.89. Also, validation was performed for 50 scans with annotations obtained from an expert radiologist achieving a mean DSC of 0.86 and tumor core DSC of 0.89.

CONCLUSION

s The fully automated brain tumor segmentation method developed on a well-established benchmark (BraTS 2021) dataset demonstrated that it can provide both efficient and robust segmentation compared to manually obtained ground truth. Additionally, our method with only three modalities as input can achieve comparable results to the state-of-the-art methods with four modalities. The proposed method enables objective assessment for clinical tasks such as surgery pre-planning, tumor grade detection and post surgery monitoring.

CLINICAL RELEVANCE/APPLICATION

This research suggests accurate and quick segmentation using deep convolutional neural networks of different subregions of a tumour, and has crucial clinical implications in brain tumour diagnosis, prognosis, treatment and presurgical planning.

W5A-SPNR-16

A light-weight deep learning web app for rapid identification of poor-quality structural MRI scans: A multi-institutional study

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Thomas Desilvio, Cleveland, OH (*Presenter*) Nothing to Disclose

PURPOSE

Screening and diagnosis of neurological disorders largely relies on T1-weighted (T1w) MRI. Presence of one or more artifacts can degrade MR image quality to the extent they are unusable for disease diagnosis, whether by machines or radiologists. Visual inspection and quality assessment of MRI scans to identify cases requiring exclusion or rescanning is often time-consuming and laborious. We present multi-institutional validation of a scalable, light-weight deep learning-based (DL) web-app for rapid identification of poor quality T1w brain MRI scans.

METHODS AND MATERIALS

We utilized publicly available cohorts from ABIDE-I (17 institutes, 1102 T1w MRIs, including 3 expert-reader quality ratings) and TCGA-GBM (5 institutes, 152 T1-POST MRIs). TCGA-GBM was internally evaluated by 3 radiologists to assign quality labels similar to ABIDE-I. Training cohort was curated from ABIDE-I (n=454, 15 institutions), where every scan was assigned "good quality (GQ)/poor quality (PQ)" based on rating agreement between 2+ readers. Remaining ABIDE-I datasets were split into internal validation (V1, n=400) and external validation (V2, n=248, 2 institutions). TCGA-GBM was additionally used for external validation (V3). For V1-V3, "ground truth" labeling of scans as GQ/PQ was based on mean opinion score of raters. A mid-brain 3D sub-volume (with foreground identification) from each scan used as input to a 3D ResNet18 model, optimized to predict PQ scans via training cohort. Additionally, 64 quality measurements (QMs) from the publicly available MRIQC tool (quantifying SNR, intensity contrast, motion, entropy artifacts) were used to train a random forest classifier for identifying PQ scans. Hold-out evaluation of ResNet and QM models was performed in terms of accuracy of identifying PQ scans on V1-V3.

RESULTS

The ResNet DL model achieved accuracies of 0.89, 0.83, and 0.89 in V1, V2, and V3, respectively for identifying PQ scans. MRIQC-based QM models performed significantly worse with accuracies of 0.77 (V1; $p<0.001$), 0.75 (V2; $p<0.001$), and 0.76 (V3; $p<0.001$) in identifying PQ scans. The DL web-app took <1 min/MRI volume for classifying each scan as PQ or GQ.

CONCLUSION

s Our light-weight deep learning based web interface can enable rapid identification of poor-quality brain MRI scans, and offers improved performance compared to standard image quality measures.

CLINICAL RELEVANCE/APPLICATION

Rapid automated identification of poor-quality MRI scans could have significant implications for downstream machine learning analysis as well as radiology interpretation and disease diagnosis.

Post-processing to improve accuracy of Deep Learning Algorithm for Intracranial Hemorrhage Detection: Our experience of introducing an analytical approach simulating Radiologist Reasoning

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Anjali Agrawal, MD, Delhi, PA (*Presenter*) Nothing to Disclose

PURPOSE

Deep learning tools are being increasingly used to optimize radiologist efficiency in the emergency setting, however, overprediction and false positive (FP) results may be counterproductive. We investigated the value of additional post-processing refinements into the deep learning algorithm developed in our lab for the detection of intracranial hemorrhage (ICH) with the intention of introducing specific reasoning and logic similar to that applied by radiologists.

METHODS AND MATERIALS

A deep learning algorithm for ICH detection was developed using a fully convolutional neural network, U-NET with image segmentation and hemorrhage classification properties. Upon validation, several recurring FPs at specific locations posed a challenge in increasing overall accuracy to acceptable levels. Various new approaches were then developed to specifically address each type of FP. Deep learning models were used to decrease FPs instance-wise and slice-wise in calcification and artifact models respectively. Image processing and coding logic were used to decrease FPs in the region of basal ganglia, falx, dural sinus, volume averaging from dense calvaria, and FPs due to accentuated appearance of grey-white matter junction in older patients.

RESULTS

We analyzed 4512 studies of which 2036 were negative and 2476 were positive for intracranial hemorrhage sequentially using the ICH detection deep learning model, without and with post-processing algorithms. The results achieved without and with post-processing were sensitivity (recall) of 96.77% and 90.47%, specificity of 41.99% and 90.28%, precision of 66.98, 91.88%, F1 score of 79.17% and 91.17%, and Area Under Curve of 0.694 and 0.904 respectively.

CONCLUSION

s Postprocessing techniques brought about significant improvement in the model performance by reducing the number of false-positive results.

CLINICAL RELEVANCE/APPLICATION

Our research explores ways to improve the analytical capabilities of deep learning tools by using postprocessing techniques with the goal to develop a more optimal triage workflow in the emergency setting.

Radiomics Analysis Distinguish Between Primary Central Nervous System Lymphoma, Glioblastoma, and Brain Metastasis

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Murat AK, MD, Pittsburgh, PA (*Presenter*) Nothing to Disclose

PURPOSE

To investigative the diagnostic performance of radiomics-based machine learning in differentiating glioblastoma (GBM), primary central nervous system lymphoma (PCNSL) and brain metastasis (BM).

METHODS AND MATERIALS

We retrospectively identified 1075 patients from three institutions with untreated solitary, pathologically proven cases of PCNSL (133), GBM (433), and breast or lung BM (509). For each tumor, we segmented edema, contrast enhancement, necrosis, and contralateral white matter (cWM) volume of interest (VOI) for T2 FLAIR and T1 post-contrast sequences. A total of 205 texture features were extracted from each sequence's VOI including 10 histogram based first-order features and 195 second-order features using gray-level co-occurrence matrices. After feature normalization using cWM, we divided the 195 second level features by the volumes of each VOI to generate another 195 volume-independent features per VOI and 2,400 features per MRI. We performed feature selection with Least Absolute Shrinkage and Selection Operator (LASSO). We split the cohort into 70% training and 30% testing sets. We used XGBoost (eXtreme Gradient Boosting) algorithm to perform three-way classification and generate the radiomics model. The predictive performance of the models for classifying each tumor type against all others (i.e., BM versus PCNSL and GBM) was estimated using the receiver operating characteristic (ROC) curve, summarized as the area under the curve (AUC).

RESULTS

LASSO identified 216 independent features, of which 20 most relevant used for model building. Our three-classification model robustly differentiated ($p < 0.001$) between PCNSL (AUC 0.95), GBM (AUC 0.97), and BM (AUC 0.96) and achieved 88% accuracy. The model obtained 76.9% sensitivity and 98.2% specificity for PCNS prediction, 86% sensitivity and 94.7% specificity for the GBM prediction and 92.7% sensitivity 86.3% specificity for the BM prediction.

CONCLUSION

s This study presents radiomics-based signature that can successfully differentiate between PCNSL, GBM, and BM. Although further independent validation is warranted the proposed predictive radiomics-based signature is cost-effective, non-invasive and enable better patient stratification, management, and clinical decision-making

CLINICAL RELEVANCE/APPLICATION

A major challenge in the management of brain tumor is distinguishing tumor type as there are currently no reliable non-invasive biomarkers to predict them. Our data suggests that radiomics using MRI is an cost-effective and non-invasive approach to identify brain tumor type.

W5A-SPNR-2

Automated Lumbar Disc Herniation Grading Through AP-Diameter Measurement in MR Imaging

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Li Zhang, PhD, Princeton, NJ (*Presenter*) Employee, Covera Health

PURPOSE

Lumbar disc herniation (LDH) is often diagnosed using MR, and automated AI pipelines are used to reduce variation in grading severity. A fully automated AI-powered pipeline was used to detect, localize, and segment LDH at each Functional Spinal Unit (FSU) level (L1-2 through L5-S1) and use the anterior-posterior diameter (APD) of the segmented LDH to grade severity.

METHODS AND MATERIALS

Sagittal T2 sequences of MR lumbar spine were collected from 589 studies. 2,872 FSU manually segmented voxel-wise as background - 0 (No segmentation), disc - 1, and herniated disc region - 2. The studies were randomly split into train-validation-test sets in a 75:10:15 ratio. A deep reinforcement model was trained to identify the L1-2 through L5-S1 disc centers. Associated FSUs were cropped to 8 x 8 x 5 cm then fed to a convolutional neural network. An Attention U-Net was trained to segment the images on a 2D slice with 2 adjacent slices provided to the left and right of the target slice. The APD was estimated by summing the voxels' resolution at the apex of the estimated LDH region. A severity is assigned based on this measurement (Normal: 0mm; Small: APD = 3mm; Moderate: 3mm < APD = 6mm; Large: 6mm < APD). If an APD measurement error misassigns the severity by 1-degree, we call it 1-degree error, 1-degree error includes misassignment between Normal and Small, Small and Moderate, Moderate and Large. Similarly, 2-degree error is defined as severity misassignment between Normal and Moderate, Small and Large.

RESULTS

The model achieves an RMSE in APD of 1.33 ± 1.33mm and an average ratio of predicted to ground truth APD of 1.14 ± 0.89 for the true positive predictions. The model accuracy is further evaluated by the assigned severities based on APD. The 1-degree misassignment is 34% where 47% of these are between normal and small and 37% are between small and moderate both with an RMSE of 1.8mm. These, however, are in general inconsequential, the clinical significant 2-degree severity classification error is only 4%.

CONCLUSION

s Segmentation of Lumbar MR has the advantage of providing visualization and location and automated measurement of LDH which can assist diagnosis and reduce interobserver variation.

CLINICAL RELEVANCE/APPLICATION

Automated detection, localization and measurement of LDH pipeline can provide precise, reproducible analysis of pathology which can be useful for quality analysis, enhancing efficiency of utilizing experts.

W5A-SPNR-3

Deep learning for classification of Cranial Ultrasound in Preterm Babies

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Tahani Ahmad, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Cranial ultrasound (CUS) is widely used as a screening tool to assess brain injury in preterm infants. Severe abnormalities on CUS are known to be associated with Neurodevelopmental impairment (NDI). This study investigates the feasibility of using deep learning to identify abnormalities in CUS images collected from a preborn preterm cohort that are routinely clinically assessed for NDI. The objective is to train a model that can classify normal vs. abnormal imaging findings and assess its usability for computer-aided diagnosis that can have merit in daily practice as a complementary decision aid.

METHODS AND MATERIALS

This is a retrospective study of a cohort of very preterm infants born between January 2004 and Dec 2016 and admitted to the Neonatal Intensive Care Unit at IWK Health, Canada. The sample size includes images from 619 patients (4180 images) collected during 3-time points (first week, 6th week of age, and a term-equivalent age). At each point, 3 coronal images were selected at specific landmarks. Each image was anonymized. CUS pixels intensities are normalized and resized to a standard 224x224 pixel. Regions outside of the brain were masked and set to pixel intensity zero. A trained radiologist manually labeled each image as either normal or abnormal. The dataset is split into training/test sets (90:10 percent split). Due to the class imbalance in the dataset, the Area Under the Curve (AUC) was chosen as the metric of reference. The abnormal cases where the model very confidently predicted the image as abnormal were selected, then an approach called Gradcam was applied. In this approach, the saliency of each individual pixel is visualized. The original image has a heatmap overlaid on it, the areas with more red are what lead the model to make its prediction.

RESULTS

We tested different CNN architectures. The total number of normal images is 3531/4180, and the total number of images with abnormal findings is 649/4180. Preliminary results indicate an average of 0.794 AUC (0.757-0.83) using 10 bootstraps stratified sampling strategies using DensNet169

CONCLUSION

s This is a preliminary work to provide a tool to assist clinicians during early NDI assessment by classifying CUS into normal scans and scans with abnormal imaging features that can have merit in daily practice as a complimentary decision aid. Although the dataset is currently limited, early results are positive and likely to improve as more images are going to be included.

CLINICAL RELEVANCE/APPLICATION

Cranial ultrasounds to assess neurodevelopmental impairment is a challenging task subject to high variability. Computer-aided diagnosis tool might help reduce false positive and false negative rates.

W5A-SPNR-4

Prediction of Primary Tumor Entity of Brain Metastases Using Machine Learning based on Radiomic Features Derived from Routine MRI

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Quirin Strotzer, MD, Regensburg, Germany (*Presenter*) Nothing to Disclose

PURPOSE

This study aims to determine the primary tumor entity of brain metastases using machine learning based on radiomic features obtained from routine MRI sequences.

METHODS AND MATERIALS

This multicenter project included 251 patients for whom non-standardized routine MRI sequences T1, T1CE, T2, and FLAIR (from various scanners, 1.5T and 3T) and histologic determination of the primary tumor were available. A preprocessing pipeline was set up using Python libraries, including co-registration, normalization, and automated tumor segmentation using a Convolutional Neural Network with U-shaped architecture. Radiomic features were extracted and selected with a LASSO regression. Metastases were grouped into five classes: the four most frequently occurring primary entities (adenocarcinoma of the lung, melanoma, breast cancer, colorectal cancer) and a fifth group including all less common primaries. Using a five-fold cross-validation scheme, machine learning classifiers were tested on the train/validation partition of the dataset (80%) to predict the primary tumor based on the radiomic features. The performance was evaluated using a holdout test set (20%).

RESULTS

A total of 728 brain metastases were individually segmented. For each metastasis, 3852 radiomic features were extracted. The LASSO regression identified 60 variables with the greatest impact on classification. An AdaBoost classifier yielded the best results for this five-class classification task on the holdout test set (accuracy: 0.601; area under the receiver operating characteristic curve: 0.854). A feature importance analysis showed that the most essential variables for the classifier were second-order statistics features derived from the contrast-enhanced T1-weighted sequences.

CONCLUSION

s Primary tumor entity prediction might be feasible via radiomic feature analysis of non-standardized routine MRI sequences. Further relevant read-outs such as oncogenic driver mutations could be within reach.

CLINICAL RELEVANCE/APPLICATION

Predicting the primary tumor of brain metastases using radiomic features derived from non-standardized routine MRI sequences would significantly enhance the diagnostic value of routine MRI scans and reduce morbidity from invasive biopsies.

Accelerated Creation of a Glioma Database for Machine Learning Prediction Model Development using PACS-Integrated Tools

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Victor Becerra, MD, Albany, NY (*Presenter*) Nothing to Disclose

PURPOSE

The creation of well-annotated imaging datasets is crucial for the development of accurate and reproducible machine learning (ML) algorithms. Although an increasing number of ML algorithms are being developed in the academic setting, many of them are created in research-specific software incompatible with the routine clinical workflow. Our purpose was to facilitate the creation of a large, annotated glioma database by implementing clinical PACS-integrated tools for image segmentation and radiomic feature extraction.

METHODS AND MATERIALS

Data from our institution's radiation oncology registry from 2012 to 2019 was used. Glioma images from these patients and the BRaTS 2021 challenge were segmented using a home-grown PACS-integrated (Visage Imaging, Inc) U-net algorithm. These were subsequently validated by a board-certified neuroradiologist. A home-grown PACS-integrated PyRadiomics feature extraction tool was then deployed on the annotated dataset.

RESULTS

Over the course of only 5 months, segmentations and annotations were completed in 595 patients (236 females, 359 males, with a mean age of 50.92 years). Grade distribution was as follows: 245 Grade 4, 52 Grade 3; 97 Grade 2; 26 Grade 1; 175 unknown. Molecular subtypes included IDH (87 mutated, 355 wild-type, 153 unknown), 1p/19q (65 deleted or co-deleted, 87 intact, 443 unknown), MGMT promotor (162 methylated, 70 partially methylated, 207 unmethylated, 156 unknown), EGFR (55 amplified, 121 not amplified, 419 unknown), ATRX (28 mutated, 130 retained, 437 unknown), Ki-67 (433 known, 162 unknown) and p53 (395 known, 200 unknown). To generate a geographically distinct validation set, metadata labels were created for imaging acquired outside our institution.

CONCLUSION

s Our PACS-integrated image annotation tools have allowed us to curate a large number of images in an accelerated manner that is compatible with the clinical workflow. On average, over 100 gliomas were annotated per month, thus establishing that these tools may be game-changing in the development of annotated imaging databases.

CLINICAL RELEVANCE/APPLICATION

The development of clinical PACS-integrated tools for data curation has the potential to facilitate and accelerate the development of large-scale well-annotated imaging datasets which can be used for algorithm development, radiomic feature extraction, among others.

Multi-Scale Fusion 3D Convolutional Neural Networks Based on Attention Mechanism for Survival Prediction of Glioma Patients

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Xuan Yu, (*Presenter*) Nothing to Disclose

PURPOSE

Due to the individual differences of different patients with glioma and individualized precision treatment, the survival time performance of different patients is quite different. Constructing a reliable survival prediction model and analyzing the MRIs of patients with glioma, further mining objective features from the images have extremely important clinical value for the prognosis of patients. we develop a multi-scale fusion 3D convolutional neural networks deep learning model based on attention mechanism to predict the survival time of glioma patients.

METHODS AND MATERIALS

MRIs from 270 cases were included, of which 207 from BraTS 2019 datasets and 63 from the private datasets of the hospital. Firstly, MRIs are preprocessed and a saliency-aware method is adopted to enhance the tumor region. Next we present a 3D convolutional structure to refine multiple scale characteristics of enhanced T1 Weighted imaging. Two crucial designs are shown in the model, one of which is fusing multi-scale features to explore level information in MRIs, and another is the attention gate make the model automatically focus on the crucial area in the images. Finally through the full connection layer to achieve the survival time analysis. The model includes prediction of short, medium, and long-term survival risk classification.

RESULTS

The cases were divided into low-risk group(SD>=450), medium-risk group(300>=SD>=450) and high-risk group(SD<=300) according to the Survival Days(SD). The ROC results show low-risk group AUC is always higher than medium-and high-risk group AUC in training, verification and test sets, which indicates low-risk group is easier to classify. The classification performance of medium-risk group and high-risk group are close. And the medium or high survival risk of patients is relative difficult to study due to the survival time is affected by more complex factors including the degree of tumor necrosis, the individual differences, whether has other disease and so on. By comparing with the popular 3D Unet model, sensitivity, specificity and AUC in our model displays relatively better performance.

CONCLUSION

s Our research demonstrates that appropriate MRIs data preprocessing and saliency-aware enhancement could better show the lesion characteristics of images. 3D convolutional structure preserves the important spatial features. Fusing different scale features is helpful to achieve higher classification accuracy, and the attention gate focuses more on the key areas in the MRIs. Our method is effective to mine MRIs deep features thus to achieve the goal of glioma patients' survival time prediction.

CLINICAL RELEVANCE/APPLICATION

This work provides some support for the operation, treatment and survival evaluation of patients with gliomas.

Deep Learning of Dynamic Susceptibility Contrast Perfusion-weighted Imaging to Predict the Local Recurrence in Glioblastoma Patients

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Roh-Eul Yoo, MD, PhD, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To develop a deep learning model based on multiparametric MR imaging including dynamic susceptibility contrast perfusion-weighted imaging (DSC-PWI) that predict the local recurrence in patients with glioblastoma (GBM).

METHODS AND MATERIALS

This retrospective study included 213 consecutive GBM patients who underwent standard treatment between May 2010 and April 2021 and had both preoperative MR including DSC-PWI and 1 year follow-up 3T MRI. Patients were divided into the training set (172 patients [58 ± 14 years; 90 men] from 2010 to 2019) and test set (41 patients [56 ± 14 years; 23 men] from 2020 to 2021). Each patient was categorized as local recurrence or non-recurrence group with respect to the presence of local recurrence at 1 year after the diagnosis. Using the follow-up contrast-enhanced T1-weighted image (CE-T1WI) as the reference standard, the sites of local recurrence were annotated in a non-enhancing T2 hyperintense lesion on preoperative T2 FLAIR images. A deep learning model based on conventional MR and DSC-PWI was developed using nnU-Net. The deep learning model performance was validated on the test set. Diagnostic performance of the two models were compared using the McNemar test.

RESULTS

Training set and test set included 73 and 17 recurrence cases, respectively. In the test set, the multiparametric deep learning model using the combination of conventional MR and DSC-PWI showed a significantly higher sensitivity than the model based on conventional MRI alone in predicting the risk of recurrence (71% [12 of 17] vs. 29% [5 of 17], P = .031). The specificity of the model based on the combination of conventional MR and DSC-PWI did not significantly differ from that based on the conventional MRI alone (42% [10 of 24] vs. 58% [14 of 24], P = .34).

CONCLUSION

s A deep learning model based on multiparametric MR imaging including DSC-PWI can be used to predict the risk of local recurrence in GBM patients.

CLINICAL RELEVANCE/APPLICATION

A deep learning model based on the combination of conventional and DSC-MRI could be used to stratify the risk of local recurrence in GBM patients and potentially to guide radiation treatment planning.

From Accuracy to Consensus: Towards a New Paradigm for Assessing Model Performance

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - NR DPS

Participants
Simas Glinskis, Ithaca, NY (*Presenter*) Employee, Covera Health, Inc

PURPOSE

Machine learning model performance is typically analyzed through accuracy and other statistical measures contingent on consistent ground truth labels. This assumption falls apart with medical applications where considerable inter-reader variability is present due to variation in clinical interpretation. We designed a new statistical mechanism to assess model performance which incorporates multiple sources of truth.

METHODS AND MATERIALS

MRI lumbar spine studies from 207 patients, 1035 functional spine units, were collected and multi-annotated by 10 subspecialty radiologists. The data was partitioned into a ground truth set using labels from the most experienced radiologist available and a secondary set from the remaining experts. Deep learning based models for classification of disc herniation (DH), central canal stenosis (CCS), and nerve root compression (NRC) were used to generate severity predictions. Those predictions were split into two groups, where they agreed with ground truth (agree) and where they did not (disagree). Distributions of label consensus (LC) were generated for both groups by computing the average agreement between ground truth and external annotations for each prediction.

RESULTS

Accuracy of normal, mean agree LC and mean disagree LC are 87%, 97%, and 41% for NRC, 91%, 98% and 37% for CCS, and 74%, 92%, and 47% for DH, respectively. While accuracy is sensitive to the annotation that is selected as the gold standard, LC distributions generate a better measure of model performance which incorporates information from all of the experts. For the disagree set, there is low consensus which unfairly lowers accuracy and for the agree set we see very high consensus which the models are able to capture. Agree LC consistently outperforms accuracy and better represents the predictive power of the model when measured against a group of labels.

CONCLUSION

s We designed label consensus to analyze the performance of machine learning models by incorporating multi-annotated data. When there is inter-reader variability among experts conventional accuracy fails to incorporate information from the corpus of annotators and is sensitive to the choice of gold standard label while consensus is not.

CLINICAL RELEVANCE/APPLICATION

Our proposed label consensus evaluation provides a more effective way of assessing AI model performance in applications with significant inter-reader variability.

W5A-SPPD-1 A Clinical-Radiomics of Pituitary MRI to Differentiate the Growth Hormone Deficiency from Idiopathic Short Stature

Participants
Shiyun Tian, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Growth retardation can be caused by Growth Hormone Deficiency (GHD) and Idiopathic Short Stature (ISS). Radiomics recognizes complex patterns in imaging data by extracting high-throughput features of Anterior pituitary heterogeneity in a non-invasive manner. Based on non-contrast-enhanced (NCE)/contrast-enhanced (CE) Magnetic Resonance (MR) T1WI images, we try to develop a clinical-radiomics model and validate its predictive capacity to identify GHD and ISS presented as no visual abnormality in pituitary on MRI.

METHODS AND MATERIALS

The clinical and MRI data of 102 patients first diagnosed as growth retardation in pediatrics and scanned with pituitary MRI from May 2011 to August 2021 were collected retrospectively. According to the clinical findings and hormone examination, the patients were divided into GHD ((n = 74) and ISS ((n = 28). It is randomly divided into training set (n = 71) and verification set (n = 31) by random number table method. In total, 851 radiomics features were extracted from the 3D region of anterior pituitary (ROI), we performed a clinical-radiomics analysis based on pretreatment NCE-MRI (NCE-radiomics) and CE-MRI images (CE-radiomics), respectively. Meanwhile, a combined-radiomics model based on NCE-MRI and CE-MRI images was constructed. Finally, we developed their corresponding nomograms incorporating clinical factors. ROC was used to evaluate models' predictive performance in the training and testing set, and a DeLong test was employed to compare the differences between different models.

RESULTS

In total, 851 features were extracted from the T1WI-MRI and CET1WI images, respectively. The ICC was used to screen out 140 and 154 related features. Subsequently, to prevent model overfitting, the 8 and 11 features with optimal correlation coefficients were retained, respectively. The AUCs of the Clinical-T1WI, Clinical-CE-T1WI and Combine radiomics models were 0.7267 (95% CI: 0.5856, 0.8679), 0.8421 (95% CI: 0.7422, 0.9420), and 0.8462 (95% CI: 0.7465, 0.9458) in the training set, respectively, which were confirmed in the test set by AUCs of 0.5960 (95% CI: 0.3715, 0.8204), 0.6162 (95% CI: 0.4037, 0.8286), and 0.6515 (95% CI: 0.4351, 0.8679), respectively.

CONCLUSION

s The MRI-based radiomics model can be helpful to distinguish GHD and ISS, and combined with clinical features, which can improve diagnostic accuracy on MRI provides histological information for pituitary without abnormality.

CLINICAL RELEVANCE/APPLICATION

The MRI-based radiomics of the pituitary is helpful in the diagnosis of patients with growth retardation.

W5A-SPPH-1 Evaluation of Residual Disease after Neoadjuvant Chemotherapy Using Manganese-Enhanced Magnetic Resonance Imaging in an Orthotopic Mouse Model

Participants
Myoung Kyoung Kim, seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Manganese-enhanced magnetic resonance imaging using hollow manganese silicate (HMS-MRI) predicts a pathologic complete response (pCR) more accurately than does gadolinium-enhanced MRI (Gd-MRI) because manganese-enhanced MRI reflects not only vascularity but also viable tumor cellularity after chemotherapy. This study aimed to compare the accuracy of HMS-MRI and Gd-MRI in predicting lesion size and viable tumor burden after chemotherapy using in vivo and in vitro experiments.

METHODS AND MATERIALS

BT474 cells and orthotopic xenograft mouse models of human breast cancer, based on BT474 cell inoculation, were used for the in vivo and in vitro experiments, respectively. In vivo, 18 female mice underwent Gd-MRI and HMS-MRI before and after chemotherapy. Two sets of BT474 cell pellets, treated with or without chemotherapy, were imaged by adding MnCl2 or gadolinium. Tumor size and residual tumor cellularity after treatment obtained from Gd-MRI and HMS-MRI were compared with pathological findings.

RESULTS

Differences in residual tumor size and cellularity measured by MRIs were also correlated with pathological findings. Agreements in both tumor size and residual tumor cellularity between HMS-MRI and pathology were stronger than those between Gd-MRI and pathology. The lower the tumor?stroma ratio in pathological specimens, the larger was the difference in residual tumor cellularity between Gd-MRI and HMS-MRI (R = -0.62, P = 0.018). BT474 cell pellets showed signal enhancement after exposure to MnCl2, and the degree of enhancement decreased when cell pellets were exposed to chemotherapeutic agents.

CONCLUSION

s Our results suggested that HMS-MRI can predict pCR more accurately than Gd-MRI when a pCR is suspected.

CLINICAL RELEVANCE/APPLICATION

Considering the active clinical trend for omitting surgery if pCR is highly suspected, our study suggested that HMS-MRI is a promising method for patient selection. In particular, HMS can be used to image breast cancer, which would be the first step in the wider use of HMS.

W5A-SPPH-2 When Will PROPELLER Technique Improve Quality in Acquisition of T2W-FRFSE Images of Abdomen MRI? Comparative Analysis According to Patient's Respiratory Patterns

Participants
Kyungmin Lee, Gyeounggi-Do, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the value of periodically rotated overlapping parallel lines with enhanced reconstruction (PROPELLER) technique to reduce respiratory artifacts and improve image quality in acquisition of T2-weighted (T2W) respiratory triggering fast recovery fast spin echo (FRFSE) images according to patient’s respiratory pattern.

METHODS AND MATERIALS

In 200 consecutive patients who underwent abdominal MRI, T2W-FRFSE images were obtained with and without PROPELLER. Patients were divided into four groups according to respiratory patterns and rates (Group A: regular, =14 times/min; B: regular, 15-17 times/min; C: regular, =18 times/min; D: irregular, any rate). Qualitative image quality was assessed independently by two radiologists for ghost artifacts, edge sharpness, image noise, and overall image quality. Quantitative indices of signal-to-noise-ratio (SNR) and contrast-to-noise-ratio (CNR) were also analyzed by two radiologists. These indices were compared between two techniques in each group using Wilcoxon signed-rank test. Inter-observer agreement was assessed using Cohen’s Kappa test and intraclass correlation coefficient.

RESULTS

In group A and B, T2W-FRFSE images without PROPELLER showed better image quality than those with PROPELLER in all qualitative and quantitative indices ($p<0.05$), except for ghost artifact in group A ($p=0.404$). In contrast, in group C and D, T2W-FRFSE images with PROPELLER showed better image quality than those without PROPELLER in all qualitative and quantitative indices ($p<0.05$) except for SNR in group C ($p=0.339$). Inter-observer agreements between two radiologists were excellent in all qualitative indices (kappa values >0.8) and quantitative indices (ICCs>0.8).

CONCLUSION

s Acquisition of T2W-FRFSE with PROPELLER yielded better image quality in patients with fast or inconsistent respiration than T2W-FRFSE without PROPELLER, and vice versa in patients with slow and steady respiration.

CLINICAL RELEVANCE/APPLICATION

Whether or not to utilize PROPELLER in acquisition of T2W-FRFSE should be determined according to the patient's respiratory pattern and rate.

W5A-SPPH-3 Toward a Simple Surrogate for Abdominopelvic Adipose Tissue Volume - Systematic MRI Assessment in Patients With Different BMI Classes

Participants
Nicolas Linder, MD, Leipzig, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Obesity is a leading health problem worldwide with numerous comorbidities, such as cardiovascular disease, with the amount of visceral fat often regarded as an important factor for prognosis. In routine practice, many have used the sagittal abdominal diameter (SAD) as a simple clinical marker of visceral fat. The aim of this work was to systematically correlate (MRI-derived) SADMR with the abdominopelvic visceral and subcutaneous adipose tissue (VAT/SAT) volume in patients with obesity.

METHODS AND MATERIALS

Full abdominopelvic MR datasets were available from 266 patients (196 females and 70 males) with obesity. SADMR was determined on axial images by the respective distance of a line through the center of the vertebral body at different levels (lumbar disc compartments L1-L2 to L5-S1 and umbilicus). VAT and SAT volumes were determined with a semiautomatic segmentation software. Agreement between SADMR and AT volumes was evaluated by correlation coefficients R.

RESULTS

SADMR ranged from 21.7 cm to 39.0 cm and total volume of VAT (SAT) ranged from 0.9 to 14.0 L (4.8 to 39.4 L). Over all patients, R values between SADMR and VAT ranged from 0.66 at L5-S1 to 0.71 at L2-L3 (mean R of 0.69). Between sexes, the highest R value was larger for women (0.74 at L2-L3 vs. 0.69 at L3-L4). Similarly strong correlations were also seen between SADMR and SAT with R values between 0.67 (L2-L3) and 0.73 (L5-S1) overall, and higher values for each sex. Strong correlations of SADMR were also maintained within BMI subgroups for each sex with VAT but not with SAT

CONCLUSION

s A gender-specific sagittal abdominal diameter has been shown to be a reliable measure for simple and rapid estimation of visceral fat volume in patients with different degrees of obesity.

CLINICAL RELEVANCE/APPLICATION

The presented parameter MRI-derived sagittal abdominal diameter (SADMR) promises to be a simple but reliable imaging marker of visceral obesity.

W5A-SPPH-4 Novel Free-Breathing Day-Optimizing-Throughput Sequences in Comparison with Conventional Breath-Hold Examinations During Whole-Body MRI

Participants
Vitali Koch, MD, Frankfurt am Main, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To assess and compare novel free-breathing DOT sequences (Day Optimizing Throughput) with conventional breath-hold examinations in whole-body magnetic resonance imaging (MRI).

METHODS AND MATERIALS

This prospective study included 26 subjects with a variety of pathologies who had undergone whole body 1.5-Tesla MRI. Image quality, diagnostic confidence, and image noise were evaluated by two experienced radiologists. Diagnostic performance for the overall detection of pathologies in both sequences was assessed using the area under the receiver operating characteristics curve (AUC). Additionally, study participants were asked to rate their examination experience in a satisfaction survey using a 10-point Likert scale.

RESULTS

MR free-breathing scans were rated as at least equivalent to conventional MR scans in more than 90% of cases, showing high overall diagnostic accuracy (95% [95% CI 92-100]) and performance (AUC 0.971, 95% CI 0.942 to 0.988; $P < 0.0001$) for the assessment of pathologies at simultaneously reduced examination time (50 ± 4 vs. 59 ± 5 minutes; $P < 0.0001$). Interrater agreement was excellent for both, free-breathing (? = 0.96 [95% CI, 0.88-1.00]) and conventional scans (? = 0.93 [95% CI, 0.84-1.00]). Ratings for image quality, image noise, and diagnostic confidence differed not significantly between the two types of MR image acquisition (all $P > 0.05$).

CONCLUSION

s MR images generated with free-breathing DOT sequences yielded similar diagnostic performance at equivalent image quality and noise levels compared to conventional breath-hold algorithms. Moreover, the long examination time of whole-body MRI could be considerably shortened for a more tolerable whole-body MRI experience.

CLINICAL RELEVANCE/APPLICATION

Free-breathing Day-Optimizing-Throughput (DOT) MRI yields comparable diagnostic accuracy compared to breath-hold MRI. Free-breathing DOT sequences provide high diagnostic confidence at low image noise levels. Free-breathing DOT whole-body MRI may represent a viable alternative to conventional MRI.

W5A-SPPH-5 Technical and Clinical Considerations of a Physical Phantom for CT Radiomics Analysis

Participants
Bino A. Varghese, PhD, Los Angeles, CA (*Presenter*) Nothing to Disclose

PURPOSE

Radiomic measurements can be impacted by differences in protocol and equipment. Statistical approaches such as ComBat reduces this impact, however, they ignore the variable relationship, between different radiomic metrics and imaging parameters, leading to suboptimal harmonization for some metrics. We identify key phantom characteristics to help build a physical phantom for CT-radiomics harmonization, particularly, the higher-order texture metrics.

METHODS AND MATERIALS

CT scans of a radiomics phantom comprising of 18 novel 3D printed inserts with varying size, shape, and material combinations were acquired on a 64-slice CT scanner (Brilliance 64, Philips Healthcare). The images were acquired at 120 kV, 250mAs, CTDIvol of 16.36 mGy, 2mm slice thickness and reconstructed using iDose1. Radiomics analysis was performed using the Cancer Imaging Phenomics Toolkit (CaPTk), following automated segmentation of volumes of interests (VOIs) of the 18 inserts. To add perspective to our findings we compared them to 3 additional VOIs obtained of an anthropomorphic liver phantom, a patient liver CT scan, and a water phantom, at comparable imaging settings. Percent difference in Hounsfield units (HU) between phantom and tissue was used to assess the biological equivalency and <10% was used to claim equivalent.

RESULTS

The HU for all 18 VOIs from the phantom ranged from -30 to 120 compared with a range of 0-118 for liver tissue. One of our novel phantom inserts, T3-6B, had >50% radiomic features that have <10% difference from liver tissue (patient). Second-order texture metrics, particularly, those of Neighborhood Gray Tone Difference Matrix (NGTDM), which are also representatives of the signal to noise ratio of CT scans, mostly show extreme values in the water phantom VOI compared to the VOIs from the phantom.

CONCLUSION

s The practice of using water phantom values which represent a structureless entity, will help identify limits of threshold for radiomic metrics, particularly texture. The practice of comparing the values to those from patient scans will help establish clinical relevance. By adopting some of the patterns from the radiomics phantom within the liver phantom, we will be able to selectively harmonize texture metrics, depending on its order and explore its association with imaging variables.

CLINICAL RELEVANCE/APPLICATION

Development of phantoms untangling the relationship between radiomic metrics and imaging variables will help establish quality assurance and control standards which are warranted for the clinical translation of radiomics.

W5A-SPPH-6 Postural Effect on Renal Volume: Evaluation Using Multi-Posture MRI

Participants
Seiya Nakagawa, BA, (*Presenter*) Nothing to Disclose

PURPOSE

Measurement of renal volume is vital for the early identification and monitoring of renal diseases. Nevertheless, it is unclear how postural changes, i.e., differences in the effects of gravity, alter renal volume. In this study, we evaluated the postural effect on renal volume in the supine and upright positions using an original magnetic resonance imaging (MRI) system that can image in any posture (multiposture MRI).

METHODS AND MATERIALS

Renal volume was evaluated in seven healthy volunteers (mean age, 22.7 ± 1.0 years; body mass index, 20.5 ± 1.0 kg/m2) in the supine and upright positions using multiposture MRI (0.4 T). A breath-hold 3D gradient-echo sequence was used to acquire coronal T1-weighted images of the right and left kidneys in the supine and upright positions. Then, the right and left renal volumes (whole kidney, renal cortex, medulla, and pelvis) were measured and compared across positions.

RESULTS

The whole kidney volume in the upright position (right kidney, 122.3 ± 20.1 mL; left kidney, 120.0 ± 14.5 mL) was significantly lower than that in the supine position (right kidney, 139.9 ± 21.0 mL; left kidney, 133.8 ± 18.9 mL) for both the right and left kidneys ($P < 0.05$ for both). The renal cortex volume in the upright position (right kidney, 77.0 ± 12.2 mL; left kidney, 75.3 ± 6.3 mL) was significantly lower than that in the supine position (right kidney, 89.3 ± 12.9 mL; left kidney, 85.0 ± 10.1 mL) for both the right and left kidneys ($P < 0.05$ for both). The renal medulla volume in the upright position (right kidney, 40.6 ± 7.3 mL; left kidney, 38.5 ± 7.1 mL) was significantly lower than that in the supine position (right kidney, 45.5 ± 8.7 mL; left kidney, 42.7 ± 7.7 mL) for both the right and left kidneys ($P < 0.05$ for both). These findings revealed a decrease in blood volume and urine volume owing to the fluid shift effect when standing. Moreover, in comparison with the standard MRI examination of the kidney, multiposture MRI provided additional diagnostic information on the regulatory function to the gravity. However, no significant difference was observed in the renal pelvis volume between the supine and upright positions for both the right and left kidneys. Furthermore, no significant differences were observed in the volume change ratio from the supine to upright between the right and left kidneys.

CONCLUSION

s An upright position reduces renal volume. Multiposture MRI enables the assessment of the postural effect on renal volume.

CLINICAL RELEVANCE/APPLICATION

An upright position reduces renal volume. Multiposture MRI revealed differences in the renal volume between the upright and supine

positions, thereby providing new diagnostic information on the regulatory function to the gravity as compared with the standard MRI examination of the kidney.

W5A-SPPH-7 Comparison of Image Quality Metrics Between Solid-State Digital-BGO PET/CT and Time-of-Flight LSO Systems

Participants
Tala Palchan Hazan, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

A recently designed digital solid-state positron emission tomography/x-ray CT system (PET/CT) scanner with bismuth germanate (BGO) scintillators coupled to silicon photomultipliers provides for a 32 cm axial field of view. Image quality metrics from this ultra-high sensitivity digital-BGO system without time-of-flight (TOF) were compared to a lutetium oxyorthosilicate (LSO) based TOF PET/CT scanner.

METHODS AND MATERIALS

A national electrical manufacturers association (NEMA) image quality (IQ) phantom was prepared as per NEMA NU 2-2018 with a fluorine-18 radiotracer. The 6 hot spheres (10 to 37 mm in diameter) were scanned on the LSO and digital-BGO systems. List mode data were binned to 12 decay-corrected 2-minute equivalent acquisitions, each with approximately the same number of incident counts. In both systems, images were reconstructed using an ordered subset expectation maximization (OSEM) algorithm and compared (Kruskal-Wallis test) to TOF-OSEM from the LSO system. Additional LSO OSEM reconstructions relisted scans to 1.4, 2.25 and 3.6 times the number of incident counts. The IQ metric was the contrast to noise ratio (CNR), calculated by dividing the contrast of hot sphere activity with respect to the background by the coefficient of variation of the background.

RESULTS

All CNRs of the digital-BGO system were the same or greater compared to LSO TOF-OSEM. For the smallest feature, there was no statistically significant difference ($p<0.001$) in the CNR of the 10 mm sphere (CNR10) between LSO TOF-OSEM (25.8 ± 2.1, mean ± std. dev.) and the digital-BGO (24.8 ± 1.4). There was also no significant difference ($p<0.001$) in CNR10 between LSO TOF-OSEM and LSO OSEM using 2.25 times the number of incident counts (26.8 ± 1.9). Using 1.0 or 1.4 times the number of incident counts were insufficient to match LSO TOF-OSEM (19.0 ± 1.8, and 21.5 ± 1.8, respectively). Using 3.6 times the number of incident counts significantly improved CNR10 (35.0 ± 0.9, $p<0.001$) compared to LSO TOF-OSEM.

CONCLUSION

s The ultra-high sensitivity of a solid-state 32 cm axial FOV digital-BGO PET/CT system provides for image quality similar to TOF systems, as measured by CNR in NEMA phantoms.

CLINICAL RELEVANCE/APPLICATION

The ultra-high sensitivity of a novel solid-state digital-BGO PET/CT system provides for high quality imaging of small features, enabling the diagnosis of pathology through functional imaging.

W5A-SPPH-8 Multiparametric MRI Method Development for Clinical Prostate Imaging Using 5T MR Imaging

Participants
Liyun Zheng, Shanghai, China (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this study was to evaluate the development of prostate MRI at 5T by providing assessment of image quality on clinical sequences, including T1-weighted (T1W), T2-weighted (T2W) and diffusion-weighted imaging (DWI) sequences.

METHODS AND MATERIALS

Ten healthy subjects (mean age, 55.5 ± 7.5) were measured on a 5T MR scanner (uMR Jupiter, United Imaging Healthcare, Shanghai, China), using a 24-channel transmit/receive body array coil. SAR-monitoring and B0 and B1+ shimming were performed. Imaging sequences including: (1) axial T1W quick3d gradient echo (GRE) sequence (TR/TE = 3.34/1.42 ms, FA = 15°, Bandwidth = 850 Hz, 60 slices, Slice thickness = 3 mm, FOV = 300 × 400 mm, Matrix = 410 × 608, Number of averages = 2, Acquisition time = 16.9s); (2) axial T2W fat-saturated fast spin echo (FSE) sequence (TR/TE = 2600/128.24 ms, FA = 90°, Bandwidth = 200 Hz, 30 slices, Slice thickness = 5mm, FOV = 380 × 300 mm, Matrix = 639 × 504 , Number of averages = 2, Acquisition time = 2min10s); and (3) echo-planar imaging (EPI) - DWI (TR/TE = 3650/53 ms, FA = 90°, Bandwidth = 2100 Hz, 30 slices, Slice thickness = 5 mm, FOV = 180 × 380 mm, Matrix = 410 × 608, b = 50, 800 s/mm2, Number of averages = 2, 4). Image analysis was performed by two experienced radiologists in consensus. For all the sequences, overall image quality (5 = excellent, 1 = non-diagnostic) and presence of artifacts (5 = pronounced, 1 = none) were assessed on a 5-point scale. Visibility of anatomical structures, defined as distinction between peripheral and transition zone, seminal vesicles, and delineation of the prostate, was graded on T2W images utilizing a five-point scale (5 = excellent, 1 = unacceptable). For DWI, geometric distortion (defined as modification in size, profile, and/or orientation due to inhomogeneities of the magnetic field in relation to T2W images) was evaluated on a 5-point scale (5 = very high distortion, 1 = no distortion).

RESULTS

Overall image quality of T1W image was scored as moderate to good (3.9 ± 0.5), T2W image was scored as good to excellent (4.1 ± 0.8), while DWI was scored as moderate (3.0 ± 0.6). Presence of artifacts of T1W, T2W and DWI images were scored as none to minimal (1.5 ± 0.5 for T1W, 1.4 ± 0.5 for T2W, 1.8 ± 0.5 for DWI). Visibility of anatomical structures for T2W at 5T was graded as good to excellent (4.2 ± 0.7). Upon DWI at 5T, the geometric distortion was graded as no distortion to low distortion (1.5 ± 0.9).

CONCLUSION

s This study proved that prostate MRI, including T1W, T2W and DWI sequences at 5T can achieve diagnostic image quality.

CLINICAL RELEVANCE/APPLICATION

According to current results about image quality, presence of artifacts, visibility of anatomical structures of T2W images, and geometric distortion of DWI, clinical prostate imaging is feasible at 5T MRI.

W5A-SPPH-9 How to Handle Zero Counts in Low Dose Photon Counting CT Imaging?

Participants
Dan Bushe, MSc, BSc, Madison, WI (*Presenter*) Nothing to Disclose

PURPOSE

The probability of registering a count of zero for a given pixel is significantly higher for photon counting detectors (PCDs) when compared with energy integrating detectors (EIDs). This is a result of the general one-to-one correspondence between the digital output of the PCD with the absorbed x-ray photons and the higher spatial resolution of PCD detectors (0.15-0.3 mm). In contrast, a single x-ray photon can generate tens to hundreds of digital counts in EID elements with a size of 1 mm or larger. This problem becomes further exacerbated when considering low dose PCD-CT applications, large patient imaging, and the allocation of counts to various energy bins for spectral imaging. Zero counts must be corrected before the nonlinear log transform is taken to generate the sinograms for CT image reconstruction. However, replacing zeros by any positive number alters the statistical distribution of counts and introduces biases that can manifest as severe shading or blooming artifacts. The purpose of this work was to develop a novel PCD-CT zero-count correction method that not only corrects zero-counts but also minimizes CT number biases.

METHODS AND MATERIALS

In this work, a novel Laurent expansion was introduced to approximate the log-transformed projection data. The coefficients of the truncated Laurent expansion were calibrated using the correspondence between low dose scans with zero counts and high-dose scans without zero counts. This method was experimentally validated using a CdTe-based PCD-CT system with 4 test objects and under 4 different dose levels. The severity of the zero counts problem ranged from less than 0.1% to 22%.

RESULTS

With a conventional zero-count replacement correction, images demonstrated severe blooming and shading artifacts due to sinogram biases. The proposed method eliminated those artifacts and reduced CT number biases from -930 HU (95% CI: -1267, -592HU) to -0.8 HU (95% CI: -1.5, -0.2 HU) for a Teflon insert and from 790 HU (95% CI: 552, 1028 HU) to 3.4 HU (95% CI: 3.0, 3.9 HU) for an air insert. For both conventional and proposed corrections, the limiting spatial resolution of the CT images was matched at 9 lp/cm.

CONCLUSION

s The proposed PCD-CT zero-count correction strategy not only corrects for zero-count pixels but also removes the associated biases. The method takes only a single pass and is computationally efficient. Furthermore, the method does not use any spatial filtering and thus does not introduce any spatial resolution loss.

CLINICAL RELEVANCE/APPLICATION

Zero detector counts are common in PCD-CT and severely degrade clinical diagnostic performance. This work addresses the long-standing zero-count correction problem and further elevates the clinical trustworthiness of PCD-CT.

Evaluation of Residual Disease after Neoadjuvant Chemotherapy Using Manganese-Enhanced Magnetic Resonance Imaging in an Orthotopic Mouse Model

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Myoung Kyoung Kim, seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Manganese-enhanced magnetic resonance imaging using hollow manganese silicate (HMS-MRI) predicts a pathologic complete response (pCR) more accurately than does gadolinium-enhanced MRI (Gd-MRI) because manganese-enhanced MRI reflects not only vascularity but also viable tumor cellularity after chemotherapy. This study aimed to compare the accuracy of HMS-MRI and Gd-MRI in predicting lesion size and viable tumor burden after chemotherapy using in vivo and in vitro experiments.

METHODS AND MATERIALS

BT474 cells and orthotopic xenograft mouse models of human breast cancer, based on BT474 cell inoculation, were used for the in vivo and in vitro experiments, respectively. In vivo, 18 female mice underwent Gd-MRI and HMS-MRI before and after chemotherapy. Two sets of BT474 cell pellets, treated with or without chemotherapy, were imaged by adding MnCl2 or gadolinium. Tumor size and residual tumor cellularity after treatment obtained from Gd-MRI and HMS-MRI were compared with pathological findings.

RESULTS

Differences in residual tumor size and cellularity measured by MRIs were also correlated with pathological findings. Agreements in both tumor size and residual tumor cellularity between HMS-MRI and pathology were stronger than those between Gd-MRI and pathology. The lower the tumor?stroma ratio in pathological specimens, the larger was the difference in residual tumor cellularity between Gd-MRI and HMS-MRI ($R = -0.62$, $P = 0.018$). BT474 cell pellets showed signal enhancement after exposure to MnCl2, and the degree of enhancement decreased when cell pellets were exposed to chemotherapeutic agents.

CONCLUSION

s Our results suggested that HMS-MRI can predict pCR more accurately than Gd-MRI when a pCR is suspected.

CLINICAL RELEVANCE/APPLICATION

Considering the active clinical trend for omitting surgery if pCR is highly suspected, our study suggested that HMS-MRI is a promising method for patient selection. In particular, HMS can be used to image breast cancer, which would be the first step in the wider use of HMS.

When Will PROPELLER Technique Improve Quality in Acquisition of T2W-FRFSE Images of Abdomen MRI? Comparative Analysis According to Patient's Respiratory Patterns

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Kyungmin Lee, Gyeounggi-Do, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To evaluate the value of periodically rotated overlapping parallel lines with enhanced reconstruction (PROPELLER) technique to reduce respiratory artifacts and improve image quality in acquisition of T2-weighted (T2W) respiratory triggering fast recovery fast spin echo (FRFSE) images according to patient's respiratory pattern.

METHODS AND MATERIALS

In 200 consecutive patients who underwent abdominal MRI, T2W-FRFSE images were obtained with and without PROPELLER. Patients were divided into four groups according to respiratory patterns and rates (Group A: regular, =14 times/min; B: regular, 15-17 times/min; C: regular, =18 times/min; D: irregular, any rate). Qualitative image quality was assessed independently by two radiologists for ghost artifacts, edge sharpness, image noise, and overall image quality. Quantitative indices of signal-to-noise-ratio (SNR) and contrast-to-noise-ratio (CNR) were also analyzed by two radiologists. These indices were compared between two techniques in each group using Wilcoxon signed-rank test. Inter-observer agreement was assessed using Cohen's Kappa test and intraclass correlation coefficient.

RESULTS

In group A and B, T2W-FRFSE images without PROPELLER showed better image quality than those with PROPELLER in all qualitative and quantitative indices ($p<0.05$), except for ghost artifact in group A ($p=0.404$). In contrast, in group C and D, T2W-FRFSE images with PROPELLER showed better image quality than those without PROPELLER in all qualitative and quantitative indices ($p<0.05$) except for SNR in group C ($p=0.339$). Inter-observer agreements between two radiologists were excellent in all qualitative indices (kappa values >0.8) and quantitative indices (ICCs>0.8).

CONCLUSION

s Acquisition of T2W-FRFSE with PROPELLER yielded better image quality in patients with fast or inconsistent respiration than T2W-FRFSE without PROPELLER, and vice versa in patients with slow and steady respiration.

CLINICAL RELEVANCE/APPLICATION

Whether or not to utilize PROPELLER in acquisition of T2W-FRFSE should be determined according to the patient's respiratory pattern and rate.

W5A-SPPH-3

Toward a Simple Surrogate for Abdominopelvic Adipose Tissue Volume - Systematic MRI Assessment in Patients With Different BMI Classes

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Nicolas Linder, MD, Leipzig, Germany (*Presenter*) Nothing to Disclose

PURPOSE

Obesity is a leading health problem worldwide with numerous comorbidities, such as cardiovascular disease, with the amount of visceral fat often regarded as an important factor for prognosis. In routine practice, many have used the sagittal abdominal diameter (SAD) as a simple clinical marker of visceral fat. The aim of this work was to systematically correlate (MRI-derived) SADMR with the abdominopelvic visceral and subcutaneous adipose tissue (VAT/SAT) volume in patients with obesity.

METHODS AND MATERIALS

Full abdominopelvic MR datasets were available from 266 patients (196 females and 70 males) with obesity. SADMR was determined on axial images by the respective distance of a line through the center of the vertebral body at different levels (lumbar disc compartments L1-L2 to L5-S1 and umbilicus). VAT and SAT volumes were determined with a semiautomatic segmentation software. Agreement between SADMR and AT volumes was evaluated by correlation coefficients R.

RESULTS

SADMR ranged from 21.7 cm to 39.0 cm and total volume of VAT (SAT) ranged from 0.9 to 14.0 L (4.8 to 39.4 L). Over all patients, R values between SADMR and VAT ranged from 0.66 at L5-S1 to 0.71 at L2-L3 (mean R of 0.69). Between sexes, the highest R value was larger for women (0.74 at L2-L3 vs. 0.69 at L3-L4). Similarly strong correlations were also seen between SADMR and SAT with R values between 0.67 (L2-L3) and 0.73 (L5-S1) overall, and higher values for each sex. Strong correlations of SADMR were also maintained within BMI subgroups for each sex with VAT but not with SAT

CONCLUSION

s A gender-specific sagittal abdominal diameter has been shown to be a reliable measure for simple and rapid estimation of visceral fat volume in patients with different degrees of obesity.

CLINICAL RELEVANCE/APPLICATION

The presented parameter MRI-derived sagittal abdominal diameter (SADMR) promises to be a simple but reliable imaging marker of visceral obesity.

W5A-SPPH-4

Novel Free-Breathing Day-Optimizing-Throughput Sequences in Comparison with Conventional Breath-Hold Examinations During Whole-Body MRI

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Vitali Koch, MD, Frankfurt am Main, Germany (*Presenter*) Nothing to Disclose

PURPOSE

To assess and compare novel free-breathing DOT sequences (Day Optimizing Throughput) with conventional breath-hold examinations in whole-body magnetic resonance imaging (MRI).

METHODS AND MATERIALS

This prospective study included 26 subjects with a variety of pathologies who had undergone whole body 1.5-Tesla MRI. Image quality, diagnostic confidence, and image noise were evaluated by two experienced radiologists. Diagnostic performance for the overall detection of pathologies in both sequences was assessed using the area under the receiver operating characteristics curve (AUC). Additionally, study participants were asked to rate their examination experience in a satisfaction survey using a 10-point Likert scale.

RESULTS

MR free-breathing scans were rated as at least equivalent to conventional MR scans in more than 90% of cases, showing high overall diagnostic accuracy (95% [95% CI 92-100]) and performance (AUC 0.971, 95% CI 0.942 to 0.988; $P < 0.0001$) for the assessment of pathologies at simultaneously reduced examination time (50 ± 4 vs. 59 ± 5 minutes; $P < 0.0001$). Interrater agreement was excellent for both, free-breathing (? = 0.96 [95% CI, 0.88-1.00]) and conventional scans (? = 0.93 [95% CI, 0.84-1.00]). Ratings for image quality, image noise, and diagnostic confidence differed not significantly between the two types of MR image acquisition (all $P > 0.05$).

CONCLUSION

s MR images generated with free-breathing DOT sequences yielded similar diagnostic performance at equivalent image quality and noise levels compared to conventional breath-hold algorithms. Moreover, the long examination time of whole-body MRI could be considerably shortened for a more tolerable whole-body MRI experience.

CLINICAL RELEVANCE/APPLICATION

Free-breathing Day-Optimizing-Throughput (DOT) MRI yields comparable diagnostic accuracy compared to breath-hold MRI. Free-breathing DOT sequences provide high diagnostic confidence at low image noise levels. Free-breathing DOT whole-body MRI may represent a viable alternative to conventional MRI.

Technical and Clinical Considerations of a Physical Phantom for CT Radiomics Analysis

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Bino A. Varghese, PhD, Los Angeles, CA (*Presenter*) Nothing to Disclose

PURPOSE

Radiomic measurements can be impacted by differences in protocol and equipment. Statistical approaches such as ComBat reduces this impact, however, they ignore the variable relationship, between different radiomic metrics and imaging parameters, leading to suboptimal harmonization for some metrics. We identify key phantom characteristics to help build a physical phantom for CT-radiomics harmonization, particularly, the higher-order texture metrics.

METHODS AND MATERIALS

CT scans of a radiomics phantom comprising of 18 novel 3D printed inserts with varying size, shape, and material combinations were acquired on a 64-slice CT scanner (Brilliance 64, Philips Healthcare). The images were acquired at 120 kV, 250mAs, CTDIvol of 16.36 mGy, 2mm slice thickness and reconstructed using iDose1. Radiomics analysis was performed using the Cancer Imaging Phenomics Toolkit (CaPTk), following automated segmentation of volumes of interests (VOIs) of the 18 inserts. To add perspective to our findings we compared them to 3 additional VOIs obtained of an anthropomorphic liver phantom, a patient liver CT scan, and a water phantom, at comparable imaging settings. Percent difference in Hounsfield units (HU) between phantom and tissue was used to assess the biological equivalency and <10% was used to claim equivalent.

RESULTS

The HU for all 18 VOIs from the phantom ranged from -30 to 120 compared with a range of 0-118 for liver tissue. One of our novel phantom inserts, T3-6B, had >50% radiomic features that have <10% difference from liver tissue (patient). Second-order texture metrics, particularly, those of Neighborhood Gray Tone Difference Matrix (NGTDM), which are also representatives of the signal to noise ratio of CT scans, mostly show extreme values in the water phantom VOI compared to the VOIs from the phantom.

CONCLUSION

s The practice of using water phantom values which represent a structureless entity, will help identify limits of threshold for radiomic metrics, particularly texture. The practice of comparing the values to those from patient scans will help establish clinical relevance. By adopting some of the patterns from the radiomics phantom within the liver phantom, we will be able to selectively harmonize texture metrics, depending on its order and explore its association with imaging variables.

CLINICAL RELEVANCE/APPLICATION

Development of phantoms untangling the relationship between radiomic metrics and imaging variables will help establish quality assurance and control standards which are warranted for the clinical translation of radiomics.

Postural Effect on Renal Volume: Evaluation Using Multi-Posture MRI

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Seiya Nakagawa, BA, (*Presenter*) Nothing to Disclose

PURPOSE

Measurement of renal volume is vital for the early identification and monitoring of renal diseases. Nevertheless, it is unclear how postural changes, i.e., differences in the effects of gravity, alter renal volume. In this study, we evaluated the postural effect on renal volume in the supine and upright positions using an original magnetic resonance imaging (MRI) system that can image in any posture (multiposture MRI).

METHODS AND MATERIALS

Renal volume was evaluated in seven healthy volunteers (mean age, 22.7 ± 1.0 years; body mass index, 20.5 ± 1.0 kg/m2) in the supine and upright positions using multiposture MRI (0.4 T). A breath-hold 3D gradient-echo sequence was used to acquire coronal T1-weighted images of the right and left kidneys in the supine and upright positions. Then, the right and left renal volumes (whole kidney, renal cortex, medulla, and pelvis) were measured and compared across positions.

RESULTS

The whole kidney volume in the upright position (right kidney, 122.3 ± 20.1 mL; left kidney, 120.0 ± 14.5 mL) was significantly lower than that in the supine position (right kidney, 139.9 ± 21.0 mL; left kidney, 133.8 ± 18.9 mL) for both the right and left kidneys ($P < 0.05$ for both). The renal cortex volume in the upright position (right kidney, 77.0 ± 12.2 mL; left kidney, 75.3 ± 6.3 mL) was significantly lower than that in the supine position (right kidney, 89.3 ± 12.9 mL; left kidney, 85.0 ± 10.1 mL) for both the right and left kidneys ($P < 0.05$ for both). The renal medulla volume in the upright position (right kidney, 40.6 ± 7.3 mL; left kidney, 38.5 ± 7.1 mL) was significantly lower than that in the supine position (right kidney, 45.5 ± 8.7 mL; left kidney, 42.7 ± 7.7 mL) for both the right and left kidneys ($P < 0.05$ for both). These findings revealed a decrease in blood volume and urine volume owing to the fluid shift effect when standing. Moreover, in comparison with the standard MRI examination of the kidney, multiposture MRI provided additional diagnostic information on the regulatory function to the gravity. However, no significant difference was observed in the renal pelvis volume between the supine and upright positions for both the right and left kidneys. Furthermore, no significant differences were observed in the volume change ratio from the supine to upright between the right and left kidneys.

CONCLUSION

s An upright position reduces renal volume. Multiposture MRI enables the assessment of the postural effect on renal volume.

CLINICAL RELEVANCE/APPLICATION

An upright position reduces renal volume. Multiposture MRI revealed differences in the renal volume between the upright and supine positions, thereby providing new diagnostic information on the regulatory function to the gravity as compared with the standard MRI examination of the kidney.

Comparison of Image Quality Metrics Between Solid-State Digital-BGO PET/CT and Time-of-Flight LSO Systems

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Tala Palchan Hazan, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

A recently designed digital solid-state positron emission tomography/x-ray CT system (PET/CT) scanner with bismuth germanate (BGO) scintillators coupled to silicon photomultipliers provides for a 32 cm axial field of view. Image quality metrics from this ultra-high sensitivity digital-BGO system without time-of-flight (TOF) were compared to a lutetium oxyorthosilicate (LSO) based TOF PET/CT scanner.

METHODS AND MATERIALS

A national electrical manufacturers association (NEMA) image quality (IQ) phantom was prepared as per NEMA NU 2-2018 with a fluorine-18 radiotracer. The 6 hot spheres (10 to 37 mm in diameter) were scanned on the LSO and digital-BGO systems. List mode data were binned to 12 decay-corrected 2-minute equivalent acquisitions, each with approximately the same number of incident counts. In both systems, images were reconstructed using an ordered subset expectation maximization (OSEM) algorithm and compared (Kruskal-Wallis test) to TOF-OSEM from the LSO system. Additional LSO OSEM reconstructions relisted scans to 1.4, 2.25 and 3.6 times the number of incident counts. The IQ metric was the contrast to noise ratio (CNR), calculated by dividing the contrast of hot sphere activity with respect to the background by the coefficient of variation of the background.

RESULTS

All CNRs of the digital-BGO system were the same or greater compared to LSO TOF-OSEM. For the smallest feature, there was no statistically significant difference ($p<0.001$) in the CNR of the 10 mm sphere (CNR10) between LSO TOF-OSEM (25.8 ± 2.1, mean ± std. dev.) and the digital-BGO (24.8 ± 1.4). There was also no significant difference ($p<0.001$) in CNR10 between LSO TOF-OSEM and LSO OSEM using 2.25 times the number of incident counts (26.8 ± 1.9). Using 1.0 or 1.4 times the number of incident counts were insufficient to match LSO TOF-OSEM (19.0 ± 1.8, and 21.5 ± 1.8, respectively). Using 3.6 times the number of incident counts significantly improved CNR10 (35.0 ± 0.9, $p<0.001$) compared to LSO TOF-OSEM.

CONCLUSION

s The ultra-high sensitivity of a solid-state 32 cm axial FOV digital-BGO PET/CT system provides for image quality similar to TOF systems, as measured by CNR in NEMA phantoms.

CLINICAL RELEVANCE/APPLICATION

The ultra-high sensitivity of a novel solid-state digital-BGO PET/CT system provides for high quality imaging of small features, enabling the diagnosis of pathology through functional imaging.

Multiparametric MRI Method Development for Clinical Prostate Imaging Using 5T MR Imaging

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Liyun Zheng, Shanghai, China (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this study was to evaluate the development of prostate MRI at 5T by providing assessment of image quality on clinical sequences, including T1-weighted (T1W), T2-weighted (T2W) and diffusion-weighted imaging (DWI) sequences.

METHODS AND MATERIALS

Ten healthy subjects (mean age, 55.5 ± 7.5) were measured on a 5T MR scanner (uMR Jupiter, United Imaging Healthcare, Shanghai, China), using a 24-channel transmit/receive body array coil. SAR-monitoring and B0 and B1+ shimming were performed. Imaging sequences including: (1) axial T1W quick3d gradient echo (GRE) sequence (TR/TE = 3.34/1.42 ms, FA = 15°, Bandwidth = 850 Hz, 60 slices, Slice thickness = 3 mm, FOV = 300 × 400 mm, Matrix = 410 × 608, Number of averages = 2, Acquisition time = 16.9s); (2) axial T2W fat-saturated fast spin echo (FSE) sequence (TR/TE = 2600/128.24 ms, FA = 90°, Bandwidth = 200 Hz, 30 slices, Slice thickness = 5mm, FOV = 380 × 300 mm, Matrix = 639 × 504 , Number of averages = 2, Acquisition time = 2min10s); and (3) echo-planar imaging (EPI) - DWI (TR/TE = 3650/53 ms, FA = 90°, Bandwidth = 2100 Hz, 30 slices, Slice thickness = 5 mm, FOV = 180 × 380 mm, Matrix = 410 × 608, b = 50, 800 s/mm2, Number of averages = 2, 4). Image analysis was performed by two experienced radiologists in consensus. For all the sequences, overall image quality (5 = excellent, 1 = non-diagnostic) and presence of artifacts (5 = pronounced, 1 = none) were assessed on a 5-point scale. Visibility of anatomical structures, defined as distinction between peripheral and transition zone, seminal vesicles, and delineation of the prostate, was graded on T2W images utilizing a five-point scale (5 = excellent, 1 = unacceptable). For DWI, geometric distortion (defined as modification in size, profile, and/or orientation due to inhomogeneities of the magnetic field in relation to T2W images) was evaluated on a 5-point scale (5 = very high distortion, 1 = no distortion).

RESULTS

Overall image quality of T1W image was scored as moderate to good (3.9 ± 0.5), T2W image was scored as good to excellent (4.1 ± 0.8), while DWI was scored as moderate (3.0 ± 0.6). Presence of artifacts of T1W, T2W and DWI images were scored as none to minimal (1.5 ± 0.5 for T1W, 1.4 ± 0.5 for T2W, 1.8 ± 0.5 for DWI). Visibility of anatomical structures for T2W at 5T was graded as good to excellent (4.2 ± 0.7). Upon DWI at 5T, the geometric distortion was graded as no distortion to low distortion (1.5 ± 0.9).

CONCLUSION

s This study proved that prostate MRI, including T1W, T2W and DWI sequences at 5T can achieve diagnostic image quality.

CLINICAL RELEVANCE/APPLICATION

According to current results about image quality, presence of artifacts, visibility of anatomical structures of T2W images, and geometric distortion of DWI, clinical prostate imaging is feasible at 5T MRI.

How to Handle Zero Counts in Low Dose Photon Counting CT Imaging?

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - PH DPS

Participants
Dan Bushe, MSc, BSc, Madison, WI (*Presenter*) Nothing to Disclose

PURPOSE

The probability of registering a count of zero for a given pixel is significantly higher for photon counting detectors (PCDs) when compared with energy integrating detectors (EIDs). This is a result of the general one-to-one correspondence between the digital output of the PCD with the absorbed x-ray photons and the higher spatial resolution of PCD detectors (0.15-0.3 mm). In contrast, a single x-ray photon can generate tens to hundreds of digital counts in EID elements with a size of 1 mm or larger. This problem becomes further exacerbated when considering low dose PCD-CT applications, large patient imaging, and the allocation of counts to various energy bins for spectral imaging. Zero counts must be corrected before the nonlinear log transform is taken to generate the sinograms for CT image reconstruction. However, replacing zeros by any positive number alters the statistical distribution of counts and introduces biases that can manifest as severe shading or blooming artifacts. The purpose of this work was to develop a novel PCD-CT zero-count correction method that not only corrects zero-counts but also minimizes CT number biases.

METHODS AND MATERIALS

In this work, a novel Laurent expansion was introduced to approximate the log-transformed projection data. The coefficients of the truncated Laurent expansion were calibrated using the correspondence between low dose scans with zero counts and high-dose scans without zero counts. This method was experimentally validated using a CdTe-based PCD-CT system with 4 test objects and under 4 different dose levels. The severity of the zero counts problem ranged from less than 0.1% to 22%.

RESULTS

With a conventional zero-count replacement correction, images demonstrated severe blooming and shading artifacts due to sinogram biases. The proposed method eliminated those artifacts and reduced CT number biases from -930 HU (95% CI: -1267, -592HU) to -0.8 HU (95% CI: -1.5, -0.2 HU) for a Teflon insert and from 790 HU (95% CI: 552, 1028 HU) to 3.4 HU (95% CI: 3.0, 3.9 HU) for an air insert. For both conventional and proposed corrections, the limiting spatial resolution of the CT images was matched at 9 lp/cm.

CONCLUSION

s The proposed PCD-CT zero-count correction strategy not only corrects for zero-count pixels but also removes the associated biases. The method takes only a single pass and is computationally efficient. Furthermore, the method does not use any spatial filtering and thus does not introduce any spatial resolution loss.

CLINICAL RELEVANCE/APPLICATION

Zero detector counts are common in PCD-CT and severely degrade clinical diagnostic performance. This work addresses the long-standing zero-count correction problem and further elevates the clinical trustworthiness of PCD-CT.

Radiation Oncology Wednesday Poster Discussions - A

Wednesday, Nov. 30 12:15PM - 12:45PM Room: Learning Center - RO DPS

Participants
Tracy M. Sherertz, MD, Seattle, WA (*Moderator*) Nothing to Disclose

Sub-Events

W5A-SPRO-1 Performance of Conventional and Machine Learning Approaches for the Diagnosis of Tumor Recurrence on MRI After Radiation Therapy of Brain Metastases

Participants
Samy Ammari, MD, PhD, Villejuif, France (*Presenter*) Nothing to Disclose

PURPOSE

Objective of this study : To compare the performance of conventional and machine-learning approaches for the diagnosis of tumor recurrence after radiation therapy of brain metastases

METHODS AND MATERIALS

184 symptomatic patients with solitary metastatic brain lesions treated with radiation therapy were enrolled in a monocentric retrospective study from June 2013 to May 2018. The diagnosis was tumor recurrence (n=71) and radiation necrosis (n=113) using as reference standard expert-consensus derived from pathology and long-term follow-up. 37 potential predictors were recorded at the time of radiological progression (7-15 months after therapy): 6 clinical features and 31 imaging features including 20 radiomics features derived from standard of care 3D T1-gadolinium sequences. We compared four approaches (A, B, C, D): expert report using MRI sequences without (A) and with delayed-contrast MRI (TRAM) sequences (B), 11 non-Radiomics imaging features alone (C) and a signature combining variables selected using unsupervised machine-learning algorithms (D, training:validation sets: n=144:40 pts).

RESULTS

Overall (n=184), approaches B and C (using TRAM sequence alone) reached comparable performances with respective AUCs[95CI] of 78.7%[72.3%-85.1%] and 76.8%[70.3%-83.3%]. Both significantly outperformed approach A with AUC[95CI] of 57.4%[50.7%-64.1%] (DeLong's test, p-value=10-7). In the validation set (n=40), the signature reached an AUC[95CI] of 92%[87%-97%]

CONCLUSION

s A quantitative analysis of TRAM sequence seems the best approach for the diagnosis of recurrent tumor after radiation therapy. It is parsimonious, objective and less time-consuming than interpreting all sequences. A signature derived from the analysis of standard of care 3D T1-gadolinium sequence showed promising results that warrant prospective validation.

CLINICAL RELEVANCE/APPLICATION

radiomics in combination with clinical data have successfully predicted the survival of recurrent GBM patients treated with bevacizumab. Three different binary models for survival prediction at 9, 12, and 15 months with high performances were built, which could lead to the creation of a convenient tool for decision making and the orientation to a more patient-specific treatment in the era of personalized medicine. Larger trials are needed for better identification and adaptation of these models in GBM patients.

W5A-SPVA-1 The Role of Dual-Energy CT Spectral Parameters in the Differentiation Between Thrombosis and Intravenous Bolus Injection Caused Superior Vena Cava Artifacts

Participants
Qingle Wang, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

To explore the value of dual-energy CT spectral parameters in distinguishing right upper pulmonary artery (PA) artifact (caused by intravenous bolus injection) and thrombus.

METHODS AND MATERIALS

18 patients with thrombosis (verified by two experienced radiologists) underwent pulmonary artery computed tomography angiography (CTPA)(Revolution,GE healthcare) were included. Virtual monochromatic images at 70, 90 keV, iodine-based decomposition images and effective atomic number (Eff-Z) images were obtained. ROIs were placed on the low-density area of the right upper PA (artifacts, AF), the corresponding normal area of left upper PA (NOM), and embolism area (PE, if left upper PA embolism, change the nearby normal right middle PA). Then, slopes of spectral curves from 40 to 90 keV (?40-90 keV) and 50 to 100 keV (?50-100 keV), CT values of monochromatic images at 70, 90 keV (HU70keV, 90keV), Eff-Z, iodine concentration (IC), were measured and calculated. Eff-Z and IC were normalized by the values on PA trunk to derive a normalized Eff-Z (Neff-Z) and normalized IC (NIC). One-way ANOVA, Kruskal Wallis U, LSD and Mann-Whitney U were used for comparison, and receiver operation curve (ROC) was utilized for evaluating the differentiation performance of spectral parameters, and sensitivity, specificity and area under curve (AUC) were calculated.

RESULTS

On NOM, AF and PE, HU70keV were (362.12±83.59, 292.55±71.83, 164.32±85.31, $p<0.05$), HU90keV were (211.37±51.84, 161.30±47.21, 66.03±66.22,$p<0.05$), NIC were (1.49±1.99, 0.88±0.13, 0.69±0.26,), NEff-Z were (1.00±0.03, 0.98±0.03, 0.92±0.10),?40-90 keV were (0.81±0.01, 0.83±0.03, 0.91±0.08), ?50-100 keV were (0.77±0.02, 0.80±0.05, 0.93±0.15), with statistical differences between AF and PE ($p<0.05$), NOM and PE ($p<0.05$). For the differentiation between AF and PE, HU70keV (threshold of 228.51), HU90keV (threshold of 78.89), NEff-Z (0.92), NIC (0.72),?40-90 keV (0.89),?50-100 keV (0.89) showed sensitivities of (0.88, 0.94, 1.00, 0.94, 0.67, 0.67), specificities of (0.78, 0.72, 0.44, 0.50, 0.94, 0.94), AUC of (0.87, 0.89, 0.67, 0.73, 0.85, 0.85). The diagnostic efficiency of HU90 keV is the highest.

CONCLUSION

s CT spectral parameters played an important role in differentiating the right upper PA artifact interference of contrast medium in superior vena cava from PE, therein HU90 keV had highest diagnostic efficiency.

CLINICAL RELEVANCE/APPLICATION

When CTPA, contrast accumulation in superior vena cava results in focal artifacts, which is similar to small emboli. Spectral CT quantitative parameters are helpful for the differentiation and increasing diagnostic confidence.

W5B-SPBR-1 Automated Breast Arterial Calcification Detection is Improved with Digital Breast Tomosynthesis

Participants
Tara Retson, MD, PhD, San Diego, CA (*Presenter*) Research Consultant, CureMetrix, Inc;Stock options, CureMetrix, Inc

PURPOSE

Breast arterial calcification (BAC) represents a risk marker for cardiovascular disease (CVD) but is widely underreported by radiologists. Automated detection software may improve BAC reporting by radiologists and also provide a consistent scale for characterizing BAC extent. We demonstrate the accuracy of an artificial intelligence (AI) model for breast arterial calcification (BAC) detection and localization on full field digital (FFDM) and digital breast tomosynthesis (DBT) mammograms.

METHODS AND MATERIALS

A total of 1204 images from 473 patients from 3 different institutions in the United States were studied. Of these, 256 patients underwent FFDM exams and 217 patients had DBT exams. The AI model, cmAngio™ (CureMetrix, Inc, La Jolla, CA) is a deep convolutional neural network for BAC segmentation and quantification which can provide both binary (BAC presence vs absence) results and the Bradley scoreTM (which ranges from 0-100). The Bradley score quantitates characteristics of BAC at the case level, including extent. The area under the receiver operating characteristic curve (AUROC) for presence or absence of BAC was calculated, with 95% bootstrap confidence intervals (CI). For BAC segmentation, average precision (AP) of BAC positive pixels is used as the primary performance metric. Precision, sensitivity, specificity of cmAngio form FFDM vs. DBT was obtained.

RESULTS

For BAC detection, cmAngio achieved an image-level area under the curve (AUROC) of 0.966 [CI:0.956, 0.984] and a case level AUROC of 0.945 [CI:0.894, 0.973] for FFDM. The image-level AUROC of 0.977 [CI:0.961, 0.988] and a case level AUROC of 0.966 [CI:0.939, 0.988] was achieved with cmAngio for DBT.For BAC segmentation, cmAngio achieved an AP of 0.614 [CI:0.599, 0.629] and 0.752 [CI:0.731, 0.773] for FFDM and DBT respectively. At the threshold level of 0.5, cmAngio achieved a precision, sensitivity, specificity of 0.629, 0.512, 1.000 for FFDM and on DBT achieved a precision, sensitivity and specificity of 0.733, 0.557, 1.000.

CONCLUSION

s BAC detection with cmAngio is excellent, and noted to be slightly superior for DBT compared to FFDM. This is partially due to the fact that the masking effect of dense tissue on BAC, as occurs with other types of lesions on FFDM, is reduced in DBT.

CLINICAL RELEVANCE/APPLICATION

Reporting of breast arterial calcifications may be enhanced through the use of this highly accurate automated artificial intelligence model for both full field digital and digital breast tomosynthesis mammography.

W5B-SPBR-2 Radiomic Features at Breast MRI Predict Non-Upgrade of DCIS Lesions to Invasive Malignancy

Participants
Dana Ataya, MD, Tampa, FL (*Presenter*) Nothing to Disclose

PURPOSE

Identification of ductal carcinoma in-situ (DCIS) lesions diagnosed on core biopsy which will not be upgraded to invasive breast cancer on excision could guide clinical management in cases where de-escalation of therapy is preferred. We investigated whether radiomic features extracted from DCIS lesions on dynamic contrast enhanced (DCE)-MRI predicted non-upgrade to invasive malignancy.

METHODS AND MATERIALS

113 DCIS lesions diagnosed on core biopsy were divided into training (80) and testing (33) cohorts. DCIS lesions were identified by a sub-specialized breast radiologist and segmented on pre-operative DCE-MRI. Four perfusion parameters were used to generate voxel multi-parametric maps: wash-in (WIS) and washout (WOS) slopes, percentage enhancement (PE), and signal enhancement ratio (SER). Consensus clustering and superpixel maps divided each tumor into three perfusional subregions (habitats). Following z-score normalization of total signal intensity on T1 weighted post-gadolinium acquisition, 306 radiomics features were extracted from the three habitat subregions (Model 1) and from the whole DCIS lesion (Model 2). Using a minimum redundancy maximum relevance (MRMR) algorithm, correlation of features to outcome was rank ordered with the top 10% of features selected for further analysis. The selected radiomic features were used to train a binary (upgrade vs. no upgrade) decision tree classification system for each

model. The final trained models were used to classify each core biopsy DCIS lesion in the testing cohort into the binary outcome of upgrade to invasive malignancy on surgical pathology.

RESULTS

The frequency of upgrade from DCIS on core biopsy to invasive malignancy on excision was similar in both cohorts (22.5% training; 22.2% testing). Radiomic features extracted from each subregion and from the whole lesion within both cohorts were examined. Of 306 extracted radiomic features, the MRMR algorithm identified an optimal set of 4 features from the three subregions (habitats) and 4 features from the whole lesion that were most informative. Model 1 predicted non-upgrade to invasive malignancy with 78% accuracy (66.7% true positives (TP), 81.5% true negatives (TN)). Model 2 predicted non-upgrade to invasive malignancy with 87.9% accuracy (83.3% TP, 88.9% TN).

CONCLUSION

s Radiomic features on dynamic contrast enhanced breast MRI can assist at identifying DCIS lesions at low risk of upgrade to invasive malignancy.

CLINICAL RELEVANCE/APPLICATION

Identification of DCIS lesions at low-risk of upgrade to invasive malignancy can help guide clinical management of patients, particularly if de-escalation of therapy is desired.

W5B-SPBR-3 Multi-Parametric MRI-Based Radiomics Models for Early Neoadjuvant Systemic Treatment Response Prediction in Triple Negative Breast Cancer (TNBC)

Participants
Bikash Panthi, Houston, TX (*Presenter*) Nothing to Disclose

PURPOSE

TNBC accounts for 10-20 % of all breast cancers and is often treated with neoadjuvant systemic therapy (NAST). Early prediction of the treatment response can potentially triage the patients without pathological complete response (pCR) to alternative treatments to improve outcomes. In this study, we investigated if the radiomic models based on the dynamic contrast-enhanced (DCE) and diffusion-weighted imaging (DWI) MRI images obtained early during NAST can be a noninvasive biomarker for pCR prediction.

METHODS AND MATERIALS

Our analysis included 182 stage I-III TNBC patients who were enrolled in an IRB-approved prospective clinical trial (NCT02276433) and who had multiparametric MRIs at baseline (BL), post 2 cycles (C2), and post 4 cycles (C4) of NAST before surgery. Tumors were segmented on the 2.5 minutes DCE subtraction images and on the b=800 DWI images. Whole-tumor histogram-based first-order texture features (p=10) and radiomic features were extracted (p=300 radiomic Grey Level Co-occurrence matrix (GLCM) features) with an in-house Matlab toolbox. Treatment response at surgery (pCR vs non-pCR) was assessed. The samples were split into training and testing data sets by a 2:1 ratio. Area under the receiver operating characteristics curve (AUC ROC) was performed for univariate analysis in predicting pCR status. Logistic regression with elastic net regularization was performed for texture feature selection. Parameter optimization was performed by using 5-fold cross-validation based on mean cross-validated AUC in the training set.

RESULTS

Of the total 182 patients, 94 (52%) had pCR and 88 (48%) had non-pCR. Thirty-six multivariate models combining radiomic features from both DCE and DWI had AUC > 0.7 ($p<0.003$), two of which showed AUC > 0.8 ($p<0.001$) in both training and testing data. The first model combined 4 radiomic features from C2 (1 GLCM feature), C4 (percentile 5, 1 GLCM feature) and their changes in C4/C2 (mean) with AUC=0.808, and the second model combined 13 radiomic features at BL (kurtosis, 2 GLCM features), C2 (1 GLCM feature), C4 (3 GLCM features) and their changes in C2/BL (1 GLCM feature), C4/BL (percentile 99, minimum, mean) and C4/C2 (mean, 1 GLCM feature) with AUC=0.816.

CONCLUSION

s Multi-parametric MRI-based radiomics models showed high accuracy for early prediction of NAST response in TNBC patients.

CLINICAL RELEVANCE/APPLICATION

Radiomic models based on multi-parametric MRI can potentially be helpful for the selection of the appropriate treatment strategy for TNBC patients undergoing NAST.

W5B-SPBR-4 The Impact of Social Determinants of Health on the Time Between Diagnostic Breast Imaging and Biopsy at a Safety Net Hospital

Participants
Kevin Dao, Boston, MA (*Presenter*) Nothing to Disclose

PURPOSE

There is limited literature on the direct impact of social determinants of health (SDH) on delays in breast cancer diagnosis via breast imaging. Identifying SDH associated with longer lapses between imaging and biopsy is essential to early-stage detection of breast cancer. Previous work demonstrated associations between both housing and food insecurity with longer lapses between diagnostic imaging and biopsy. With this study, we aim to expand upon this retrospective analysis with a longer study period, more participants, and improved data cleaning techniques to better understand how SDH may affect the lapse between imaging and biopsy.

METHODS AND MATERIALS

This retrospective study was IRB approved and HIPAA compliant. Informed consent was waived. Patients who underwent screening mammography between January 1 2015 and January 1 2020 were assessed for timing of recommended biopsy due to a BIRADS 4 or 5. SDH were assessed with the unique Tool for Health Resilience in Vulnerable Environments (THRIVE) screening questionnaire developed at Boston Medical Center. Associations between imaging-biopsy timing and 8 explanatory SDH variables were assessed

with multivariate Cox proportional hazard modeling, as well as demographic data.

RESULTS

2885 unique patients who underwent 3142 unique diagnostic imaging studies were included in the multivariate analysis. Of those 3142 studies, 196 (6.2%) had not yet been followed by the recommended biopsy by the end of the study period. 2159 patients (74.8%) had SDH data in at least one domain, and the individual domains ranged from 875 patients (30.3%) with complete data for education to 2073 patients (71.8%) with complete data for food insecurity. A positive screen for at least one SDH was associated with a longer lapse between diagnostic imaging and biopsy (p=0.048). Further, housing insecurity alone was nearly associated with longer lapses between diagnostic imaging and biopsy (p=0.059). Paradoxically, those who desired more education were found to have shorter lapses between diagnostic imaging and biopsy (p=0.037).

CONCLUSION

s Of the eight SDH screened, housing insecurity was most close to association with longer lapses between diagnostic imaging and biopsy. However, only the aggregate of all SDH was associated with a statistically significant lengthening of this lapse. Patients who desired more education were found to have shorter lapses, but this survey domain had the lowest completion rate.

CLINICAL RELEVANCE/APPLICATION

Identification of SDH that may affect the time from imaging to biopsy can potentially inform targeted programs to intervene. Government and health system interventions addressing SDH, notably housing insecurity, could allow for shorter time to breast cancer diagnosis and treatment.

W5B-SPBR-5 BI-RADS-0 Screening Mammography: Risk Factors Associated with Prolonged Follow-up Time to Diagnostic Evaluation

Participants
Samantha Platt, MD, New York, NY (*Presenter*) Nothing to Disclose

PURPOSE

BI-RADS-0 screening mammograms require follow-up diagnostic imaging, optimally within 60 days. Our study aims to identify risk factors for prolonged follow-up.

METHODS AND MATERIALS

We conducted a retrospective, observational, case-control study of women aged 40-91 from breast centers in the Mount Sinai System who had nondiagnostic BI-RADS-0 screening mammogram between 3/19/18-3/19/20. Sociodemographic information was collected from a self-reported screening questionnaire. Patients who underwent screening in the mobile mammography van or had incorrect follow-up dates were excluded. Analysis 1: Goal was to identify risk factors associated with the following outcomes categories: <60d follow-up, >60d follow-up or no follow-up. Chi-squared tests and univariate logistic regressions were performed. Significant variables were included in multinomial logistic regression model with <60d follow-up as the reference group. Analysis 2: Goal was to identify risk factors that lead to prolonged follow-up times among women with follow-up. Shapiro-Wilk test determined a non-normal distribution of the dependent variable (0.61, $p < 0.0001$). Spearman's rank coefficient of correlation, Mann Whitney Wilcoxon Test, and Kruskal-Wallis Tests were used.

RESULTS

Our review returned 5,034 screening mammograms. Of 4,552 patients included in the study, 904 (19.9%) had no follow-up. Of the 3,648 (80.1%) with follow-up, 2,797 (76.7%) had a follow-up examination <60d (avg. 22.1 days) and 851 (23.3%) had follow-up >60d (avg. 190.4 days). Multinomial log regression found that Asian women, black women, and those who identified as "other" were independently more likely to have no or >60d follow-up ($p<0.05$). Women who did not report their race were more likely to have no or >60d follow-up ($p<0.05$). Women who completed the questionnaire in Spanish were more likely to have no or >60d follow-up ($p<0.05$). Amongst women with follow-up, black women, those who identified as "other", LatinX women, and those completed the questionnaire in Spanish had significant follow-up delays ($p<0.05$). BRCA+ patients had shorter follow-up times ($p<0.05$).

CONCLUSION

s Follow-up time is affected by patient-specific breast cancer risk factors such as BRCA status as well as disparities in health care access by race, primary language and Latinx heritage.

CLINICAL RELEVANCE/APPLICATION

There are risk factors associated with prolonged follow-up time to diagnostic evaluation that need to be targeted in order to improve patient outcomes.

W5B-SPBR-6 Frequency and outcome of probably benign findings (BI-RADS 3) in patients with a personal history of breast cancer (PHBC) imaged with digital mammography (DM) vs. digital breast tomosynthesis (DBT)

Participants
Lily Offit, Boston, MA (*Presenter*) Nothing to Disclose

PURPOSE

Probably benign (BI-RADS 3) findings are those with <2% malignancy rate, and are followed with imaging at 6, 12, and 24 months. Few studies have reported probably benign outcomes in patients with a personal history of breast cancer (PHBC) and have shown >2% malignancy rates. The purpose of this study is to determine the frequency, findings, and outcomes of probably benign findings in patients with PHBC imaged with digital mammography (DM) versus digital breast tomosynthesis (DBT).

METHODS AND MATERIALS

This is a retrospective review of 14,845 mammogram reports in patients with PHBC (mastectomy and/or lumpectomy). Of these, 8,422 exams (56.7%) were DM between 10/2014-9/16 and 6,423 exams (43.3%) were DBT between 2/2017-12/2018. Frequency and indication of BI-RADS 3 assignment, mammographic finding (calcifications, architectural distortions, asymmetries, or mass), and

biopsy or follow-up imaging outcomes were compared between DM and DBT.

RESULTS

In the study periods, there were 901/14,845 (6.1%) examinations coded as BI-RADS 3, with 717 unique BI-RADS 3 findings. DBT led to a reduced use of probably benign assignments when compared to DM (6.4% for DM vs. 5.6% for DBT, p=0.04). DM had a higher rate of malignancy of subsequently biopsied BI-RADS findings when compared to DBT [(4.8% (21/442) DM vs. 1.8% (5/275) DBT (p=0.04)]. DBT showed a 10.1% increase in percent of masses detected compared to DM (p=0.004). There was a trend towards more probably benign calcifications detected in DM (p=0.06).

CONCLUSION

s Use of DBT in individuals with a prior history of breast cancer led to a decrease in rate of BI-RADS 3 assignment. DM BI-RADS 3 rate of malignancy was 4.8%, higher than the accepted 2% malignancy rate, and decreased to 1.8% with use of DBT.

CLINICAL RELEVANCE/APPLICATION

Insight into BI-RADS 3 usage and malignancy rates between imaging modalities will help establish whether probably benign assessments in patients with PHBC are being utilized appropriately to identify cancers early and reduce unnecessary biopsies.

W5B-SPBR-7 Interval Breast Cancers Compared to Screen Detected Breast Cancers: A Retrospective Cohort Study

Participants
Emily Ambinder, MD, MSc, Ellicott City, MD (*Presenter*) Nothing to Disclose

PURPOSE

Mammographic screening improves mortality from breast cancer through early detection. We aim to identify clinical and imaging features that differentiate screen detected breast cancers from interval breast cancers in order to inform and improve breast cancer screening for all women in the era of precision medicine.

METHODS AND MATERIALS

All screening mammograms (n= 211,514) performed between 7/1/2013 and 6/30/2020 at our institution were reviewed. Patients with breast cancer diagnosed within one year of screening were included in this study. Patient, imaging, and cancer characteristics of screen detected breast cancers and interval breast cancers were compared using the Chi square test, Fisher test, and Wilcoxon Rank Sum Test. Interval cancers were defined as breast cancers diagnosed within one year of a negative screening mammogram.

RESULTS

During the study period, 1,232 women were diagnosed with breast cancer and included in this study (mean age 64 years, standard deviation 11 years). Overall sensitivity of screening mammography was 91% (1,121 screen detected breast cancers and 111 interval cancers). Interval cancers were most often palpable (62/111=56%) or identified on a high-risk screening breast MRI (20/111=18%). Patient age, race, and screening exam modality (FFDM versus DBT) were similar for patients with screen detected cancers and interval cancers (all p>0.05). Breast density was higher for patients with interval cancers (heterogeneously dense or extremely dense: 86/111=77% versus 683/1121=61%, p<-.001).Compared to screen detected cancers, interval cancers were less often ductal carcinoma in situ or primary tumor stage 1 (69/111=62% versus 981/1121=88%, p<0.001) and less often regional lymph node stage 0 (89/111=80% versus 990/1121=88%, p<-0.001). Interval cancers were less often hormone receptor positive (ER+: 73/94=78% versus 746/824=91%, p<-001), and less often had low proliferative indices (Ki67 <20%: 21/52=40% versus 301/488=62%, p=0.005). HER2 positivity was similar for the two groups (8/91=9% versus 84/804=10%, p=0.76).

CONCLUSION

s We found that mammographic screening has a high sensitivity for detection of breast cancer (91%). Interval cancers were often palpable or identified on a screening breast MRI and were associated with dense breast tissue but did not differ by age and race compared to screen detected cancers. Interval cancers were higher stage with less favorable molecular features compared to screen detected cancers.

CLINICAL RELEVANCE/APPLICATION

While screening mammography has a high sensitivity for detecting breast cancer, novel approaches are needed to identify interval cancers earlier as these are often higher stage with unfavorable molecular features compared to screen detected cancers.

W5B-SPBR-1

Automated Breast Arterial Calcification Detection is Improved with Digital Breast Tomosynthesis

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - BR DPS

Participants
Tara Retson, MD, PhD, San Diego, CA (*Presenter*) Research Consultant, CureMetrix, Inc;Stock options, CureMetrix, Inc

PURPOSE

Breast arterial calcification (BAC) represents a risk marker for cardiovascular disease (CVD) but is widely underreported by radiologists. Automated detection software may improve BAC reporting by radiologists and also provide a consistent scale for characterizing BAC extent. We demonstrate the accuracy of an artificial intelligence (AI) model for breast arterial calcification (BAC) detection and localization on full field digital (FFDM) and digital breast tomosynthesis (DBT) mammograms.

METHODS AND MATERIALS

A total of 1204 images from 473 patients from 3 different institutions in the United States were studied. Of these, 256 patients underwent FFDM exams and 217 patients had DBT exams. The AI model, cmAngio™ (CureMetrix, Inc, La Jolla, CA) is a deep convolutional neural network for BAC segmentation and quantification which can provide both binary (BAC presence vs absence) results and the Bradley scoreTM (which ranges from 0-100). The Bradley score quantitates characteristics of BAC at the case level, including extent. The area under the receiver operating characteristic curve (AUROC) for presence or absence of BAC was calculated, with 95% bootstrap confidence intervals (CI). For BAC segmentation, average precision (AP) of BAC positive pixels is used as the primary performance metric. Precision, sensitivity, specificity of cmAngio form FFDM vs. DBT was obtained.

RESULTS

For BAC detection, cmAngio achieved an image-level area under the curve (AUROC) of 0.966 [CI:0.956, 0.984] and a case level AUROC of 0.945 [CI:0.894, 0.973] for FFDM. The image-level AUROC of 0.977 [CI:0.961, 0.988] and a case level AUROC of 0.966 [CI:0.939, 0.988] was achieved with cmAngio for DBT.For BAC segmentation, cmAngio achieved an AP of 0.614 [CI:0.599, 0.629] and 0.752 [CI:0.731, 0.773] for FFDM and DBT respectively. At the threshold level of 0.5, cmAngio achieved a precision, sensitivity, specificity of 0.629, 0.512, 1.000 for FFDM and on DBT achieved a precision, sensitivity and specificity of 0.733, 0.557, 1.000.

CONCLUSION

s BAC detection with cmAngio is excellent, and noted to be slightly superior for DBT compared to FFDM. This is partially due to the fact that the masking effect of dense tissue on BAC, as occurs with other types of lesions on FFDM, is reduced in DBT.

CLINICAL RELEVANCE/APPLICATION

Reporting of breast arterial calcifications may be enhanced through the use of this highly accurate automated artificial intelligence model for both full field digital and digital breast tomosynthesis mammography.

W5B-SPBR-2

Radiomic Features at Breast MRI Predict Non-Upgrade of DCIS Lesions to Invasive Malignancy

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - BR DPS

Participants
Dana Ataya, MD, Tampa, FL (*Presenter*) Nothing to Disclose

PURPOSE

Identification of ductal carcinoma in-situ (DCIS) lesions diagnosed on core biopsy which will not be upgraded to invasive breast cancer on excision could guide clinical management in cases where de-escalation of therapy is preferred. We investigated whether radiomic features extracted from DCIS lesions on dynamic contrast enhanced (DCE)-MRI predicted non-upgrade to invasive malignancy.

METHODS AND MATERIALS

113 DCIS lesions diagnosed on core biopsy were divided into training (80) and testing (33) cohorts. DCIS lesions were identified by a sub-specialized breast radiologist and segmented on pre-operative DCE-MRI. Four perfusion parameters were used to generate voxel multi-parametric maps: wash-in (WIS) and washout (WOS) slopes, percentage enhancement (PE), and signal enhancement ratio (SER). Consensus clustering and superpixel maps divided each tumor into three perfusional subregions (habitats). Following z-score normalization of total signal intensity on T1 weighted post-gadolinium acquisition, 306 radiomics features were extracted from the three habitat subregions (Model 1) and from the whole DCIS lesion (Model 2). Using a minimum redundancy maximum relevance (MRMR) algorithm, correlation of features to outcome was rank ordered with the top 10% of features selected for further analysis. The selected radiomic features were used to train a binary (upgrade vs. no upgrade) decision tree classification system for each model. The final trained models were used to classify each core biopsy DCIS lesion in the testing cohort into the binary outcome of upgrade to invasive malignancy on surgical pathology.

RESULTS

The frequency of upgrade from DCIS on core biopsy to invasive malignancy on excision was similar in both cohorts (22.5% training; 22.2% testing). Radiomic features extracted from each subregion and from the whole lesion within both cohorts were examined. Of 306 extracted radiomic features, the MRMR algorithm identified an optimal set of 4 features from the three subregions (habitats) and 4 features from the whole lesion that were most informative. Model 1 predicted non-upgrade to invasive malignancy with 78% accuracy (66.7% true positives (TP), 81.5% true negatives (TN)). Model 2 predicted non-upgrade to invasive malignancy with 87.9% accuracy (83.3% TP, 88.9% TN).

CONCLUSION

s Radiomic features on dynamic contrast enhanced breast MRI can assist at identifying DCIS lesions at low risk of upgrade to invasive malignancy.

CLINICAL RELEVANCE/APPLICATION

Identification of DCIS lesions at low-risk of upgrade to invasive malignancy can help guide clinical management of patients, particularly if de-escalation of therapy is desired.

W5B-SPBR-3

Multi-Parametric MRI-Based Radiomics Models for Early Neoadjuvant Systemic Treatment Response Prediction in Triple Negative Breast Cancer (TNBC)

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - BR DPS

Participants
Bikash Panthi, Houston, TX (*Presenter*) Nothing to Disclose

PURPOSE

TNBC accounts for 10-20 % of all breast cancers and is often treated with neoadjuvant systemic therapy (NAST). Early prediction of the treatment response can potentially triage the patients without pathological complete response (pCR) to alternative treatments to improve outcomes. In this study, we investigated if the radiomic models based on the dynamic contrast-enhanced (DCE) and diffusion-weighted imaging (DWI) MRI images obtained early during NAST can be a noninvasive biomarker for pCR prediction.

METHODS AND MATERIALS

Our analysis included 182 stage I-III TNBC patients who were enrolled in an IRB-approved prospective clinical trial (NCT02276433) and who had multiparametric MRIs at baseline (BL), post 2 cycles (C2), and post 4 cycles (C4) of NAST before surgery. Tumors were segmented on the 2.5 minutes DCE subtraction images and on the b=800 DWI images. Whole-tumor histogram-based first-order texture features (p=10) and radiomic features were extracted (p=300 radiomic Grey Level Co-occurrence matrix (GLCM) features) with an in-house Matlab toolbox. Treatment response at surgery (pCR vs non-pCR) was assessed. The samples were split into training and testing data sets by a 2:1 ratio. Area under the receiver operating characteristics curve (AUC ROC) was performed for univariate analysis in predicting pCR status. Logistic regression with elastic net regularization was performed for texture feature selection. Parameter optimization was performed by using 5-fold cross-validation based on mean cross-validated AUC in the training set.

RESULTS

Of the total 182 patients, 94 (52%) had pCR and 88 (48%) had non-pCR. Thirty-six multivariate models combining radiomic features from both DCE and DWI had AUC > 0.7 ($p<0.003$), two of which showed AUC > 0.8 ($p<0.001$) in both training and testing data. The first model combined 4 radiomic features from C2 (1 GLCM feature), C4 (percentile 5, 1 GLCM feature) and their changes in C4/C2 (mean) with AUC=0.808, and the second model combined 13 radiomic features at BL (kurtosis, 2 GLCM features), C2 (1 GLCM feature), C4 (3 GLCM features) and their changes in C2/BL (1 GLCM feature), C4/BL (percentile 99, minimum, mean) and C4/C2 (mean, 1 GLCM feature) with AUC=0.816.

CONCLUSION

s Multi-parametric MRI-based radiomics models showed high accuracy for early prediction of NAST response in TNBC patients.

CLINICAL RELEVANCE/APPLICATION

Radiomic models based on multi-parametric MRI can potentially be helpful for the selection of the appropriate treatment strategy for TNBC patients undergoing NAST.

W5B-SPBR-4

The Impact of Social Determinants of Health on the Time Between Diagnostic Breast Imaging and Biopsy at a Safety Net Hospital

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - BR DPS

Participants
Kevin Dao, Boston, MA (*Presenter*) Nothing to Disclose

PURPOSE

There is limited literature on the direct impact of social determinants of health (SDH) on delays in breast cancer diagnosis via breast imaging. Identifying SDH associated with longer lapses between imaging and biopsy is essential to early-stage detection of breast cancer. Previous work demonstrated associations between both housing and food insecurity with longer lapses between diagnostic imaging and biopsy. With this study, we aim to expand upon this retrospective analysis with a longer study period, more participants, and improved data cleaning techniques to better understand how SDH may affect the lapse between imaging and biopsy.

METHODS AND MATERIALS

This retrospective study was IRB approved and HIPAA compliant. Informed consent was waived. Patients who underwent screening mammography between January 1 2015 and January 1 2020 were assessed for timing of recommended biopsy due to a BIRADS 4 or 5. SDH were assessed with the unique Tool for Health Resilience in Vulnerable Environments (THRIVE) screening questionnaire developed at Boston Medical Center. Associations between imaging-biopsy timing and 8 explanatory SDH variables were assessed with multivariate Cox proportional hazard modeling, as well as demographic data.

RESULTS

2885 unique patients who underwent 3142 unique diagnostic imaging studies were included in the multivariate analysis. Of those 3142 studies, 196 (6.2%) had not yet been followed by the recommended biopsy by the end of the study period. 2159 patients (74.8%) had SDH data in at least one domain, and the individual domains ranged from 875 patients (30.3%) with complete data for education to 2073 patients (71.8%) with complete data for food insecurity. A positive screen for at least one SDH was associated with a longer lapse between diagnostic imaging and biopsy (p=0.048). Further, housing insecurity alone was nearly associated with longer lapses between diagnostic imaging and biopsy (p=0.059). Paradoxically, those who desired more education were found to have shorter lapses between diagnostic imaging and biopsy (p=0.037).

CONCLUSION

s Of the eight SDH screened, housing insecurity was most close to association with longer lapses between diagnostic imaging and biopsy. However, only the aggregate of all SDH was associated with a statistically significant lengthening of this lapse. Patients who desired more education were found to have shorter lapses, but this survey domain had the lowest completion rate.

CLINICAL RELEVANCE/APPLICATION

Identification of SDH that may affect the time from imaging to biopsy can potentially inform targeted programs to intervene. Government and health system interventions addressing SDH, notably housing insecurity, could allow for shorter time to breast cancer diagnosis and treatment.

BI-RADS-0 Screening Mammography: Risk Factors Associated with Prolonged Follow-up Time to Diagnostic Evaluation

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - BR DPS

Participants
Samantha Platt, MD, New York, NY (*Presenter*) Nothing to Disclose

PURPOSE

BI-RADS-0 screening mammograms require follow-up diagnostic imaging, optimally within 60 days. Our study aims to identify risk factors for prolonged follow-up.

METHODS AND MATERIALS

We conducted a retrospective, observational, case-control study of women aged 40-91 from breast centers in the Mount Sinai System who had nondiagnostic BI-RADS-0 screening mammogram between 3/19/18-3/19/20. Sociodemographic information was collected from a self-reported screening questionnaire. Patients who underwent screening in the mobile mammography van or had incorrect follow-up dates were excluded. Analysis 1: Goal was to identify risk factors associated with the following outcomes categories: <60d follow-up, >60d follow-up or no follow-up. Chi-squared tests and univariate logistic regressions were performed. Significant variables were included in multinomial logistic regression model with <60d follow-up as the reference group. Analysis 2: Goal was to identify risk factors that lead to prolonged follow-up times among women with follow-up. Shapiro-Wilk test determined a non-normal distribution of the dependent variable (0.61, $p < 0.0001$). Spearman's rank coefficient of correlation, Mann Whitney Wilcoxon Test, and Kruskal-Wallis Tests were used.

RESULTS

Our review returned 5,034 screening mammograms. Of 4,552 patients included in the study, 904 (19.9%) had no follow-up. Of the 3,648 (80.1%) with follow-up, 2,797 (76.7%) had a follow-up examination <60d (avg. 22.1 days) and 851 (23.3%) had follow-up >60d (avg. 190.4 days). Multinomial log regression found that Asian women, black women, and those who identified as "other" were independently more likely to have no or >60d follow-up ($p<0.05$). Women who did not report their race were more likely to have no or >60d follow-up ($p<0.05$). Women who completed the questionnaire in Spanish were more likely to have no or >60d follow-up ($p<0.05$). Amongst women with follow-up, black women, those who identified as "other", LatinX women, and those completed the questionnaire in Spanish had significant follow-up delays ($p<0.05$). BRCA+ patients had shorter follow-up times ($p<0.05$).

CONCLUSION

s Follow-up time is affected by patient-specific breast cancer risk factors such as BRCA status as well as disparities in health care access by race, primary language and Latinx heritage.

CLINICAL RELEVANCE/APPLICATION

There are risk factors associated with prolonged follow-up time to diagnostic evaluation that need to be targeted in order to improve patient outcomes.

W5B-SPBR-6

Frequency and outcome of probably benign findings (BI-RADS 3) in patients with a personal history of breast cancer (PHBC) imaged with digital mammography (DM) vs. digital breast tomosynthesis (DBT)

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - BR DPS

Participants
Lily Offit, Boston, MA (*Presenter*) Nothing to Disclose

PURPOSE

Probably benign (BI-RADS 3) findings are those with <2% malignancy rate, and are followed with imaging at 6, 12, and 24 months. Few studies have reported probably benign outcomes in patients with a personal history of breast cancer (PHBC) and have shown >2% malignancy rates. The purpose of this study is to determine the frequency, findings, and outcomes of probably benign findings in patients with PHBC imaged with digital mammography (DM) versus digital breast tomosynthesis (DBT).

METHODS AND MATERIALS

This is a retrospective review of 14,845 mammogram reports in patients with PHBC (mastectomy and/or lumpectomy). Of these, 8,422 exams (56.7%) were DM between 10/2014-9/16 and 6,423 exams (43.3%) were DBT between 2/2017-12/2018. Frequency and indication of BI-RADS 3 assignment, mammographic finding (calcifications, architectural distortions, asymmetries, or mass), and biopsy or follow-up imaging outcomes were compared between DM and DBT.

RESULTS

In the study periods, there were 901/14,845 (6.1%) examinations coded as BI-RADS 3, with 717 unique BI-RADS 3 findings. DBT led to a reduced use of probably benign assignments when compared to DM (6.4% for DM vs. 5.6% for DBT, p=0.04). DM had a higher rate of malignancy of subsequently biopsied BI-RADS findings when compared to DBT [(4.8% (21/442) DM vs. 1.8% (5/275) DBT (p=0.04)]. DBT showed a 10.1% increase in percent of masses detected compared to DM (p=0.004). There was a trend towards more probably benign calcifications detected in DM (p=0.06).

CONCLUSION

s Use of DBT in individuals with a prior history of breast cancer led to a decrease in rate of BI-RADS 3 assignment. DM BI-RADS 3 rate of malignancy was 4.8%, higher than the accepted 2% malignancy rate, and decreased to 1.8% with use of DBT.

CLINICAL RELEVANCE/APPLICATION

Insight into BI-RADS 3 usage and malignancy rates between imaging modalities will help establish whether probably benign assessments in patients with PHBC are being utilized appropriately to identify cancers early and reduce unnecessary biopsies.

W5B-SPBR-7

Interval Breast Cancers Compared to Screen Detected Breast Cancers: A Retrospective Cohort Study

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - BR DPS

Participants
Emily Ambinder, MD, MSc, Ellicott City, MD (*Presenter*) Nothing to Disclose

PURPOSE

Mammographic screening improves mortality from breast cancer through early detection. We aim to identify clinical and imaging features that differentiate screen detected breast cancers from interval breast cancers in order to inform and improve breast cancer screening for all women in the era of precision medicine.

METHODS AND MATERIALS

All screening mammograms (n= 211,514) performed between 7/1/2013 and 6/30/2020 at our institution were reviewed. Patients with breast cancer diagnosed within one year of screening were included in this study. Patient, imaging, and cancer characteristics of screen detected breast cancers and interval breast cancers were compared using the Chi square test, Fisher test, and Wilcoxon Rank Sum Test. Interval cancers were defined as breast cancers diagnosed within one year of a negative screening mammogram.

RESULTS

During the study period, 1,232 women were diagnosed with breast cancer and included in this study (mean age 64 years, standard deviation 11 years). Overall sensitivity of screening mammography was 91% (1,121 screen detected breast cancers and 111 interval cancers). Interval cancers were most often palpable (62/111=56%) or identified on a high-risk screening breast MRI (20/111=18%). Patient age, race, and screening exam modality (FFDM versus DBT) were similar for patients with screen detected cancers and interval cancers (all p>0.05). Breast density was higher for patients with interval cancers (heterogeneously dense or extremely dense: 86/111=77% versus 683/1121=61%, p<-.001).Compared to screen detected cancers, interval cancers were less often ductal carcinoma in situ or primary tumor stage 1 (69/111=62% versus 981/1121=88%, p<0.001) and less often regional lymph node stage 0 (89/111=80% versus 990/1121=88%, p<-0.001). Interval cancers were less often hormone receptor positive (ER+: 73/94=78% versus 746/824=91%, p<-001), and less often had low proliferative indices (Ki67 <20%: 21/52=40% versus 301/488=62%, p=0.005). HER2 positivity was similar for the two groups (8/91=9% versus 84/804=10%, p=0.76).

CONCLUSION

s We found that mammographic screening has a high sensitivity for detection of breast cancer (91%). Interval cancers were often palpable or identified on a screening breast MRI and were associated with dense breast tissue but did not differ by age and race compared to screen detected cancers. Interval cancers were higher stage with less favorable molecular features compared to screen detected cancers.

CLINICAL RELEVANCE/APPLICATION

While screening mammography has a high sensitivity for detecting breast cancer, novel approaches are needed to identify interval cancers earlier as these are often higher stage with unfavorable molecular features compared to screen detected cancers.

Cardiac Wednesday Poster Discussions - B

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - CA DPS

Sub-Events

W5B-SPCA-1 Changes of Cardiac Function in Diabetic Pigs: A Pilot Study Using Cardiac MRI

Participants
Wei-Feng Yan, MD, Chengdu, China (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the feasibility of cardiac MRI in the evaluation of cardiac dysfunction in diabetic pigs.

METHODS AND MATERIALS

The diabetic pig model induced by streptozotocin (STZ) was established in 16 adult Bama mini-pigs. The porcine heart was scanned by 3.0T MRI at different times, and the left ventricular (LV) myocardial strain was analyzed by tissue tracking technique.The changes of left ventricular (LV) structure, function and myocardial strain over time were compared in diabetic pigs.

RESULTS

13 pigs were successfully modeled (fasting blood glucose was higher than 7.0mmol/L for three consecutive weeks). Cardiac MRI scans were performed in pigs before modeling (n = 13), one month after modeling (n = 13), 6 months after modeling (n = 13), 10 months after modeling (n = 11) and 16 months after modeling (n = 6). As the disease progresses,, there were no significant changes in LV remodeling index (1.27±0.34 vs. 1.14±0.55 vs. 0.96±0.2 vs.1.16±0.22 vs. 1.16±0.37) and ejection fraction (57.93±9.81 vs. 50.82±11.21 vs. 54.58±15.29 vs. 60.23±10.88 vs. 63.75±14.65), but the longitudinal peak strain of LV decreased gradually(-10.37±2.92 vs. -9.89±2.92 vs. -9.49±3.53 vs.-8.72±2.59 vs. -6.97±3.55).

CONCLUSION

s The decrease of LV longitudinal peak strain could be the early manifestation of cardiac dysfunction in diabetic pigs.

CLINICAL RELEVANCE/APPLICATION

Cardiac MRI tissue tracking technique may reflect the early changes of the heart in diabetic cardiomyopathy.

W5B-SPCA-2 Identification of Fibrosis in Hypertrophic Cardiomyopathy: A Radiomic Study on Cardiac Magnetic Resonance Cine Imaging

Participants
Cailing Pu, (*Presenter*) Nothing to Disclose

PURPOSE

Hypertrophic cardiomyopathy (HCM) patients often need to undergo repeated enhanced cardiac magnetic resonance (CMR) to detect fibrosis during their lifetime follow-up. We aimed to develop a practical model based on cine imaging to help identify patients with a high risk of fibrosis and screen patients without fibrosis to avoid unnecessary injection of contrast.

METHODS AND MATERIALS

273 HCM patients were divided into training set and test set at the ratio of 7:3. Logistic regression analysis was used to find predictive image features to construct CMR model. Radiomic features were derived from the maximal wall thickness (MWT) slice and entire left ventricular (LV) myocardium, and extreme gradient boosting was used to build radiomic models. Integrated models were established by fusing image features and radiomic model. Model performance was validated in the test set and was presented by receiver operating characteristic curve, calibration curve and decision curve analysis (DCA).

RESULTS

We established five prediction models, including CMR model, R1 and R2 model (constructed based on the MWT layer and entire LV myocardium respectively) and two integrated models (ICMR+R1 and ICMR+R2). In the test set, ICMR+R2 model had excellent AUC value, diagnostic accuracy, sensitivity and F1 score in identifying positive late gadolinium enhancement patients, performance values were 0.898, 89.02%, 92.54%, 93.23% respectively. The calibration plot and DCA indicated that ICMR+R2 model was well calibrated and had better net benefit than other models.

CONCLUSION

s The predictive model fusing image features and radiomics from entire LV myocardium had good diagnostic performance, robustness and clinic utility.

CLINICAL RELEVANCE/APPLICATION

1. HCM is prone to fibrosis. Patients with HCM need to undergo repeated enhanced cardiac magnetic resonance to detect fibrosis during their lifetime follow-up. 2. The predictive model constructed based on entire left ventricular myocardium outperformed than that by maximal wall thickness slice. 3. The predictive model fusing image features and radiomics from entire left ventricular myocardium had excellent diagnostic performance, robustness and clinic utility.

W5B-SPCA-3 Utility of Dual-energy CT Radiomics in The Detection of Left Atrial Appendage Thrombi in Patients with Atrial Fibrillation

Participants
Wenhuan Li, MD, (*Presenter*) Nothing to Disclose

PURPOSE

This study aimed to investigate whether radiomics from dual-energy computed tomography (CT)-derived iodine overlay maps performed better than that from routine contrast-enhanced CT images in the detection of left atrial appendage (LAA) thrombus in patients with atrial fibrillation.

METHODS AND MATERIALS

One hundred and ten consecutive patients were prospectively recruited and scanned in the early contrast-enhanced phase using third-generation dual-source CT in dual-energy mode. Radiomic features were extracted from three-dimensional segmentation of the filling defect. The ratios of iodine concentration and Hounsfield units (HU) in the filling defects to those in the ascending aorta (AA) were calculated. The diagnostic performances of radiomics from iodine overlay maps and routine contrast-enhanced CT images in the detection of LAA thrombus were assessed and compared with the ratios of iodine concentration and HU, respectively.

RESULTS

Transesophageal echocardiography (TEE) demonstrated thrombus in 16 (15%), spontaneous echo contrast in 24 (22%), and no abnormality in 70 (64%) patients. With TEE findings as the reference standard in LAA thrombus detection, radiomics from iodine overlay maps performed better than that from routine contrast-enhanced CT images (area under the receiver operating characteristic curve, 0.96 vs. 0.89; $P < 0.05$). Radiomics from iodine overlay maps performed better than LAA/AA iodine concentration ratio (0.96 vs. 0.93; $P < 0.05$) and radiomics from routine contrast-enhanced CT images performed better than LAA/AA HU ratio (0.89 vs. 0.85; $P < 0.05$).

CONCLUSION

s Radiomics from iodine overlay maps performed better than radiomics from routine contrast-enhanced CT images in LAA thrombus detection.

CLINICAL RELEVANCE/APPLICATION

Accurate detection of LAA thrombus is extremely important. Radiomics from iodine overlay maps performed better than radiomics from routine contrast-enhanced CT images in LAA thrombus detection.

W5B-SPCA-1

Changes of Cardiac Function in Diabetic Pigs: A Pilot Study Using Cardiac MRI

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - CA DPS

Participants
Wei-Feng Yan, MD, Chengdu, China (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the feasibility of cardiac MRI in the evaluation of cardiac dysfunction in diabetic pigs.

METHODS AND MATERIALS

The diabetic pig model induced by streptozotocin (STZ) was established in 16 adult Bama mini-pigs. The porcine heart was scanned by 3.0T MRI at different times, and the left ventricular (LV) myocardial strain was analyzed by tissue tracking technique.The changes of left ventricular (LV) structure, function and myocardial strain over time were compared in diabetic pigs.

RESULTS

13 pigs were successfully modeled (fasting blood glucose was higher than 7.0mmol/L for three consecutive weeks). Cardiac MRI scans were performed in pigs before modeling (n = 13), one month after modeling (n = 13), 6 months after modeling (n = 13), 10 months after modeling (n = 11) and 16 months after modeling (n = 6). As the disease progresses,, there were no significant changes in LV remodeling index (1.27±0.34 vs. 1.14±0.55 vs. 0.96±0.2 vs.1.16±0.22 vs. 1.16±0.37) and ejection fraction (57.93±9.81 vs. 50.82±11.21 vs. 54.58±15.29 vs. 60.23±10.88 vs. 63.75±14.65), but the longitudinal peak strain of LV decreased gradually(-10.37±2.92 vs. -9.89±2.92 vs. -9.49±3.53 vs.-8.72±2.59 vs. -6.97±3.55).

CONCLUSION

s The decrease of LV longitudinal peak strain could be the early manifestation of cardiac dysfunction in diabetic pigs.

CLINICAL RELEVANCE/APPLICATION

Cardiac MRI tissue tracking technique may reflect the early changes of the heart in diabetic cardiomyopathy.

W5B-SPCA-2

Identification of Fibrosis in Hypertrophic Cardiomyopathy: A Radiomic Study on Cardiac Magnetic Resonance Cine Imaging

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - CA DPS

Participants
Cailing Pu, (*Presenter*) Nothing to Disclose

PURPOSE

Hypertrophic cardiomyopathy (HCM) patients often need to undergo repeated enhanced cardiac magnetic resonance (CMR) to detect fibrosis during their lifetime follow-up. We aimed to develop a practical model based on cine imaging to help identify patients with a high risk of fibrosis and screen patients without fibrosis to avoid unnecessary injection of contrast.

METHODS AND MATERIALS

273 HCM patients were divided into training set and test set at the ratio of 7:3. Logistic regression analysis was used to find predictive image features to construct CMR model. Radiomic features were derived from the maximal wall thickness (MWT) slice and entire left ventricular (LV) myocardium, and extreme gradient boosting was used to build radiomic models. Integrated models were established by fusing image features and radiomic model. Model performance was validated in the test set and was presented by receiver operating characteristic curve, calibration curve and decision curve analysis (DCA).

RESULTS

We established five prediction models, including CMR model, R1 and R2 model (constructed based on the MWT layer and entire LV myocardium respectively) and two integrated models (ICMR+R1 and ICMR+R2). In the test set, ICMR+R2 model had excellent AUC value, diagnostic accuracy, sensitivity and F1 score in identifying positive late gadolinium enhancement patients, performance values were 0.898, 89.02%, 92.54%, 93.23% respectively. The calibration plot and DCA indicated that ICMR+R2 model was well calibrated and had better net benefit than other models.

CONCLUSION

s The predictive model fusing image features and radiomics from entire LV myocardium had good diagnostic performance, robustness and clinic utility.

CLINICAL RELEVANCE/APPLICATION

1. HCM is prone to fibrosis. Patients with HCM need to undergo repeated enhanced cardiac magnetic resonance to detect fibrosis during their lifetime follow-up. 2. The predictive model constructed based on entire left ventricular myocardium outperformed than that by maximal wall thickness slice. 3. The predictive model fusing image features and radiomics from entire left ventricular myocardium had excellent diagnostic performance, robustness and clinic utility.

Utility of Dual-energy CT Radiomics in The Detection of Left Atrial Appendage Thrombi in Patients with Atrial Fibrillation

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - CA DPS

Participants
Wenhuan Li, MD, (*Presenter*) Nothing to Disclose

PURPOSE

This study aimed to investigate whether radiomics from dual-energy computed tomography (CT)-derived iodine overlay maps performed better than that from routine contrast-enhanced CT images in the detection of left atrial appendage (LAA) thrombus in patients with atrial fibrillation.

METHODS AND MATERIALS

One hundred and ten consecutive patients were prospectively recruited and scanned in the early contrast-enhanced phase using third-generation dual-source CT in dual-energy mode. Radiomic features were extracted from three-dimensional segmentation of the filling defect. The ratios of iodine concentration and Hounsfield units (HU) in the filling defects to those in the ascending aorta (AA) were calculated. The diagnostic performances of radiomics from iodine overlay maps and routine contrast-enhanced CT images in the detection of LAA thrombus were assessed and compared with the ratios of iodine concentration and HU, respectively.

RESULTS

Transesophageal echocardiography (TEE) demonstrated thrombus in 16 (15%), spontaneous echo contrast in 24 (22%), and no abnormality in 70 (64%) patients. With TEE findings as the reference standard in LAA thrombus detection, radiomics from iodine overlay maps performed better than that from routine contrast-enhanced CT images (area under the receiver operating characteristic curve, 0.96 vs. 0.89; $P < 0.05$). Radiomics from iodine overlay maps performed better than LAA/AA iodine concentration ratio (0.96 vs. 0.93; $P < 0.05$) and radiomics from routine contrast-enhanced CT images performed better than LAA/AA HU ratio (0.89 vs. 0.85; $P < 0.05$).

CONCLUSION

s Radiomics from iodine overlay maps performed better than radiomics from routine contrast-enhanced CT images in LAA thrombus detection.

CLINICAL RELEVANCE/APPLICATION

Accurate detection of LAA thrombus is extremely important. Radiomics from iodine overlay maps performed better than radiomics from routine contrast-enhanced CT images in LAA thrombus detection.

W5B-SPCH-1 Comparing UTE1H-MRI Derived Ventilation Measurement and19F-MRI Ventilation Parameters in Patients with Cystic Fibrosis

Participants
Maria Mihailescu, BS, Chapel Hill, NC (*Presenter*) Nothing to Disclose

PURPOSE

UTE 1H-MRI could allow for non-invasive ventilation measurements in the lungs by examining changes in structure during ventilatory cycles. 19F-MRI with inhaled perfluoropropane (PFP) gas has been established as a reliable assessment of lung ventilation. Our goal is to better understand the potential of 1H-MRI derived ventilation parameters by comparing values to 19F-MRI derived ventilation parameters.

METHODS AND MATERIALS

15 19F-MRI and 1H-MRI scans from patients with cystic fibrosis before and after treatment with elexacaftor/tezacaftor/ivacaftor were used for method development. To analyze ventilation from 19F-MRI, signal intensity-time curves during PFP wash-in and wash-out for each voxel were fitted to a bi-exponential model to find the time constant that characterize gas wash-out (t2). To determine ventilation maps for 1H-MRI images, a 3D Jacobian was computed on a voxel-by-voxel basis between maximum inhalation and maximum exhalation. Heat maps of ventilation parameters from each imaging modality were created. Ventilation defect percentages (VDP) were calculated to compare the two ventilation parameters.

RESULTS

When comparing 19F-MRI and 1H-MRI VDP for 15 scans, there was no significant correlation coefficient. If scans with minimum lung disease are excluded (Defined as 19F-MRI determined VDP <3%), the remaining 11 scans had a correlation coefficient of 0.77 when comparing VDPs.

CONCLUSION

s For moderate to severe lung disease VDP determined from 19F-MRI and 1H-MRI have a high correlation coefficient, suggesting that 1H-MRI determined VDP may be a useful functional assessment marker in these patients. For mild lung disease, ventilation parameters are not significantly related. One explanation for this is that severe lung disease has drastic effects on the lung parenchyma altering its normal movement and allowing for detection as the magnitude of the Jacobian between inspiration and expiration. For mild lung disease, factors that impact air movement such as inflammation or minimal mucus plugging may not register at the level of structural movement. With higher resolution 1H-MRI scans, the Jacobian magnitude could be calculated at the alveolar level to allow for measurement of ventilation in mild lung disease.

CLINICAL RELEVANCE/APPLICATION

The 1H-MRI Jacobian magnitude may be useful in characterizing VDP for moderate to severe lung disease without the need for 19F-MRI imaging, a potentially financially prohibitive modality that is not suitable for all patient populations.

W5B-SPCH-10 How Normal Is a Normal Chest X-Ray: Does a Comprehensive Artificial Intelligence Model Identify Significant Findings in Chest Radiographs Interpreted as Normal in Clinical Practice?

Participants
Arpit Talwar, MBBS, MMEd, (*Presenter*) Nothing to Disclose

PURPOSE

Chest x-ray (CXR) interpretation is one of the most subjective and complex of radiology tasks. Accuracy depends on the radiologists' level of experience and training with the potential of human error related to workload, fatigue and interruptions impacting on patient care. Validated comprehensive deep-learning models may assist in improving diagnostic accuracy and departmental workflow. We therefore aimed to evaluate the performance of radiologist reported normal chest x-rays within the hospital setting against a comprehensive deep-learning model.

METHODS AND MATERIALS

A retrospective analysis of CXRs that had been reported as normal in adults (= 18 years) was performed on consecutive patients at St. Vincent's Hospital Melbourne from Jan-May 2016. A validated deep-learning model with a total dataset of 60 significant findings was applied on the included studies. Significant findings were adjudicated by two chest radiologists with over 10 years-experience.

Disagreements were re-reviewed to reach a consensus. Level of agreement between radiologists and the model was also assessed.

RESULTS

Of the 490 studies included in this preliminary analysis, 444 (90.6%) showed no significant finding predictions by the model (specificity 93.3%). 64 significant findings were identified by the model across 46 studies (9.4%). 50% were rejected by the adjudicators (model PPV 0.5) with 32 findings (6.3%) across 22 studies deemed to be missed by the reporting radiologist. The most common missed finding was distended bowel (18.8%) with a single case of solitary pulmonary nodule (3.1%) and superior mediastinal mass (3.1%) identified. Within our cohort, a total of 4 studies (0.8%) had findings that were of particular concern. Substantial inter-rater agreement was achieved between the model and radiologists (weighted ? value of 0.64 (95% CI 0.52 - 0.75)).

CONCLUSION

s Our preliminary results demonstrate that an AI model provided a useful tool in auditing CXRs reported as normal in a public hospital setting, where radiology trainees report the majority of these studies. The AI model demonstrated that a significant percentage (6.3%) of CXRs had findings deemed significant, missed in the initial report.

CLINICAL RELEVANCE/APPLICATION

Integration of a highly specific AI model in a real-world reporting environment has the potential to improve departmental workflow and reduce human error, ultimately improving patient care.

W5B-SPCH-2 Predicting Outcomes of Lung Transplants Based on Pre-operative Chest CT Scans in Patients with Scleroderma

Participants
Jiantao Pu, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the feasibility of predicting the outcomes of lung transplants in patients with scleroderma based on pre-treatment chest CT scans.

METHODS AND MATERIALS

We created a cohort consisting of 104 subjects who were diagnosed with scleroderma and underwent lung transplants from 2005 to 2020. Based on the pre-treatment chest CT scans, we quantified: (1) lung volume, (2) heart volume, (3) chest cavity volume, (4) distances between sternum and spines, (5) artery and vein volumes, and (6) the volume and density of five body tissues (i.e., skeleton muscle, subcutaneous fat, visceral fat, intramuscular fat, and bone). The backward stepwise logistic/linear regression was used to predict chest open, postoperative mechanical support, AKI requiring dialysis, primary graft dysfunction (PGD), and ICU stay (days). For PGD, we dichotomized these patients on whether they were Grade 3 or not on postoperative day 3. The prediction models were evaluated using the area under the receiver-operating characteristic (ROC) curve (AUC). The R-squared (R2) was used to assess the performance of the model for predicting ICU stay.

RESULTS

The prediction models showed an AUC of 0.899 (95% CI: 0.837-0.960) for assessing chest open, an AUC of 0.930 (95% CI: 0.880-0.980) for assessing AKI requiring dialysis demonstrated, an AUC of 0.953 (95% CI: 0.917-0.989) for predicting postoperative mechanical support. When assessing PGD Grade 3, the prediction model had an AUC of 0.988 (95% CI: 0.965-1.0) with variables formed primarily by the body tissues and the geometric characteristics of the chest cavity. When predicting the total ICU stay, the computer model demonstrated an R2 of 0.37, indicating that 37% of the variance in the outcome was explained by the model.

CONCLUSION

s The outcomes of lung transplants in patients with scleroderma are significantly associated with the geometric characteristics of the lungs and the body compositions of the recipients.

CLINICAL RELEVANCE/APPLICATION

Patients with scleroderma have an increased risk of complications after lung transplantation. Awareness of the factors contributing to the complications will maximize the benefit of lung transplants.

W5B-SPCH-3 Artificial Intelligence-assisted Analysis to Facilitate Effective Detection of Humeral Lesions in the Simple Chest Radiograph

Participants
Harim Kim, MD, (*Presenter*) Nothing to Disclose

PURPOSE

While chest radiograph (CR) is a basic modality for patient assessment, the humerus remains an easily negligible spot. Thus, it can be of great aid to the reader if an artificial intelligence (AI) system automatically diagnoses and visualizes tumors of humerus in CR, particularly with high sensitivity. However, as there is no prior AI study on this subject, we newly proposed an advanced AI system for detecting humerus tumors, with better sensitivity and tumor visualization, and compared its usefulness with radiologists.

METHODS AND MATERIALS

Our AI system differs from existing ones in that it uses a new training objective named false-positive activation area reduction (FPAR), which improves both the tumor detection sensitivity and tumor visualization ability of AI by learning not to activate the class activation map in areas unrelated to the region of interest (i.e., outside humerus or tumor). A total of 2994 CRs for 1500 normal and 1494 CT-proven humeral tumor CRs were provided as an AI training set. The AI program and two trainee radiologists (R1 and R2) were commonly tested with holdout test data, not used for AI training, of 119 normal and 102 tumor patients. The radiologists were tested twice with the same test set, and the second time, they were provided with AI test results.

RESULTS

Technically, the proposed AI system improved the sensitivity (83.4%) by 3.2% compared to the baseline (80.2%) and it also

Technically, the proposed AI system improved the sensitivity (83.4%) by 5.2% compared to the baseline (80.2%) and it also improved the tumor localization accuracy (82%) by 13% compared to the baseline (69%), demonstrating the effectiveness of FPAR. In comparison with radiologists, trainee radiologists showed different sensitivity and accuracy in detecting humerus lesions. Overall sensitivity, specificity, and accuracy of radiologists were 54.4%, 94.9%, and 82.3% and when compared with AI, AI showed a significantly higher sensitivity of 68.6% (p=0025). Also, AI showed higher sensitivity and accuracy (p=0.0007 and 0.0339 respectively) but did not outperform in specificity (p=0.1298). When assisted by AI, the performance of two trainee radiologists did not differ significantly. And compared with results not assisted by AI, sensitivity and accuracy showed improvement, most notably in the trainee with lower sensitivity.

CONCLUSION

s The utilization of FPAR effectively enhances true-positives in humeral tumor detection and reduces false-positives in humeral tumor visualization. This advanced AI is proven to make radiologists detect humerus lesions better, especially for trainee radiologists with less experience and lower sensitivity.

CLINICAL RELEVANCE/APPLICATION

Our AI system may help radiologists pay better attention to possible humeral lesions, as humerus can be easily overlooked in CR.

W5B-SPCH-4 Pulmonary Alveolar Echinococcosis: CT Findings and Classcification

Participants
Hai Hua Bao, Xining, China (*Presenter*) Nothing to Disclose

PURPOSE

Alveolar echinococcosis, which is prevalent on the Tibetan plateau, is a multisystemic infectious parasitic disease that poses a serious health risk to humans. Pulmonary alveolar echinococcosis (PAE) is a lesion secondarily induced by direct infiltration and hematogenous dissemination from hepatic AE lesions and mostly in the middle-late stages. Currently, studies on the CT-morphological classification of PAE are scarce. The study aims to clarify the CT imaging findings and classcification of PAE.

METHODS AND MATERIALS

The study analysed the CT manifestations of patients with AE diagnosed by clinical and imaging examinations at the Affiliated Hospital of Qinghai University from 2014 to 2021. One hunderd and eighty-nine patients (age, 43 years ± 13 [standard deviation]; gender, 93 men and 96 women) were evaluated. All patients living at a high altitude of 2500 - 3500m. A GE 256-layer CT scanner was used for plain and enhanced scan to observe the distribution, morphology and typing characteristics of the lesions. Statistics were performed using SPSS software.

RESULTS

The CT manifestations of PAE are mostly mutiple nodules, which were mainly peripheral distribution and mostly in the lower lobes. The diameter of the lesions ranged from 2mm to 9cm. 189 cases of AE in patients with primary lesions are from the liver. CT imaging characteristics were categorized into four types: I. small solid nodules (= 1 cm) (37/189, 19.6%); II. large solid nodules (> 1 cm) (158/189, 83.6%); III. solid nodules with cavity (70/189, 37.0%); IV. calcified nodules (32/189, 16.9%). Different types of nodules can be shown on CT images of the same patient. The probability of the primary foci in the liver invading blood vessels and diaphragm are hepatic vein (62.4%), inferior vena cava (52.5%), portal vein (69.3%), hepatic artery (53.5%) and diaphragm (86.1%) respectively. Approximately 54.5% of patients had operation history.

CONCLUSION

s The CT findings of PAE ,which is secondarily induced from primary foci in the liver, are mostly peripheral distribution and mainly in the lower lobes. The CT classcification of PAE is more common in types II and III.

CLINICAL RELEVANCE/APPLICATION

The CT-morphological classification of PAE could help to clarify the progression of the diease and provide a basis for the early interference and the choice of treatment schedule.

W5B-SPCH-5 Chest X-Ray at Emergency Admission, SOFA Score and NIV: Potential Value in Predicting Barotrauma in Ventilated COVID-19 Patients during the First Pandemic Peak

Participants
Francesco Stanco, (*Presenter*) Nothing to Disclose

PURPOSE

To assess the value of chest X-ray (CXR), SOFA (Sequential Organ Failure Assessment) score and NIV (non-invasive ventilation) at emergency admission to predict barotrauma in mechanically ventilated COVID-19 patients. To report the distribution of barotrauma at chest CT.

METHODS AND MATERIALS

SARS-CoV-2 positive patients, first admitted to the emergency department and then to the intensive care unit (ICU), between February 20th and April 15th, 2020, were retrospectively evaluated. All patients were divided into two groups, according to the occurrence/absence of barotrauma. CXR were assessed by 1 experienced radiologist using Brixia score (BS). SOFA score was calculated by the referring physicians at ICU admittance and NIV days prior intubation were collected. Distribution of barotrauma (pneumomediastinum/pneumothorax/subcutaneous emphysema) were annotated from unenhanced chest CT scan during ICU hospitalization.

RESULTS

A total of 117 SARS-CoV-2 patients (24 females, mean age 59.95 years) were included. Thirty-seven (37/117; 31.6%) mechanically ventilated patients developed barotrauma (25 pneumomediastinum, 23 pneumothorax, 24 subcutaneous emphysema). Compared to the non-barotrauma group, barotrauma patients demonstrated higher BS values (mean value 12.05 vs 9.38, p-value 0.0041), and underwent longer NIV (mean value 4.20 vs 2.75 days, p-value 0.0075). No significant correlation with SOFA score was found. A model using these three tested predictors (BS, SOFA score, NIV days) resulted as the best model to predict development of

barotrauma.

CONCLUSION

s Barotrauma occurred in a non-negligible percentage of mechanically ventilated patients with COVID-19 pneumonia. The best predicting model for barotrauma was obtained by the simultaneous employment of three independent variables selected with simple logistic regression: BS, SOFA score, and NIV days.

CLINICAL RELEVANCE/APPLICATION

Integrated clinical-radiological assessment may predict the risk of barotrauma in mechanically ventilated COVID-19 patients, a complication potentially impacting proper management of these cases.

W5B-SPCH-6 Second-Opinion Subspecialty Consultations in Chest Radiology

Participants
Mohammad Jalili, MD, Los Angeles, CA (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this study is twofold. The primary aim is to assess the significance of subspecialty second-opinion consultations for CT examinations in thoracic imaging. The secondary aim is to assess the prevalence and reimbursement rates of over-read interpretations across academic cardiothoracic sections.

METHODS AND MATERIALS

Reports from 100 random chest CTs referred to a single academic institution for second-opinion consultation were reviewed by two radiologists by consensus. Outside and inside reports were compared using a previously published 5-point scale. Clinically important differences were defined as those likely to change patient management.Additionally, a 6-question survey was sent to the section head of every academic cardiothoracic radiology department in the U.S.A. asking how their department handles over-read requests.

RESULTS

Of all the second-opinion examinations, 69% (69/100) had an outside report available for comparison and inclusion in the study.There were no discrepancies in 70% of cases (48/69).In the remaining 30% (21 cases), 6 cases had nonsignificant discrepancies (Type 2 or 3) and 15 cases had clinically significant discrepancies (Type 4 and 5).19 out of 56 (33%) survey recipients responded to the survey.All 19 (100%) respondents stated that their institution does provide second opinion consultations for outside studies.Out of the 19 respondents, 10 departments over-read greater than 20 studies per week, 5 departments over-read 10-20 per week and 4 over-read less than 10 per week.9 out of 19 respondents stated that they were reimbursed less for over-reads than home institution studies while 3/19 stated that reimbursement is higher than home institution studies. The remainder are unsure of reimbursement rates.

CONCLUSION

s Subspecialty second-opinion review by a cardiothoracic fellowship trained radiologist was more meticulous than outside reports in 30% of studies when clinical/pathologic confirmation was made.Of the 21 cases with a discrepancy, 71% (15/21) had clinically significant discrepancies (Type 4 and 5).Of these clinically significant discrepancies, there is almost equal numbers of interpreting vs detecting abnormalities (6 vs 7).All survey respondents (33% of total surveys) provided second-opinion interpretations in some capacity.Approximately 52% of the departments which provided second-opinion interpretations over-read over 20 studies per week.

CLINICAL RELEVANCE/APPLICATION

Formal second opinion interpretations provide added value to referring providers and ultimately the patients. However, given the increasing number of second-opinion interpretation requests, an organized workflow is necessary for proper handling and appropriate billing.

W5B-SPCH-7 Relationships between Right and Left Ventricle Function and Lung Volumes in Subjects free of Cardiovascular Diseases

Participants
Ricarda von Kruchten, MD, (*Presenter*) Nothing to Disclose

PURPOSE

The volumetric assessment of MRI-derived global cardiac function includes right (RV) and left ventricular (LV) systolic and diastolic function, but the degree to which MRI-derived lung volumes impact and/or modify parameters of RV and LV function remains unclear. The aim of our study was to investigate the relationship between lung volumes, and parameters of RV and LV function in the KORA-MRI study.

METHODS AND MATERIALS

From the KORA-MRI cohort study, 361 subjects (mean age 56.1±9.1 years; 43% women) underwent a whole-body 3T MRI scan. Cardiac function parameters were measured using a cine-steady-state free precession sequence using cvi42. Lung volumes were derived semi-automatically using an in-house algorithm. Linear regression analyses were performed to assess the relationships between lung volumes and RV and LV function parameters adjusted for age, sex, and cardiovascular risk factors.

RESULTS

RV end-diastolic volume was positively associated with LV end-diastolic volume (ß=28.1, p=<0.001), LV end-systolic volume (ß=11.0, p=<0.001), LV stroke volume (ß=17.0, p=<0.001), and inversely with LV ejection fraction (ß=-1.4, p=0.001). RV end-systolic volume was positively associated with LV end-diastolic volume (ß=21.2, p=<0.001), LV end-systolic volume (ß=11.5, p=<0.001), LV stroke volume (ß=9.7, p=<0.001), and inversely with LV ejection fraction (ß=-3.3, p=<0.001). When adjusting for lung volumes, the association between RV and LV did not attenuate, and no effect modification was observed. Despite the differences in lung volumes in both men and women, we did not observe any gender differences with respect to the association between RV and LV parameters.

CONCLUSION

s In subjects free of cardiovascular diseases, MRI-derived RV and LV function parameters were strongly associated, consistent with the notion that RV function is crucial for LV function, and independent of lung volumes.

CLINICAL RELEVANCE/APPLICATION

Cardio-pulmonary relationships in health and disease are well known. Therefore, parameters of cardiac function and pulmonary function can be useful clinical tools used for diagnosis, risk-stratification, and prognosis. MRI is an excellent tool for the assessment of both lung volumes and volumetric parameters of both right (RV) and left ventricular (LV) function. Our study aimed to examine the fundamental relationships between right and left ventricular function and lung volumes in subjects free of cardiovascular diseases.

W5B-SPCH-8 Localization-adjusted Diagnostic Performance and Diagnostic Impact of A Commercialized Computer-aided Detection System for Pneumothorax and Consolidation

Participants
Hongjun Yoon, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To develop a deep learning algorithm for automated diagnosis of chest abnormalities (consolidation and pneumothorax) and evaluate its diagnostic performance with various dice scores.?

METHODS AND MATERIALS

We, retrospectively, collected 22,338 chest radiographs from two hospitals.?All radiographs?are confirmed by the corresponding CT or radiological report. These are 12,065 consolidation (CON) cases and 6,783 of them are labeled by radiologist. For pneumothorax (PNX), 3,707 cases are selected (2,379 with segmentation mask and 1,328 without). Since manual pixel-level annotation is time-consuming and cumbersome, we exploited the semi-supervised approach. We designed a U-net based deep learning model which was trained with both segmentation and classification labels, when available. On the other hand, when not available, classification label was only used. Considering the importance of lesion localization and interpretability of algorithm, we introduced a dice-adjusted sensitivity evaluation method, which only predictions that exceeded each dice threshold were considered accurate predictions. Unlike sensitivities, specificities could not be considered because dice calculation requires a reference standard lesion annotation (i.e., radiographs without abnormalities do not have lesions to annotate).

RESULTS

We used the 1,050 examination images to test our model with external dataset (300 CON, 250 PNX, 500 normal).??The model has been evaluated with dice score, dice-adjusted sensitivity, specificity, and AUROC. For CON, our model achieved 0.691 (95% CI: 0.664=p=0.718), 0.933 (95% CI: 0.945 = p=0.975), 0.948 (95% CI: 0. 930= p=0. 963), 0.960 (95% CI: 0.945 = p=0.975) for dice score, dice-adjusted sensitivity, specificity, and AUROC, respectively. For PNX, our model achieved 0.798 (95% CI: 0.770=p=0.826), 0.956 (95% CI: 0.923 = p=0.978), 0.996 (95% CI: 0. 989= p=0. 999), 0.978 (95% CI: 0.965 = p=0.991) for dice, dice-adjusted sensitivity, specificity, and AUROC, respectively.

CONCLUSION

s Our deep learning model detected chest X-ray abnormalities (consolidation and pneumothorax) with high diagnostic performance and pixel-level segmentation score.??

CLINICAL RELEVANCE/APPLICATION

To apply deep learning based automated analysis algorithm into actual practice, we propose a semi-supervised learning model to detect abnormal findings (CON and PNX) with outperformed localization.

W5B-SPCH-9 Opportunistic Detection of Diabetes from Frontal Chest Radiography in 104,473 Patients

Participants
Ayis T. Pyrros, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Chest radiographs (CXRs) are one of the most frequently ordered radiological exams and can potentially be utilized as a biomarker. Our aim was to explore the use of a multitask deep learning (DL) model to detect diabetes from ambulatory frontal radiographs in a large clinical dataset.

METHODS AND MATERIALS

Material and Methods: A multitask DL model was trained and tested on 303,604 (55% female; mean age, 58) frontal CXRs from 2010 to 2021 at a single institution, using PyTorch and ResNet34, with 5-fold cross-validation. Patient age, BMI, HbA1c, diabetes, and select comorbidities (CHF, cardiac arrhythmias, morbid obesity, COPD, and vascular disease) from the electronic health record (EHR) were then validated on CXRs from ambulatory patients on out-of-fold predictions. Ground truth labels for diabetes were based on current ICD10 codes and HbA1c >=6.5%. Days between diagnosis of diabetes and initial CXR were calculated. Patients with a diagnosis of diabetes predating the CXR were excluded, as well as patients with less than a year of follow-up. The discriminatory ability of the DL model was assessed using area under receiver operating characteristic curve (ROC AUC) compared with the ground truth labels and with other predictors (BMI, Social Deprivation Index). An optimal threshold was calculated using Youden's index from the DL predictor. CXR saliency maps were generated.

RESULTS

A total of 104,473 CXRs in unique patient (mean age, 53; ±17 [SD]; 56% women) were evaluated in the final validation set, of whom 9,319 (8.9%) had a diagnosis of diabetes. The model's overall discriminatory ability for diabetes was an ROC AUC of 0.819 (95% CI:0.815-0.823), versus ROC AUC of 0.542 (95% CI: 0.536-0.548) using SDI as a predictor, and AUC 0.686 (95% CI: 0.681-0.692) using BMI, with all curves demonstrating comparative p-values <0.001. The mean number of days from CXR to diabetes diagnosis was 1,009 (±953 [SD]). At an optimal threshold of 0.11 for the DL predictor, the sensitivity, specificity, negative predictive value, and positive predictive value was 79%, 69%, 97%, and 20%, respectively. Of the 37,625 patients above the threshold, 29,800 (79%) patients did not have a diagnosis of diabetes, and of those, 13,804 (46%) did not have a HbA1c value and 8,109 (27%) had a HbA1c between 5.7-6.4%.

CONCLUSION

s Chest radiography can be utilized opportunistically to aid in detecting patients with diabetes and prediabetes.

CLINICAL RELEVANCE/APPLICATION

Earlier detection of diabetes may allow for improved screening and intervention, potentially reducing the time to diagnosis and treatment.

Comparing UTE1H-MRI Derived Ventilation Measurement and19F-MRI Ventilation Parameters in Patients with Cystic Fibrosis

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - CH DPS

Participants
Maria Mihailescu, BS, Chapel Hill, NC (*Presenter*) Nothing to Disclose

PURPOSE

UTE 1H-MRI could allow for non-invasive ventilation measurements in the lungs by examining changes in structure during ventilatory cycles. 19F-MRI with inhaled perfluoropropane (PFP) gas has been established as a reliable assessment of lung ventilation. Our goal is to better understand the potential of 1H-MRI derived ventilation parameters by comparing values to 19F-MRI derived ventilation parameters.

METHODS AND MATERIALS

15 19F-MRI and 1H-MRI scans from patients with cystic fibrosis before and after treatment with elexacaftor/tezacaftor/ivacaftor were used for method development. To analyze ventilation from 19F-MRI, signal intensity-time curves during PFP wash-in and wash-out for each voxel were fitted to a bi-exponential model to find the time constant that characterize gas wash-out (t2). To determine ventilation maps for 1H-MRI images, a 3D Jacobian was computed on a voxel-by-voxel basis between maximum inhalation and maximum exhalation. Heat maps of ventilation parameters from each imaging modality were created. Ventilation defect percentages (VDP) were calculated to compare the two ventilation parameters.

RESULTS

When comparing 19F-MRI and 1H-MRI VDP for 15 scans, there was no significant correlation coefficient. If scans with minimum lung disease are excluded (Defined as 19F-MRI determined VDP <3%), the remaining 11 scans had a correlation coefficient of 0.77 when comparing VDPs.

CONCLUSION

s For moderate to severe lung disease VDP determined from 19F-MRI and 1H-MRI have a high correlation coefficient, suggesting that 1H-MRI determined VDP may be a useful functional assessment marker in these patients. For mild lung disease, ventilation parameters are not significantly related. One explanation for this is that severe lung disease has drastic effects on the lung parenchyma altering its normal movement and allowing for detection as the magnitude of the Jacobian between inspiration and expiration. For mild lung disease, factors that impact air movement such as inflammation or minimal mucus plugging may not register at the level of structural movement. With higher resolution 1H-MRI scans, the Jacobian magnitude could be calculated at the alveolar level to allow for measurement of ventilation in mild lung disease.

CLINICAL RELEVANCE/APPLICATION

The 1H-MRI Jacobian magnitude may be useful in characterizing VDP for moderate to severe lung disease without the need for 19F-MRI imaging, a potentially financially prohibitive modality that is not suitable for all patient populations.

How Normal Is a Normal Chest X-Ray: Does a Comprehensive Artificial Intelligence Model Identify Significant Findings in Chest Radiographs Interpreted as Normal in Clinical Practice?

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - CH DPS

Participants
Arpit Talwar, MBBS, MMEd, (*Presenter*) Nothing to Disclose

PURPOSE

Chest x-ray (CXR) interpretation is one of the most subjective and complex of radiology tasks. Accuracy depends on the radiologists' level of experience and training with the potential of human error related to workload, fatigue and interruptions impacting on patient care. Validated comprehensive deep-learning models may assist in improving diagnostic accuracy and departmental workflow. We therefore aimed to evaluate the performance of radiologist reported normal chest x-rays within the hospital setting against a comprehensive deep-learning model.

METHODS AND MATERIALS

A retrospective analysis of CXRs that had been reported as normal in adults (= 18 years) was performed on consecutive patients at St. Vincent's Hospital Melbourne from Jan-May 2016. A validated deep-learning model with a total dataset of 60 significant findings was applied on the included studies. Significant findings were adjudicated by two chest radiologists with over 10 years-experience. Disagreements were re-reviewed to reach a consensus. Level of agreement between radiologists and the model was also assessed.

RESULTS

Of the 490 studies included in this preliminary analysis, 444 (90.6%) showed no significant finding predictions by the model (specificity 93.3%). 64 significant findings were identified by the model across 46 studies (9.4%). 50% were rejected by the adjudicators (model PPV 0.5) with 32 findings (6.3%) across 22 studies deemed to be missed by the reporting radiologist. The most common missed finding was distended bowel (18.8%) with a single case of solitary pulmonary nodule (3.1%) and superior mediastinal mass (3.1%) identified. Within our cohort, a total of 4 studies (0.8%) had findings that were of particular concern. Substantial inter-rater agreement was achieved between the model and radiologists (weighted ? value of 0.64 (95% CI 0.52 - 0.75)).

CONCLUSION

s Our preliminary results demonstrate that an AI model provided a useful tool in auditing CXRs reported as normal in a public hospital setting, where radiology trainees report the majority of these studies. The AI model demonstrated that a significant percentage (6.3%) of CXRs had findings deemed significant, missed in the initial report.

CLINICAL RELEVANCE/APPLICATION

Integration of a highly specific AI model in a real-world reporting environment has the potential to improve departmental workflow and reduce human error, ultimately improving patient care.

W5B-SPCH-2

Predicting Outcomes of Lung Transplants Based on Pre-operative Chest CT Scans in Patients with Scleroderma

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - CH DPS

Participants
Jiantao Pu, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the feasibility of predicting the outcomes of lung transplants in patients with scleroderma based on pre-treatment chest CT scans.

METHODS AND MATERIALS

We created a cohort consisting of 104 subjects who were diagnosed with scleroderma and underwent lung transplants from 2005 to 2020. Based on the pre-treatment chest CT scans, we quantified: (1) lung volume, (2) heart volume, (3) chest cavity volume, (4) distances between sternum and spines, (5) artery and vein volumes, and (6) the volume and density of five body tissues (i.e., skeleton muscle, subcutaneous fat, visceral fat, intramuscular fat, and bone). The backward stepwise logistic/linear regression was used to predict chest open, postoperative mechanical support, AKI requiring dialysis, primary graft dysfunction (PGD), and ICU stay (days). For PGD, we dichotomized these patients on whether they were Grade 3 or not on postoperative day 3. The prediction models were evaluated using the area under the receiver-operating characteristic (ROC) curve (AUC). The R-squared (R2) was used to assess the performance of the model for predicting ICU stay.

RESULTS

The prediction models showed an AUC of 0.899 (95% CI: 0.837-0.960) for assessing chest open, an AUC of 0.930 (95% CI: 0.880-0.980) for assessing AKI requiring dialysis demonstrated, an AUC of 0.953 (95% CI: 0.917-0.989) for predicting postoperative mechanical support. When assessing PGD Grade 3, the prediction model had an AUC of 0.988 (95% CI: 0.965-1.0) with variables formed primarily by the body tissues and the geometric characteristics of the chest cavity. When predicting the total ICU stay, the computer model demonstrated an R2 of 0.37, indicating that 37% of the variance in the outcome was explained by the model.

CONCLUSION

s The outcomes of lung transplants in patients with scleroderma are significantly associated with the geometric characteristics of the lungs and the body compositions of the recipients.

CLINICAL RELEVANCE/APPLICATION

Patients with scleroderma have an increased risk of complications after lung transplantation. Awareness of the factors contributing to the complications will maximize the benefit of lung transplants.

W5B-SPCH-3

Artificial Intelligence-assisted Analysis to Facilitate Effective Detection of Humeral Lesions in the Simple Chest Radiograph

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - CH DPS

Participants
Harim Kim, MD, (*Presenter*) Nothing to Disclose

PURPOSE

While chest radiograph (CR) is a basic modality for patient assessment, the humerus remains an easily negligible spot. Thus, it can be of great aid to the reader if an artificial intelligence (AI) system automatically diagnoses and visualizes tumors of humerus in CR, particularly with high sensitivity. However, as there is no prior AI study on this subject, we newly proposed an advanced AI system for detecting humerus tumors, with better sensitivity and tumor visualization, and compared its usefulness with radiologists.

METHODS AND MATERIALS

Our AI system differs from existing ones in that it uses a new training objective named false-positive activation area reduction (FPAR), which improves both the tumor detection sensitivity and tumor visualization ability of AI by learning not to activate the class activation map in areas unrelated to the region of interest (i.e., outside humerus or tumor). A total of 2994 CRs for 1500 normal and 1494 CT-proven humeral tumor CRs were provided as an AI training set. The AI program and two trainee radiologists (R1 and R2) were commonly tested with holdout test data, not used for AI training, of 119 normal and 102 tumor patients. The radiologists were tested twice with the same test set, and the second time, they were provided with AI test results.

RESULTS

Technically, the proposed AI system improved the sensitivity (83.4%) by 3.2% compared to the baseline (80.2%) and it also improved the tumor localization accuracy (82%) by 13% compared to the baseline (69%), demonstrating the effectiveness of FPAR. In comparison with radiologists, trainee radiologists showed different sensitivity and accuracy in detecting humerus lesions. Overall sensitivity, specificity, and accuracy of radiologists were 54.4%, 94.9%, and 82.3% and when compared with AI, AI showed a significantly higher sensitivity of 68.6% (p=0025). Also, AI showed higher sensitivity and accuracy (p=0.0007 and 0.0339 respectively) but did not outperform in specificity (p=0.1298). When assisted by AI, the performance of two trainee radiologists did not differ significantly. And compared with results not assisted by AI, sensitivity and accuracy showed improvement, most notably in the trainee with lower sensitivity.

CONCLUSION

s The utilization of FPAR effectively enhances true-positives in humeral tumor detection and reduces false-positives in humeral tumor visualization. This advanced AI is proven to make radiologists detect humerus lesions better, especially for trainee radiologists with less experience and lower sensitivity.

CLINICAL RELEVANCE/APPLICATION

Our AI system may help radiologists pay better attention to possible humeral lesions, as humerus can be easily overlooked in CR.

W5B-SPCH-4

Pulmonary Alveolar Echinococcosis: CT Findings and Classcification

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - CH DPS

Participants
Hai Hua Bao, Xining, China (*Presenter*) Nothing to Disclose

PURPOSE

Alveolar echinococcosis, which is prevalent on the Tibetan plateau, is a multisystemic infectious parasitic disease that poses a serious health risk to humans. Pulmonary alveolar echinococcosis (PAE) is a lesion secondarily induced by direct infiltration and hematogenous dissemination from hepatic AE lesions and mostly in the middle-late stages. Currently, studies on the CT-morphological classification of PAE are scarce. The study aims to clarify the CT imaging findings and classcification of PAE.

METHODS AND MATERIALS

The study analysed the CT manifestations of patients with AE diagnosed by clinical and imaging examinations at the Affiliated Hospital of Qinghai University from 2014 to 2021. One hunderd and eighty-nine patients (age, 43 years ± 13 [standard deviation]; gender, 93 men and 96 women) were evaluated. All patients living at a high altitude of 2500 - 3500m. A GE 256-layer CT scanner was used for plain and enhanced scan to observe the distribution, morphology and typing characteristics of the lesions. Statistics were performed using SPSS software.

RESULTS

The CT manifestations of PAE are mostly mutiple nodules, which were mainly peripheral distribution and mostly in the lower lobes. The diameter of the lesions ranged from 2mm to 9cm. 189 cases of AE in patients with primary lesions are from the liver. CT imaging characteristics were categorized into four types: I. small solid nodules (= 1 cm) (37/189, 19.6%); II. large solid nodules (> 1 cm) (158/189, 83.6%); III. solid nodules with cavity (70/189, 37.0%); IV. calcified nodules (32/189, 16.9%). Different types of nodules can be shown on CT images of the same patient. The probability of the primary foci in the liver invading blood vessels and diaphragm are hepatic vein (62.4%), inferior vena cava (52.5%), portal vein (69.3%), hepatic artery (53.5%) and diaphragm (86.1%) respectively. Approximately 54.5% of patients had operation history.

CONCLUSION

s The CT findings of PAE ,which is secondarily induced from primary foci in the liver, are mostly peripheral distribution and mainly in the lower lobes. The CT classcification of PAE is more common in types II and III.

CLINICAL RELEVANCE/APPLICATION

The CT-morphological classification of PAE could help to clarify the progression of the diease and provide a basis for the early interference and the choice of treatment schedule.

Chest X-Ray at Emergency Admission, SOFA Score and NIV: Potential Value in Predicting Barotrauma in Ventilated COVID-19 Patients during the First Pandemic Peak

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - CH DPS

Participants
Francesco Stanco, (*Presenter*) Nothing to Disclose

PURPOSE

To assess the value of chest X-ray (CXR), SOFA (Sequential Organ Failure Assessment) score and NIV (non-invasive ventilation) at emergency admission to predict barotrauma in mechanically ventilated COVID-19 patients. To report the distribution of barotrauma at chest CT.

METHODS AND MATERIALS

SARS-CoV-2 positive patients, first admitted to the emergency department and then to the intensive care unit (ICU), between February 20th and April 15th, 2020, were retrospectively evaluated. All patients were divided into two groups, according to the occurrence/absence of barotrauma. CXR were assessed by 1 experienced radiologist using Brixia score (BS). SOFA score was calculated by the referring physicians at ICU admittance and NIV days prior intubation were collected. Distribution of barotrauma (pneumomediastinum/pneumothorax/subcutaneous emphysema) were annotated from unenhanced chest CT scan during ICU hospitalization.

RESULTS

A total of 117 SARS-CoV-2 patients (24 females, mean age 59.95 years) were included. Thirty-seven (37/117; 31.6%) mechanically ventilated patients developed barotrauma (25 pneumomediastinum, 23 pneumothorax, 24 subcutaneous emphysema). Compared to the non-barotrauma group, barotrauma patients demonstrated higher BS values (mean value 12.05 vs 9.38, p-value 0.0041), and underwent longer NIV (mean value 4.20 vs 2.75 days, p-value 0.0075). No significant correlation with SOFA score was found. A model using these three tested predictors (BS, SOFA score, NIV days) resulted as the best model to predict development of barotrauma.

CONCLUSION

s Barotrauma occurred in a non-negligible percentage of mechanically ventilated patients with COVID-19 pneumonia. The best predicting model for barotrauma was obtained by the simultaneous employment of three independent variables selected with simple logistic regression: BS, SOFA score, and NIV days.

CLINICAL RELEVANCE/APPLICATION

Integrated clinical-radiological assessment may predict the risk of barotrauma in mechanically ventilated COVID-19 patients, a complication potentially impacting proper management of these cases.

Second-Opinion Subspecialty Consultations in Chest Radiology

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - CH DPS

Participants
Mohammad Jalili, MD, Los Angeles, CA (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this study is twofold. The primary aim is to assess the significance of subspecialty second-opinion consultations for CT examinations in thoracic imaging. The secondary aim is to assess the prevalence and reimbursement rates of over-read interpretations across academic cardiothoracic sections.

METHODS AND MATERIALS

Reports from 100 random chest CTs referred to a single academic institution for second-opinion consultation were reviewed by two radiologists by consensus. Outside and inside reports were compared using a previously published 5-point scale. Clinically important differences were defined as those likely to change patient management.Additionally, a 6-question survey was sent to the section head of every academic cardiothoracic radiology department in the U.S.A. asking how their department handles over-read requests.

RESULTS

Of all the second-opinion examinations, 69% (69/100) had an outside report available for comparison and inclusion in the study.There were no discrepancies in 70% of cases (48/69).In the remaining 30% (21 cases), 6 cases had nonsignificant discrepancies (Type 2 or 3) and 15 cases had clinically significant discrepancies (Type 4 and 5).19 out of 56 (33%) survey recipients responded to the survey.All 19 (100%) respondents stated that their institution does provide second opinion consultations for outside studies.Out of the 19 respondents, 10 departments over-read greater than 20 studies per week, 5 departments over-read 10-20 per week and 4 over-read less than 10 per week.9 out of 19 respondents stated that they were reimbursed less for over-reads than home institution studies while 3/19 stated that reimbursement is higher than home institution studies. The remainder are unsure of reimbursement rates.

CONCLUSION

s Subspecialty second-opinion review by a cardiothoracic fellowship trained radiologist was more meticulous than outside reports in 30% of studies when clinical/pathologic confirmation was made.Of the 21 cases with a discrepancy, 71% (15/21) had clinically significant discrepancies (Type 4 and 5).Of these clinically significant discrepancies, there is almost equal numbers of interpreting vs detecting abnormalities (6 vs 7).All survey respondents (33% of total surveys) provided second-opinion interpretations in some capacity.Approximately 52% of the departments which provided second-opinion interpretations over-read over 20 studies per week.

CLINICAL RELEVANCE/APPLICATION

Formal second opinion interpretations provide added value to referring providers and ultimately the patients. However, given the increasing number of second-opinion interpretation requests, an organized workflow is necessary for proper handling and appropriate billing.

W5B-SPCH-7

Relationships between Right and Left Ventricle Function and Lung Volumes in Subjects free of Cardiovascular Diseases

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - CH DPS

Participants
Ricarda von Kruchten, MD, (*Presenter*) Nothing to Disclose

PURPOSE

The volumetric assessment of MRI-derived global cardiac function includes right (RV) and left ventricular (LV) systolic and diastolic function, but the degree to which MRI-derived lung volumes impact and/or modify parameters of RV and LV function remains unclear. The aim of our study was to investigate the relationship between lung volumes, and parameters of RV and LV function in the KORA-MRI study.

METHODS AND MATERIALS

From the KORA-MRI cohort study, 361 subjects (mean age 56.1±9.1 years; 43% women) underwent a whole-body 3T MRI scan. Cardiac function parameters were measured using a cine-steady-state free precession sequence using cvi42. Lung volumes were derived semi-automatically using an in-house algorithm. Linear regression analyses were performed to assess the relationships between lung volumes and RV and LV function parameters adjusted for age, sex, and cardiovascular risk factors.

RESULTS

RV end-diastolic volume was positively associated with LV end-diastolic volume (ß=28.1, p=<0.001), LV end-systolic volume (ß=11.0, p=<0.001), LV stroke volume (ß=17.0, p=<0.001), and inversely with LV ejection fraction (ß=-1.4, p=0.001). RV end-systolic volume was positively associated with LV end-diastolic volume (ß=21.2, p=<0.001), LV end-systolic volume (ß=11.5, p=<0.001), LV stroke volume (ß=9.7, p=<0.001), and inversely with LV ejection fraction (ß=-3.3, p=<0.001). When adjusting for lung volumes, the association between RV and LV did not attenuate, and no effect modification was observed. Despite the differences in lung volumes in both men and women, we did not observe any gender differences with respect to the association between RV and LV parameters.

CONCLUSION

s In subjects free of cardiovascular diseases, MRI-derived RV and LV function parameters were strongly associated, consistent with the notion that RV function is crucial for LV function, and independent of lung volumes.

CLINICAL RELEVANCE/APPLICATION

Cardio-pulmonary relationships in health and disease are well known. Therefore, parameters of cardiac function and pulmonary function can be useful clinical tools used for diagnosis, risk-stratification, and prognosis. MRI is an excellent tool for the assessment of both lung volumes and volumetric parameters of both right (RV) and left ventricular (LV) function. Our study aimed to examine the fundamental relationships between right and left ventricular function and lung volumes in subjects free of cardiovascular diseases.

Localization-adjusted Diagnostic Performance and Diagnostic Impact of A Commercialized Computer-aided Detection System for Pneumothorax and Consolidation

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - CH DPS

Participants
Hongjun Yoon, Seoul, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

To develop a deep learning algorithm for automated diagnosis of chest abnormalities (consolidation and pneumothorax) and evaluate its diagnostic performance with various dice scores.?

METHODS AND MATERIALS

We, retrospectively, collected 22,338 chest radiographs from two hospitals.?All radiographs?are confirmed by the corresponding CT or radiological report. These are 12,065 consolidation (CON) cases and 6,783 of them are labeled by radiologist. For pneumothorax (PNX), 3,707 cases are selected (2,379 with segmentation mask and 1,328 without). Since manual pixel-level annotation is time-consuming and cumbersome, we exploited the semi-supervised approach. We designed a U-net based deep learning model which was trained with both segmentation and classification labels, when available. On the other hand, when not available, classification label was only used. Considering the importance of lesion localization and interpretability of algorithm, we introduced a dice-adjusted sensitivity evaluation method, which only predictions that exceeded each dice threshold were considered accurate predictions. Unlike sensitivities, specificities could not be considered because dice calculation requires a reference standard lesion annotation (i.e., radiographs without abnormalities do not have lesions to annotate).

RESULTS

We used the 1,050 examination images to test our model with external dataset (300 CON, 250 PNX, 500 normal).??The model has been evaluated with dice score, dice-adjusted sensitivity, specificity, and AUROC. For CON, our model achieved 0.691 (95% CI: 0.664=p=0.718), 0.933 (95% CI: 0.945 = p=0.975), 0.948 (95% CI: 0. 930= p=0. 963), 0.960 (95% CI: 0.945 = p=0.975) for dice score, dice-adjusted sensitivity, specificity, and AUROC, respectively. For PNX, our model achieved 0.798 (95% CI: 0.770=p=0.826), 0.956 (95% CI: 0.923 = p=0.978), 0.996 (95% CI: 0. 989= p=0. 999), 0.978 (95% CI: 0.965 = p=0.991) for dice, dice-adjusted sensitivity, specificity, and AUROC, respectively.

CONCLUSION

s Our deep learning model detected chest X-ray abnormalities (consolidation and pneumothorax) with high diagnostic performance and pixel-level segmentation score.??

CLINICAL RELEVANCE/APPLICATION

To apply deep learning based automated analysis algorithm into actual practice, we propose a semi-supervised learning model to detect abnormal findings (CON and PNX) with outperformed localization.

W5B-SPCH-9

Opportunistic Detection of Diabetes from Frontal Chest Radiography in 104,473 Patients

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - CH DPS

Participants
Ayis T. Pyrros, MD, (*Presenter*) Nothing to Disclose

PURPOSE

Chest radiographs (CXRs) are one of the most frequently ordered radiological exams and can potentially be utilized as a biomarker. Our aim was to explore the use of a multitask deep learning (DL) model to detect diabetes from ambulatory frontal radiographs in a large clinical dataset.

METHODS AND MATERIALS

Material and Methods: A multitask DL model was trained and tested on 303,604 (55% female; mean age, 58) frontal CXRs from 2010 to 2021 at a single institution, using PyTorch and ResNet34, with 5-fold cross-validation. Patient age, BMI, HbA1c, diabetes, and select comorbidities (CHF, cardiac arrhythmias, morbid obesity, COPD, and vascular disease) from the electronic health record (EHR) were then validated on CXRs from ambulatory patients on out-of-fold predictions. Ground truth labels for diabetes were based on current ICD10 codes and HbA1c >=6.5%. Days between diagnosis of diabetes and initial CXR were calculated. Patients with a diagnosis of diabetes predating the CXR were excluded, as well as patients with less than a year of follow-up. The discriminatory ability of the DL model was assessed using area under receiver operating characteristic curve (ROC AUC) compared with the ground truth labels and with other predictors (BMI, Social Deprivation Index). An optimal threshold was calculated using Youden's index from the DL predictor. CXR saliency maps were generated.

RESULTS

A total of 104,473 CXRs in unique patient (mean age, 53; ±17 [SD]; 56% women) were evaluated in the final validation set, of whom 9,319 (8.9%) had a diagnosis of diabetes. The model's overall discriminatory ability for diabetes was an ROC AUC of 0.819 (95% CI:0.815-0.823), versus ROC AUC of 0.542 (95% CI: 0.536-0.548) using SDI as a predictor, and AUC 0.686 (95% CI: 0.681-0.692) using BMI, with all curves demonstrating comparative p-values <0.001. The mean number of days from CXR to diabetes diagnosis was 1,009 (±953 [SD]). At an optimal threshold of 0.11 for the DL predictor, the sensitivity, specificity, negative predictive value, and positive predictive value was 79%, 69%, 97%, and 20%, respectively. Of the 37,625 patients above the threshold, 29,800 (79%) patients did not have a diagnosis of diabetes, and of those, 13,804 (46%) did not have a HbA1c value and 8,109 (27%) had a HbA1c between 5.7-6.4%.

CONCLUSION

s Chest radiography can be utilized opportunistically to aid in detecting patients with diabetes and prediabetes.

CLINICAL RELEVANCE/APPLICATION

Earlier detection of diabetes may allow for improved screening and intervention, potentially reducing the time to diagnosis and treatment.

Sub-Events

W5B-SPER-1 Advantages of Spectral CT Relative to Conventional CT for Detection and Characterization of Foreign Bodies in an In-Vitro Musculoskeletal and a Sinus Cavity Model

Participants
Jason Matakas, MD, MS, (*Presenter*) Nothing to Disclose

PURPOSE

The purpose of this study is to determine whether spectral CT demonstrates improved performance compared to conventional CT for detecting and characterizing foreign bodies (FBs) in in-vitro models. This study focuses on materials that are typically not well visualized on conventional CT.

METHODS AND MATERIALS

Seven commonly encountered?FB?materials including glass, graphite, wood (woodchip, toothpick, plant stem) and plastic (fork, tough plastic) were cut into cylinders of?five?designated sizes (20x3, 10x3, 5x3, 2.5x2.5, 1x1mm). These 35 FBs were randomly arranged in a plastic cassette (sinus cavity model) and imaged in a spectral CT scanner (Philips IQon, 256-slice scanner).? Subsequently,?45 vertical?tracks?were made in three fresh chicken breasts?using a 17-gauge non-coring needle,?and all 35 FBs were randomly inserted, leaving some tracks empty.? These musculoskeletal models were imaged immediately after preparation.? Two fellowship-trained musculoskeletal attending radiologists, who were blinded to FB location, size,?and number, independently reviewed the conventional CT and spectral?CT?images (effective atomic number [Z eff] and electron density maps obtained using Philips IntelliSpace Portal 9.0), assigning subjective visibility ratings to all visualized?FBs?based on a four-point Likert scale.

RESULTS

Within the musculoskeletal model, spectral?CT?demonstrated superior sensitivity and has a lower?size detection limit?for?plant stem, tough plastic, toothpick and woodchip, compared?to?conventional CT ($p<.05$).?For radiopaque materials (glass, graphite) and plastic fork, spectral CT did not appreciably increase detectability, but demonstrated comparable sensitivity. Within the sinus cavity model, spectral CT demonstrated superior sensitivity and had a lower size detection limit for all FBs ($p<.05$), except for glass, which had comparable sensitivity. Of note, spectral CT characteristics varied for different types of wood (processed versus natural).

CONCLUSION

s Spectral CT improves visibility and lowers size detection limits of most of the trialed materials of relatively low radiodensity that are poorly visualized or?non-visualized?on conventional CT. This holds true for FBs in both muscle and air.

CLINICAL RELEVANCE/APPLICATION

Utilization of spectral?CT?can augment the viewer's ability to detect FBs that may otherwise be missed on conventional CT. Furthermore, spectral data may assist in foreign body characterization.

W5B-SPGI-1 Interobserver Concordance in Predicting Complete Response on MRI in Rectal Cancer Patients Post Neoadjuvant Chemo-radiotherapy

Participants
Aashna Karbhari, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To identify the accuracy of MRI in identifying complete pathologic response (pCR) in rectal cancer patients post NACRT, to allow better patient selection for watch and wait (WW) protocol.

METHODS AND MATERIALS

This was an IRB approved retrospective review of MRIs of 80 cases of lower and mid rectal cancer patients from January 2018 to March 2022. Study cohort consisted of 40 patients on the WW protocol post NACRT, and another 40 whose post NACRT MRI suggested complete / near complete response but subsequently underwent surgery. Baseline MRIs (available in 58/80 patients) were evaluated for tumor morphology, location, craniocaudal length and circumferential involvement. Post-treatment MRIs (80 patients) were additionally evaluated for pattern of response on T2 and DWI. Overall primary tumor bed response was classified as complete (CR- only T2 dark fibrosis, no restricted diffusion), near complete (nCR- predominantly T2 dark fibrosis with patchy T2 intermediate signal/ restricted diffusion/mucinous change) or as residual disease (predominant intermediate signal / frank restricted diffusion). Patients with pCR on pathology or who had a disease free interval of 12 months post NACRT on WW protocol were regarded as complete response.Cohen's Kappa statistic was used to evaluate inter-observer concordance in prediction of pCR as well as in interpretation of individual MRI parameters like T2 and DWI.

RESULTS

Median patient age was 47 years (range = 15 - 73 years) with 47 males and 33 females. A combination of T2 and DWI in evaluating rectal MRIs post NACRT was found to have good inter-observer agreement (Cohen's Kappa=0.6). For categorising residual disease, sensitivity, specificity, negative and positive predictive values of Observer 1 were 81.5%, 58.4%, 86.1%, 50% and for Observer 2 were 70.4%, 71.7%, 82.6% and 55.9% respectively. Statistically significant association of complete response was found with <25% circumferential wall involvement (p=0.03) and polypoidal pattern of growth (0.004) at baseline.

CONCLUSION

s Combined evaluation of T2 and DWI on MRI has moderate specificity and sensitivity for characterising residual disease and a good negative predictive value. Despite good inter-observer agreement in interpreting post NACRT rectal MRIs, MRI was not found to significantly identify pCR.

CLINICAL RELEVANCE/APPLICATION

Identification of pCR on MRI can enable appropriate selection of patients to be managed under the watch and wait protocol.

W5B-SPGI-10 Inferior Vena Cava Reflux: Does it Mean There is a Right Heart Dysfunction?

Participants
Ahmad Alhamshari, MBBS, (*Presenter*) Nothing to Disclose

PURPOSE

Retrograde flow into the inferior vena caca and/or hepatic veins have been associated with right heart dysfunction such as tricuspid valve regurgitation. However, much of the studies in the literature were conducted on patients' with other medical illnesses which may affect the finding. So, we are conducting a study on population of healthy liver donors to assess the association. Also, we are reporting the frequency of each reflux grade which may range from grade I "no reflux is present" to grade VI "severe reflux that reaches peripheral hepatic veins".

METHODS AND MATERIALS

Computed tomography (CT) scan of the abdomen with contrast enhancement and transthoracic echocardiography are some of the essential investigation for evaluation of liver donors. We retrospectively reviewed all the CT scans and echocardiographic reports of potential liver donors. CT scans were used to assess the reflux on contrast material into the inferior vena cava and/or hepatic veins during the venous phase. Reflux severity were graded from grade I to grade VI. Echocardiographic reports were reviewed for the presence of the tricuspid regurgitation. Tricuspid regurgitations were reported as normal, trace or mild regurgitation.

RESULTS

We had 246 donors, with mean age of 34 and range from 23-59. There was a male predominance 180 cases (73.2%). The severity of the reflux were reported as normal or mild reflux (grade I-III), or moderate to severe reflux (grade IV-VI). We had 149 (60.6%) cases of normal to mild reflux and 97 (39.4%) of moderate to severe reflux. There was no significant correlation between the reflux severity and the presence of right heart dysfunction.

CONCLUSION

s The presence of inferior vena cava and or hepatic veins reflux is a relatively common finding in CT scans. Its presence does not correlate with right heart dysfunction.

CLINICAL RELEVANCE/APPLICATION

Since there is no correlation with right heart dysfunction, it is not warranted to perform any cardiac investigation in case of presence of reflux.

W5B-SPGI-2 A Nomogram Combining Clinicopathology, IVIM-DWI, MRI Radiomics Parameters to Predict Postoperative DFS in Patients with Rectal Adenocarcinoma

Participants
Rixin Su, (*Presenter*) Nothing to Disclose

PURPOSE

This study aimed to establish an effective prognostic nomogram to predict postoperative disease-free survival (DFS) in patients with rectal adenocarcinoma.

METHODS AND MATERIALS

A total of 156 rectal adenocarcinoma patients admitted to our hospital were retrospectively collected. The patients were divided into training and verification cohort. Clinicopathological data of the patients were collected and IVIM-DWI parameters of the primary rectal adenocarcinoma were measured. Radiomic parameters were extracted on DWI and T2-weighted images. Radiomic features were screened and radiomic scores (Rads-score) were calculated. Correlation analysis, Kaplan-Meier analysis, univariate and multivariate analysis were used in the training group to identify factors associated with disease-free survival (DFS) and to screen independent predictors. Prognostic nomograms were constructed, and the model predictive efficacy and net benefit were evaluated. Validation was performed in the validation cohort.

RESULTS

Kaplan-Meier analysis showed that patients in the poor differentiation group had worse DFS than those in the well/moderate differentiation group ($P < 0.001$), patients in the T4 stage group had worse DFS than those in the T1-3 stage group ($P < 0.001$), patients in the CEA = 5 group had worse DFS than those in the CEA < 5 group ($P < 0.001$), patients in the f value = 46.6 group had worse DFS than those in the f-value < 46.6 group ($P < 0.001$), and patients in the Radsscore = -1 group had better DFS than those in the Radsscore < -1 group. Univariate analysis revealed pretreatment the differentiation, T stage, CEA, f-value, and Rads-score were significantly correlated with DFS. Multivariate analysis showed that the differentiation , T stage, CEA, f value, and Rads-score were independent prognostic factors affecting DFS. A prognostic nomogram model combining clinicopathology, IVIM-DWI and radiomics parameters was developed. The concordance index (C-index) of the nomogram in the training and validation cohort were 0.816 and 0.861, respectively. The model showed good predictive efficacy in both training and validation groups. Decision curve analysis (DCA) in the training and validation cohort demonstrated that the prognostic nomogram was clinically useful.

CONCLUSION

s The prognostic nomogram with a combination of the differentiation, T stage, CEA, f value and Rads-score can be applied in the individualized prediction of postoperative DFS in patients with rectal adenocarcinoma.

CLINICAL RELEVANCE/APPLICATION

The prognostic nomogram with a combination of the differentiation, T stage, CEA, f value and Rads-score can be applied in the individualized prediction of postoperative DFS in patients with rectal adenocarcinoma.It is beneficial to the recovery of patients.

W5B-SPGI-3 Spectral Parameters Measured by Fast kVp Switching Dual-Energy CT: Association with Ki-67 Expression in Hepatocellular Carcinoma complicated with hepatitis

Participants
Caiyun Li, BMedSc, BS, Xiamen, China (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the correlation between spectral parameters obtained from contrast-enhanced spectral CT scanning and Ki-67 expression in hepatocellular carcinoma (HCC).

METHODS AND MATERIALS

29 HCC patients with hepatitis complicated underwent both pathological examination and two-phase contrast-enhanced CT scanning with spectral imaging mode were included in this study. Then iodine-, water- and fat-based material decomposition images as well as virtual monochromatic images acquired at energies ranging from 90 to 140 keV were reconstructed. Region of interest (ROI) was placed on the lesion, and water and fat density, iodine concentration, CT values at monochromatic energy images (HU90-140keV), as well as effective atomic number were measured. The effective atomic number and iodine concentration for lesions were normalized by those for aorta to derive normalized atomic number (Neff-Z) and normalized iodine concentration (NIC). Ki-67 expression level was determined by Ki-67 positivity rate according to immunohistochemistry analysis. Pearson coefficient was used to analyze the correlation between spectral parameters and Ki-67 positivity.

RESULTS

The Neff-Z , NIC, HU90-140keV, water and fat density were positively and fairly correlated with the Ki-67 expression, and correlation coefficient r (95% confidence interval, P value), were 0.476 (0.133-0.718, P = 0.009), 0.402 (0.041-0.670, P = 0.031),

0.381-0.459 (0.016-0.707, P = 0.042-0.012), 0.422 (0.066-0.683, P = 0.023) and 0.465 (0.119-0.710, P = 0.011), respectively. Particularly, Neff-Z showed strongest correlation with Ki-67 expression. Additionally, the correlation between CT value and Ki-67 was enhanced gradually with the increase of monochromatic energy (90keV to 140keV).

CONCLUSION

s The Neff-Z , NIC, HU90-140keV, water and fat density obtained from spectral scanning on dual-energy CT exhibited positive and fair correlation with Ki-67 expression.

CLINICAL RELEVANCE/APPLICATION

Spectral scanning on Dual energy CT provides a new noninvasive method and various parameters to evaluate Ki-67 (indicative of proliferative activity) expression in HCC, which is valuable for clinical diagnosis and treatment.

W5B-SPGI-4 Discordance rates on primary tumor assessment between Blinded Independent Central Review (BICR) readers in advanced or metastatic esophageal cancer applying RECIST 1.1 criteria

Participants
Yan Liu, MD, PhD, Forest, Belgium (*Presenter*) Nothing to Disclose

PURPOSE

The aim of this study is to assess the inter-reader variability between paired readers in the baseline lesion selection on esophagus and its impact on the response evaluation applying RECIST 1.1.

METHODS AND MATERIALS

We included 426 esophageal cancer subjects with 1506 timepoints included in the BICR process and assessed by 8 independent radiologists. We investigated TL distribution in different organs at baseline. Subsequently, we analyzed the discordance rates of baseline assessment of esophagus, categorized as no lesion, target lesion (TL), and non-target lesion (NTL) and its impact on the overall response discordance as well.

RESULTS

Two hundred forty-nine (58.5%) subjects had evidence of disease, with either TL or NTL selected on esophagus by at least one reader at baseline. When both readers considered evidence of disease on esophagus (n=125), the discordance of TL vs NTL selection was 46.4%. The most common sites of TL selected by the readers were lymph nodes. The baseline TL distribution in different organs is listed in Figure 1. Two readers considered esophageal lesions as TLs regularly. Considering overall response assessment, 13 subjects with baseline esophageal NTL had progressive disease (PD) due to the progression of the specified esophageal lesions by at least one reader, while both readers assigned PD on 6 subjects.

CONCLUSION

s This study demonstrated high discrepancies on assessing presence or measurability of primary esophageal tumor selection applying RECIST 1.1 with potential impact on local progression discrepancy. Therefore, reader training at the study initiation could be helpful to reach more consensus among readers through the group discussion on challenging cases.

CLINICAL RELEVANCE/APPLICATION

It is challenging to use RECIST 1.1 for the response assessment in esophageal cancer, because primary lesions could infiltrate the cavity organ and appear with unclear margins, the presence of scar tissue due to the prior local treatment may cause ambiguity in the evaluation, and certain examines such as the use of barium meal and endoscopy are omitted from the evaluation. Therefore, the primary lesion assessment could be classified with high discrepancy.

W5B-SPGI-6 Deep Learning for Detection of Iso-attenuating Pancreatic Adenocarcinoma in Computer Tomography

Participants
Megan Schuurmans, (*Presenter*) Nothing to Disclose

PURPOSE

Investigate the ability of deep learning to localize iso-attenuating pancreatic adenocacinoma (pCa) in computed tomography (CT) images and assess the effect of including prior anatomy information on localization performance.

METHODS AND MATERIALS

This retrospective study included contrast-enhanced CT scans in the portal-venous phase of 44 patients from the public Medical Segmentation Decathlon dataset, who had a visually iso-attenuating tumour. Two previously developed deep learning (DL) algorithms based on the 3D nnUnet framework were applied to the set of iso-attenuating lesions: one considering only tumour information (nnUnet_T) and one considering both tumour and surrounding anatomical structures, namely pancreas parenchyma, common bile duct, pancreatic duct, arteries and veins (nnUNet_MS). Each model created 10 different outputs, based on 2 random initialisations and 5-fold cross validation. The performance of the two models at pCa localization was evaluated with average precision. A permutation test was performed to show statistical significance.

RESULTS

The average precision for the nnUNet_MS was 80.0 % ± 8.6%, while for the nnUnet_T model it was 72.9% ± 7.1% ($p<0.05$). This indicates that surrounding anatomy aids in localization of iso-attenuating pCa lesions. By having prior anatomy information available for training the localization network, the nnUNet_MS network is able to better focus on regions of image where tumour is located, avoiding most confusion with other anatomical structures. The nnUNet_MS failed in 8 cases to localize the tumour, in which 4/8 cases the tumour was localized without high confidence but partially overlapping with the ground truth location, 3/8 cases the tumour was detected next to the ground truth location, and 1/8 cases the tumour was detected outside the pancreas.

CONCLUSION

s In current clinical workup the detection of iso-attenuating pCa lesions on CT is very challenging, as the attenuation is similar to the pancreas parenchyma. The proposed 3D nnUnet_MS model can be used to detect and localize iso-attenuating lesions.

CLINICAL RELEVANCE/APPLICATION

Iso-attenuating pCa is linked to earlier stages of disease and better outcome, but is challenging to detect on CT. When taking surrounding anatomic information into account DL can accurately detect iso-attenuating lesions.

W5B-SPGI-7 Tumor diversity features across pre- and post-chemoradiation MRI are associated with degree of pathologic response to chemoradiation in rectal cancers: a multi-institution study

Participants
Thomas Desilvio, Cleveland, OH (*Presenter*) Nothing to Disclose

PURPOSE

Locally advanced rectal cancers (LARC) are routinely treated with neoadjuvant therapy (chemoradiation and/or chemotherapy, nCRT), but evaluating tumor response in vivo is limited even with high-resolution MRI. Accurately categorizing LARC patients as complete, partial, poor, or incomplete/non-response could enable more personalized interventions. We evaluated a novel suite of radiomic tumor diversity features across pre- and post-chemoradiation MRI for characterizing the pathologic grade of tumor response in LARC.

METHODS AND MATERIALS

IRB-approved, retrospective study. We utilized a discovery cohort of T2-weighted (T2w) MRI scans from 3 institutions: (i) C1: 156 pre-nCRT baseline MRI scans, (ii) C2: 80 post-nCRT follow-up MRI scans. The hold-out validation cohort C3 comprised 39 patients with both pre- and post-nCRT MRI scans. LARC response to nCRT was categorized via pathologic AJCC tumor regression grade (ypTRG): ypTRG0 implying pCR (no residual tumor cells), and ypTRG1-3 corresponding to non/poor/partial response. 38 radiomic tumor diversity features were extracted from annotated tumor (on pre-nCRT) or rectal wall (on post-nCRT), to quantify fractal dimensions, surface topology, and persistent homology. Top 5 tumor diversity features associated with pCR were identified via cross-validated machine learning analysis, separately within C1 and C2. Features identified in common between C1 C2 were used to cluster unseen patients in C3 via unsupervised consensus clustering (Pearson correlation, 1000 iterations). Cluster overlap accuracies were calculated by first identifying which cluster corresponded to which ypTRG (based on precision/recall values) and then calculating what fraction of the datasets from each ypTRG group were correctly clustered together

RESULTS

3 tumor diversity measurements (capturing fractal dimensions and shape topology) were commonly associated with pCR across pre-nCRT and post-nCRT MRI. Combining pre- and post- tumor diversity features yielded excellent cluster overlap accuracies for all ypTRG groups: 0.67 for ypTRG0, 0.93 for ypTRG1, 1.00 for ypTRG2, 0.5 for ypTRG3 and 1.0 for metastatic ypTRG0

CONCLUSION

s Novel tumor diversity features across pre- and post-treatment MRI may effectively characterize the continuum for pathologic degree of tumor response (complete, partial, poor, none) after chemoradiation in LARC.

CLINICAL RELEVANCE/APPLICATION

Non-invasive, quantitative characterization of the degree of tumor response after chemoradiation via novel tumor diversity features on MRI could enable personalized risk profiling and targeted intervention in rectal cancers.

W5B-SPGI-8 Prognostic significance of Magnetic resonance imaging-detected Tumor Deposits in T3 and T4 Rectal Cancer

Participants
Yutao Que, (*Presenter*) Nothing to Disclose

PURPOSE

Tumor deposits (TD) have shown to be a marker of poor prognostic feather in colorectal cancer. However, there are limited number of studies on the relationship between Magnetic resonance imaging-detected tumor deposits (mrTDs) and their clinical outcome following neoadjuvant therapy. The aims of the study are to evaluate the incidence and clinical significance of mrTDs in T3 and T4 patients with rectal cancer, including those underwent neoadjuvant treatment.

METHODS AND MATERIALS

This retrospective study included patients with T3/T4 rectal cancer without synchronous metastasis who underwent surgery between 2015 and 2021 in a tertiary referral hospital. MRI evaluates tumor features (tumor location, T stage, N stage, mesorectal fascia [MRF], extramural venous invasion [EMVI] and mrTDs) before any treatment is performed.

RESULTS

208 patients with a median follow up of 3.3 (range 0.2 - 7.0) years were reviewed. Patients with mrTDs had higher rate of lymph node involvement (OR: 7.812; P = 0.001) and extramural venous invasion (OR: 6.952; P = 0.000). Among 95 patients underwent neoadjuvant therapy, 3-year disease free survival (DFS) was significant higher in mrTD-negative group compared mr-TD positive group (48.5% vs 78.3%; P = 0.002). Of 66 mrTD-positive patients, there was not statistically difference in 3-year disease-free survival between patients with and without neoadjuvant treatment (48.6% vs 71.0%; P = 0.069). Positive mr-EMVI and mrTDs were associated with less tumor regression.

CONCLUSION

s mrTDs are a poor prognostic marker in T3/T4 rectal cancer patients. The oncological results of tumor deposit in T3/T4 patients with and without neoadjuvant treatment are similar, which indicate that patients may benefit from more aggressive treatments.

CLINICAL RELEVANCE/APPLICATION

The oncological results of tumor deposit in T3/T4 patients with and without neoadjuvant treatment are similar, which indicate that patients may benefit from more aggressive treatments, such as induction chemotherapy followed by chemoradiation therapy.

W5B-SPGI-9 Feasibility of PCASL in noninvasive pancreatic blood perfusion

Participants
Yuling Zhang, (*Presenter*) Nothing to Disclose

PURPOSE

This study aimed to investigate the feasibility of the pseudo-continuous arterial spin labeling (PCASL) technique for evaluating pancreatic blood perfusion noninvasively in healthy volunteers.

METHODS AND MATERIALS

Forty-one healthy volunteers underwent a prototypic PCASL protocol at different time points before and after glucose stimulation (5, 10, 15, 20, and 25 minutes) on a 3T MR system (MAGNETOM Prisma, Siemens Healthcare, Erlangen, Germany). The parameters of the PCASL was performed using a 3D single-shot Turbo Gradient Spin Echo sequence with following parameters: repetition time = 7000 ms; echo time = 20.8 ms; field of view = 320 × 160 mm2; voxel size = 5 × 5 × 6 mm3; spin labeling duration = 1500 ms; post-labeling delay = 1500 ms; and acquisition time = 2 min 27 s. PCASL images were acquired in a free breathing manner with retrospective motion correction. The pancreatic blood flow (PBF) map was generated inline after data acquisition. The PBF values of the pancreatic body, tail, and pancreas (the mean value of body and tail) were recorded and analyzed.

RESULTS

The PBF values showed good reproducibility (all ICC > 0.75). Statistically significant differences in PBF were found in different parts of the pancreas before and after glucose stimulation at different time points (all $P < .05$). A similar time trend was observed; PBF reached a maximum at 5 minutes, then gradually decreased, returned to baseline levels at about 15 minutes, and thereafter decreased significantly with time (all $P < .05$). Statistically significant differences in PBF were found between the body and the tail at 0 and 5 minutes (all $P <.05$). The PBF of volunteers of different sex or age were significantly different in the same part of the pancreas at different time points, but not in the same part at the same time point (all $P > .05$).

CONCLUSION

s ASL can noninvasively evaluate the changes in PBF before and after glucose stimulation.

CLINICAL RELEVANCE/APPLICATION

PCASL, which is used to evaluate and monitor the changes in PBF, serves as a new method for revealing the changes in blood flow when islet ß cells secrete insulin.

Interobserver Concordance in Predicting Complete Response on MRI in Rectal Cancer Patients Post Neoadjuvant Chemo-radiotherapy

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - GI DPS

Participants
Aashna Karbhari, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To identify the accuracy of MRI in identifying complete pathologic response (pCR) in rectal cancer patients post NACRT, to allow better patient selection for watch and wait (WW) protocol.

METHODS AND MATERIALS

This was an IRB approved retrospective review of MRIs of 80 cases of lower and mid rectal cancer patients from January 2018 to March 2022. Study cohort consisted of 40 patients on the WW protocol post NACRT, and another 40 whose post NACRT MRI suggested complete / near complete response but subsequently underwent surgery. Baseline MRIs (available in 58/80 patients) were evaluated for tumor morphology, location, craniocaudal length and circumferential involvement. Post-treatment MRIs (80 patients) were additionally evaluated for pattern of response on T2 and DWI. Overall primary tumor bed response was classified as complete (CR- only T2 dark fibrosis, no restricted diffusion), near complete (nCR- predominantly T2 dark fibrosis with patchy T2 intermediate signal/ restricted diffusion/mucinous change) or as residual disease (predominant intermediate signal / frank restricted diffusion). Patients with pCR on pathology or who had a disease free interval of 12 months post NACRT on WW protocol were regarded as complete response.Cohen's Kappa statistic was used to evaluate inter-observer concordance in prediction of pCR as well as in interpretation of individual MRI parameters like T2 and DWI.

RESULTS

Median patient age was 47 years (range = 15 - 73 years) with 47 males and 33 females. A combination of T2 and DWI in evaluating rectal MRIs post NACRT was found to have good inter-observer agreement (Cohen's Kappa=0.6). For categorising residual disease, sensitivity, specificity, negative and positive predictive values of Observer 1 were 81.5%, 58.4%, 86.1%, 50% and for Observer 2 were 70.4%, 71.7%, 82.6% and 55.9% respectively. Statistically significant association of complete response was found with <25% circumferential wall involvement (p=0.03) and polypoidal pattern of growth (0.004) at baseline.

CONCLUSION

s Combined evaluation of T2 and DWI on MRI has moderate specificity and sensitivity for characterising residual disease and a good negative predictive value. Despite good inter-observer agreement in interpreting post NACRT rectal MRIs, MRI was not found to significantly identify pCR.

CLINICAL RELEVANCE/APPLICATION

Identification of pCR on MRI can enable appropriate selection of patients to be managed under the watch and wait protocol.

Inferior Vena Cava Reflux: Does it Mean There is a Right Heart Dysfunction?

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - GI DPS

Participants
Ahmad Alhamshari, MBBS, (*Presenter*) Nothing to Disclose

PURPOSE

Retrograde flow into the inferior vena caca and/or hepatic veins have been associated with right heart dysfunction such as tricuspid valve regurgitation. However, much of the studies in the literature were conducted on patients' with other medical illnesses which may affect the finding. So, we are conducting a study on population of healthy liver donors to assess the association. Also, we are reporting the frequency of each reflux grade which may range from grade I "no reflux is present" to grade VI "severe reflux that reaches peripheral hepatic veins".

METHODS AND MATERIALS

Computed tomography (CT) scan of the abdomen with contrast enhancement and transthoracic echocardiography are some of the essential investigation for evaluation of liver donors. We retrospectively reviewed all the CT scans and echocardiographic reports of potential liver donors. CT scans were used to assess the reflux on contrast material into the inferior vena cava and/or hepatic veins during the venous phase. Reflux severity were graded from grade I to grade VI. Echocardiographic reports were reviewed for the presence of the tricuspid regurgitation. Tricuspid regurgitations were reported as normal, trace or mild regurgitation.

RESULTS

We had 246 donors, with mean age of 34 and range from 23-59. There was a male predominance 180 cases (73.2%). The severity of the reflux were reported as normal or mild reflux (grade I-III), or moderate to severe reflux (grade IV-VI). We had 149 (60.6%) cases of normal to mild reflux and 97 (39.4%) of moderate to severe reflux. There was no significant correlation between the reflux severity and the presence of right heart dysfunction.

CONCLUSION

s The presence of inferior vena cava and or hepatic veins reflux is a relatively common finding in CT scans. Its presence does not correlate with right heart dysfunction.

CLINICAL RELEVANCE/APPLICATION

Since there is no correlation with right heart dysfunction, it is not warranted to perform any cardiac investigation in case of presence of reflux.

A Nomogram Combining Clinicopathology, IVIM-DWI, MRI Radiomics Parameters to Predict Postoperative DFS in Patients with Rectal Adenocarcinoma

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - GI DPS

Participants
Rixin Su, (*Presenter*) Nothing to Disclose

PURPOSE

This study aimed to establish an effective prognostic nomogram to predict postoperative disease-free survival (DFS) in patients with rectal adenocarcinoma.

METHODS AND MATERIALS

A total of 156 rectal adenocarcinoma patients admitted to our hospital were retrospectively collected. The patients were divided into training and verification cohort. Clinicopathological data of the patients were collected and IVIM-DWI parameters of the primary rectal adenocarcinoma were measured. Radiomic parameters were extracted on DWI and T2-weighted images. Radiomic features were screened and radiomic scores (Rads-score) were calculated. Correlation analysis, Kaplan-Meier analysis, univariate and multivariate analysis were used in the training group to identify factors associated with disease-free survival (DFS) and to screen independent predictors. Prognostic nomograms were constructed, and the model predictive efficacy and net benefit were evaluated. Validation was performed in the validation cohort.

RESULTS

Kaplan-Meier analysis showed that patients in the poor differentiation group had worse DFS than those in the well/moderate differentiation group ($P < 0.001$), patients in the T4 stage group had worse DFS than those in the T1-3 stage group ($P < 0.001$), patients in the CEA = 5 group had worse DFS than those in the CEA < 5 group ($P < 0.001$), patients in the f value = 46.6 group had worse DFS than those in the f-value < 46.6 group ($P < 0.001$), and patients in the Radsscore = -1 group had better DFS than those in the Radsscore < -1 group. Univariate analysis revealed pretreatment the differentiation, T stage, CEA, f-value, and Rads-score were significantly correlated with DFS. Multivariate analysis showed that the differentiation , T stage, CEA, f value, and Rads-score were independent prognostic factors affecting DFS. A prognostic nomogram model combining clinicopathology, IVIM-DWI and radiomics parameters was developed. The concordance index (C-index) of the nomogram in the training and validation cohort were 0.816 and 0.861, respectively. The model showed good predictive efficacy in both training and validation groups. Decision curve analysis (DCA) in the training and validation cohort demonstrated that the prognostic nomogram was clinically useful.

CONCLUSION

s The prognostic nomogram with a combination of the differentiation, T stage, CEA, f value and Rads-score can be applied in the individualized prediction of postoperative DFS in patients with rectal adenocarcinoma.

CLINICAL RELEVANCE/APPLICATION

The prognostic nomogram with a combination of the differentiation, T stage, CEA, f value and Rads-score can be applied in the individualized prediction of postoperative DFS in patients with rectal adenocarcinoma.It is beneficial to the recovery of patients.

Spectral Parameters Measured by Fast kVp Switching Dual-Energy CT: Association with Ki-67 Expression in Hepatocellular Carcinoma complicated with hepatitis

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - GI DPS

Participants
Caiyun Li, BMedSc, BS, Xiamen, China (*Presenter*) Nothing to Disclose

PURPOSE

To investigate the correlation between spectral parameters obtained from contrast-enhanced spectral CT scanning and Ki-67 expression in hepatocellular carcinoma (HCC).

METHODS AND MATERIALS

29 HCC patients with hepatitis complicated underwent both pathological examination and two-phase contrast-enhanced CT scanning with spectral imaging mode were included in this study. Then iodine-, water- and fat-based material decomposition images as well as virtual monochromatic images acquired at energies ranging from 90 to 140 keV were reconstructed. Region of interest (ROI) was placed on the lesion, and water and fat density, iodine concentration, CT values at monochromatic energy images (HU90-140keV), as well as effective atomic number were measured. The effective atomic number and iodine concentration for lesions were normalized by those for aorta to derive normalized atomic number (Neff-Z) and normalized iodine concentration (NIC). Ki-67 expression level was determined by Ki-67 positivity rate according to immunohistochemistry analysis. Pearson coefficient was used to analyze the correlation between spectral parameters and Ki-67 positivity.

RESULTS

The Neff-Z , NIC, HU90-140keV, water and fat density were positively and fairly correlated with the Ki-67 expression, and correlation coefficient r (95% confidence interval, P value), were 0.476 (0.133-0.718, P = 0.009), 0.402 (0.041-0.670, P = 0.031), 0.381-0.459 (0.016-0.707, P = 0.042-0.012), 0.422 (0.066-0.683, P = 0.023) and 0.465 (0.119-0.710, P = 0.011), respectively. Particularly, Neff-Z showed strongest correlation with Ki-67 expression. Additionally, the correlation between CT value and Ki-67 was enhanced gradually with the increase of monochromatic energy (90keV to 140keV).

CONCLUSION

s The Neff-Z , NIC, HU90-140keV, water and fat density obtained from spectral scanning on dual-energy CT exhibited positive and fair correlation with Ki-67 expression.

CLINICAL RELEVANCE/APPLICATION

Spectral scanning on Dual energy CT provides a new noninvasive method and various parameters to evaluate Ki-67 (indicative of proliferative activity) expression in HCC, which is valuable for clinical diagnosis and treatment.

W5B-SPGI-4

Discordance rates on primary tumor assessment between Blinded Independent Central Review (BICR) readers in advanced or metastatic esophageal cancer applying RECIST 1.1 criteria

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - GI DPS

Participants
Yan Liu, MD, PhD, Forest, Belgium (*Presenter*) Nothing to Disclose

PURPOSE

The aim of this study is to assess the inter-reader variability between paired readers in the baseline lesion selection on esophagus and its impact on the response evaluation applying RECIST 1.1.

METHODS AND MATERIALS

We included 426 esophageal cancer subjects with 1506 timepoints included in the BICR process and assessed by 8 independent radiologists. We investigated TL distribution in different organs at baseline. Subsequently, we analyzed the discordance rates of baseline assessment of esophagus, categorized as no lesion, target lesion (TL), and non-target lesion (NTL) and its impact on the overall response discordance as well.

RESULTS

Two hundred forty-nine (58.5%) subjects had evidence of disease, with either TL or NTL selected on esophagus by at least one reader at baseline. When both readers considered evidence of disease on esophagus (n=125), the discordance of TL vs NTL selection was 46.4%. The most common sites of TL selected by the readers were lymph nodes. The baseline TL distribution in different organs is listed in Figure 1. Two readers considered esophageal lesions as TLs regularly. Considering overall response assessment, 13 subjects with baseline esophageal NTL had progressive disease (PD) due to the progression of the specified esophageal lesions by at least one reader, while both readers assigned PD on 6 subjects.

CONCLUSION

s This study demonstrated high discrepancies on assessing presence or measurability of primary esophageal tumor selection applying RECIST 1.1 with potential impact on local progression discrepancy. Therefore, reader training at the study initiation could be helpful to reach more consensus among readers through the group discussion on challenging cases.

CLINICAL RELEVANCE/APPLICATION

It is challenging to use RECIST 1.1 for the response assessment in esophageal cancer, because primary lesions could infiltrate the cavity organ and appear with unclear margins, the presence of scar tissue due to the prior local treatment may cause ambiguity in the evaluation, and certain examines such as the use of barium meal and endoscopy are omitted from the evaluation. Therefore, the primary lesion assessment could be classified with high discrepancy.

W5B-SPGI-6

Deep Learning for Detection of Iso-attenuating Pancreatic Adenocarcinoma in Computer Tomography

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - GI DPS

Participants
Megan Schuurmans, (*Presenter*) Nothing to Disclose

PURPOSE

Investigate the ability of deep learning to localize iso-attenuating pancreatic adenocacinoma (pCa) in computed tomography (CT) images and assess the effect of including prior anatomy information on localization performance.

METHODS AND MATERIALS

This retrospective study included contrast-enhanced CT scans in the portal-venous phase of 44 patients from the public Medical Segmentation Decathlon dataset, who had a visually iso-attenuating tumour. Two previously developed deep learning (DL) algorithms based on the 3D nnUnet framework were applied to the set of iso-attenuating lesions: one considering only tumour information (nnUnet_T) and one considering both tumour and surrounding anatomical structures, namely pancreas parenchyma, common bile duct, pancreatic duct, arteries and veins (nnUNet_MS). Each model created 10 different outputs, based on 2 random initialisations and 5-fold cross validation. The performance of the two models at pCa localization was evaluated with average precision. A permutation test was performed to show statistical significance.

RESULTS

The average precision for the nnUNet_MS was 80.0 % ± 8.6%, while for the nnUnet_T model it was 72.9% ± 7.1% ($p<0.05$). This indicates that surrounding anatomy aids in localization of iso-attenuating pCa lesions. By having prior anatomy information available for training the localization network, the nnUNet_MS network is able to better focus on regions of image where tumour is located, avoiding most confusion with other anatomical structures. The nnUNet_MS failed in 8 cases to localize the tumour, in which 4/8 cases the tumour was localized without high confidence but partially overlapping with the ground truth location, 3/8 cases the tumour was detected next to the ground truth location, and 1/8 cases the tumour was detected outside the pancreas.

CONCLUSION

s In current clinical workup the detection of iso-attenuating pCa lesions on CT is very challenging, as the attenuation is similar to the pancreas parenchyma. The proposed 3D nnUnet_MS model can be used to detect and localize iso-attenuating lesions.

CLINICAL RELEVANCE/APPLICATION

Iso-attenuating pCa is linked to earlier stages of disease and better outcome, but is challenging to detect on CT. When taking surrounding anatomic information into account DL can accurately detect iso-attenuating lesions.

W5B-SPGI-7

Tumor diversity features across pre- and post-chemoradiation MRI are associated with degree of pathologic response to chemoradiation in rectal cancers: a multi-institution study

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - GI DPS

Participants
Thomas Desilvio, Cleveland, OH (*Presenter*) Nothing to Disclose

PURPOSE

Locally advanced rectal cancers (LARC) are routinely treated with neoadjuvant therapy (chemoradiation and/or chemotherapy, nCRT), but evaluating tumor response in vivo is limited even with high-resolution MRI. Accurately categorizing LARC patients as complete, partial, poor, or incomplete/non-response could enable more personalized interventions. We evaluated a novel suite of radiomic tumor diversity features across pre- and post-chemoradiation MRI for characterizing the pathologic grade of tumor response in LARC.

METHODS AND MATERIALS

IRB-approved, retrospective study. We utilized a discovery cohort of T2-weighted (T2w) MRI scans from 3 institutions: (i) C1: 156 pre-nCRT baseline MRI scans, (ii) C2: 80 post-nCRT follow-up MRI scans. The hold-out validation cohort C3 comprised 39 patients with both pre- and post-nCRT MRI scans. LARC response to nCRT was categorized via pathologic AJCC tumor regression grade (ypTRG): ypTRG0 implying pCR (no residual tumor cells), and ypTRG1-3 corresponding to non/poor/partial response. 38 radiomic tumor diversity features were extracted from annotated tumor (on pre-nCRT) or rectal wall (on post-nCRT), to quantify fractal dimensions, surface topology, and persistent homology. Top 5 tumor diversity features associated with pCR were identified via cross-validated machine learning analysis, separately within C1 and C2. Features identified in common between C1 C2 were used to cluster unseen patients in C3 via unsupervised consensus clustering (Pearson correlation, 1000 iterations). Cluster overlap accuracies were calculated by first identifying which cluster corresponded to which ypTRG (based on precision/recall values) and then calculating what fraction of the datasets from each ypTRG group were correctly clustered together

RESULTS

3 tumor diversity measurements (capturing fractal dimensions and shape topology) were commonly associated with pCR across pre-nCRT and post-nCRT MRI. Combining pre- and post- tumor diversity features yielded excellent cluster overlap accuracies for all ypTRG groups: 0.67 for ypTRG0, 0.93 for ypTRG1, 1.00 for ypTRG2, 0.5 for ypTRG3 and 1.0 for metastatic ypTRG0

CONCLUSION

s Novel tumor diversity features across pre- and post-treatment MRI may effectively characterize the continuum for pathologic degree of tumor response (complete, partial, poor, none) after chemoradiation in LARC.

CLINICAL RELEVANCE/APPLICATION

Non-invasive, quantitative characterization of the degree of tumor response after chemoradiation via novel tumor diversity features on MRI could enable personalized risk profiling and targeted intervention in rectal cancers.

W5B-SPGI-8

Prognostic significance of Magnetic resonance imaging-detected Tumor Deposits in T3 and T4 Rectal Cancer

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - GI DPS

Participants
Yutao Que, (*Presenter*) Nothing to Disclose

PURPOSE

Tumor deposits (TD) have shown to be a marker of poor prognostic feather in colorectal cancer. However, there are limited number of studies on the relationship between Magnetic resonance imaging-detected tumor deposits (mrTDs) and their clinical outcome following neoadjuvant therapy. The aims of the study are to evaluate the incidence and clinical significance of mrTDs in T3 and T4 patients with rectal cancer, including those underwent neoadjuvant treatment.

METHODS AND MATERIALS

This retrospective study included patients with T3/T4 rectal cancer without synchronous metastasis who underwent surgery between 2015 and 2021 in a tertiary referral hospital. MRI evaluates tumor features (tumor location, T stage, N stage, mesorectal fascia [MRF], extramural venous invasion [EMVI] and mrTDs) before any treatment is performed.

RESULTS

208 patients with a median follow up of 3.3 (range 0.2 - 7.0) years were reviewed. Patients with mrTDs had higher rate of lymph node involvement (OR: 7.812; P = 0.001) and extramural venous invasion (OR: 6.952; P = 0.000). Among 95 patients underwent neoadjuvant therapy, 3-year disease free survival (DFS) was significant higher in mrTD-negative group compared mr-TD positive group (48.5% vs 78.3%; P = 0.002). Of 66 mrTD-positive patients, there was not statistically difference in 3-year disease-free survival between patients with and without neoadjuvant treatment (48.6% vs 71.0%; P = 0.069). Positive mr-EMVI and mrTDs were associated with less tumor regression.

CONCLUSION

s mrTDs are a poor prognostic marker in T3/T4 rectal cancer patients. The oncological results of tumor deposit in T3/T4 patients with and without neoadjuvant treatment are similar, which indicate that patients may benefit from more aggressive treatments.

CLINICAL RELEVANCE/APPLICATION

The oncological results of tumor deposit in T3/T4 patients with and without neoadjuvant treatment are similar, which indicate that patients may benefit from more aggressive treatments, such as induction chemotherapy followed by chemoradiation therapy.

W5B-SPGI-9

Feasibility of PCASL in noninvasive pancreatic blood perfusion

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - GI DPS

Participants
Yuling Zhang, (*Presenter*) Nothing to Disclose

PURPOSE

This study aimed to investigate the feasibility of the pseudo-continuous arterial spin labeling (PCASL) technique for evaluating pancreatic blood perfusion noninvasively in healthy volunteers.

METHODS AND MATERIALS

Forty-one healthy volunteers underwent a prototypic PCASL protocol at different time points before and after glucose stimulation (5, 10, 15, 20, and 25 minutes) on a 3T MR system (MAGNETOM Prisma, Siemens Healthcare, Erlangen, Germany). The parameters of the PCASL was performed using a 3D single-shot Turbo Gradient Spin Echo sequence with following parameters: repetition time = 7000 ms; echo time = 20.8 ms; field of view = 320 × 160 mm2; voxel size = 5 × 5 × 6 mm3; spin labeling duration = 1500 ms; post-labeling delay = 1500 ms; and acquisition time = 2 min 27 s. PCASL images were acquired in a free breathing manner with retrospective motion correction. The pancreatic blood flow (PBF) map was generated inline after data acquisition. The PBF values of the pancreatic body, tail, and pancreas (the mean value of body and tail) were recorded and analyzed.

RESULTS

The PBF values showed good reproducibility (all ICC > 0.75). Statistically significant differences in PBF were found in different parts of the pancreas before and after glucose stimulation at different time points (all $P < .05$). A similar time trend was observed; PBF reached a maximum at 5 minutes, then gradually decreased, returned to baseline levels at about 15 minutes, and thereafter decreased significantly with time (all $P < .05$). Statistically significant differences in PBF were found between the body and the tail at 0 and 5 minutes (all $P < .05$). The PBF of volunteers of different sex or age were significantly different in the same part of the pancreas at different time points, but not in the same part at the same time point (all $P > .05$).

CONCLUSION

s ASL can noninvasively evaluate the changes in PBF before and after glucose stimulation.

CLINICAL RELEVANCE/APPLICATION

PCASL, which is used to evaluate and monitor the changes in PBF, serves as a new method for revealing the changes in blood flow when islet ß cells secrete insulin.

W5B-SPGU-1 Spatial Distribution of Prostate Cancer Detection using Multiparametric MRI

Participants
Fatemeh Zabihollahy, Los Angeles, CA (*Presenter*) Nothing to Disclose

PURPOSE

Multiparametric MRI (mpMRI) has significantly improved prostate cancer (PCa) diagnosis, but its spatial characteristic of tumor detection has not been fully understood. We aim to investigate the spatial correlations of the mpMRI performance in detecting clinically significant (cs)PCa with PI-RADS= 3 across different subjects.

METHODS AND MATERIALS

In this IRB approved, HIPAA compliant study cohort, 704 consecutive men underwent mpMRI prior to radical prostatectomy with thin-section whole-mount histopathology (WMHP) correlation at a single tertiary institution between 2010 and 2020 with annotation of true positive (TP), false negative (FN), and false-positive (FP) lesions. All WMHP and MRI-based findings were cognitively registered to the PI-RADS v2.1 based prostate sector map and the TP, FN, and FP lesions in each sector were assigned. Sector-based cancer prevalence (CP) and detection rate (DR) of mpMRI were then calculated as the number of csPCa divided by the whole number of csPCa lesions and TP/(TP+FN) in each sector, respectively. The correlation between DR and various locations of csPCa (GS= 7) tumors across the prostate sector map was evaluated using a chi-square test.

RESULTS

As shown in Figure 1 the CP and DR maps for csPCa lesions varied across sectors. csPCa lesions were most prevalent in the left and right posterior-lateral mid-gland peripheral zone (PZ), and the DR in the corresponding locations was significantly higher than the overall DR (70.2%; p-value<0.01). The most compromised DR in the right posterior basal transitional zone (TZ) and the left anterior apical PZ. The csPCa lesions in TZ were missed more than in the PZ (DR 63.3% vs. 69.3%; (p<0.01)) while the prevalence of csPCa was higher in PZ over TZ (CP of 64.5% vs. 23.2%). There was no significant difference in the laterality of CP and DR in the PZ. The csPCa lesions in the anterior PZ were also most likely to be missed by mpMRI (p-value<0.001).

CONCLUSION

s In a 704-patient cohort with mpMRI and WMHP with per lesion sector-based detection mpMRI was best in the PZ and least in the anterior TZ and PZ; attention to these sectors may further improve PCa diagnosis.

CLINICAL RELEVANCE/APPLICATION

The results may reduce the need for systematic prostate biopsy as it helps obtain samples from areas with the highest CP instead of removing samples from random areas of the prostate gland.

W5B-SPGU-2 MR-US fusion biopsy of the prostate assisted by artificial intelligence segmentation based on deep learning

Participants
Sung Il Hwang, MD, PhD, Seongnam-si, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Performing target biopsies at the lesions suspected by a radiologist and by artificial intelligence (AI) segmented, to compare the cancer detection rates from these target lesions.

METHODS AND MATERIALS

This is a prospective, explorative study performed in a single institution with IRB approval. From Oct 2021 to Feb 2022, a total of 100 patients who requested for the fusion biopsy of the prostate were enrolled. Multiparametric MRI including diffusion weighted image and dynamic contrast enhancement was performed with 3.0T machine. Under Prostate Imaging Reporting and Data System (Pi-RADS) 2.1, a human index lesion with score over three was annotated by a uroradiologist. Automatic cancer detection and segmentation were done using PROMISE-I software, based on deep learning. The largest segmented lesion was marked as an AI Index lesion. If more than two lesions were segmented, a lesion with higher PI-RADS scoring or larger volume was chosen. Two core targeted biopsy was done for each index lesion by another uroradiologist. If human and AI index lesions are identical, only target biopsy with two cores was done, and marked as both human and AI index lesions. Twelve core systemic randomized biopsy was followed after target biopsy. Clinically significant cancer detection rates (CSCDR) per patient and per core were calculated and compared.

RESULTS

Overall CDR by the patient was 51% and CSCDR was 39%, respectively. In 52 out of 100 patients, the human and AI index lesion was identical and underwent fourteen cores of biopsy. In another 44 patients, either the index lesions from human and AI were different from each other (N=14), or only one index lesion by human (N=3)/ AI (N=27) was present. In the remaining four patients, neither human nor AI could detect lesion, resulting in systemic biopsy only. Core-based CSCDR from human index lesion was 44.9% (31/69) and CSCDR from AI was 33.3% (31/93) ($p < 0.05$). In a subgroup analysis of excluding PI-RADS score 2 lesions (N=27) from AI index lesions, CSCDR rose to 47.0% (31/66).

CONCLUSION

s Core-based CSCDR from the human index lesion was higher than from the AI index. False positive detection from AI was the main problem, necessitating expert PI-RADS scoring after automatic segmentation.

CLINICAL RELEVANCE/APPLICATION

Review by the expert is essential to decide target lesion from the segmented lesions by AI.

W5B-SPGU-3 Integration of MRI biomarkers with molecular profiling for prostate cancer early detection: a prospective cohort validation study

Participants
Martina Pecoraro, MD, Roma, Italy (*Presenter*) Nothing to Disclose

PURPOSE

(i) to comprehensively integrate MRI biomarkers, validated microRNAs, and clinical data to implement PCa early detection; (ii) to test different proposed diagnostic pathways to compare performance and patients' outcomes in terms of biopsy avoidance, accurate diagnosis of clinically significant cancer (csPCa), and reduction in overdiagnosis of clinically insignificant cancer (cisPCa); (iii) to build a risk-based diagnostic algorithm using the identified biomarkers.

METHODS AND MATERIALS

We prospectively enrolled 123 consecutive naïve patients with the suspicion of PCa. All patients underwent MRI and, according to PI-RADS categorization, target biopsy and blood sampling for molecular profiling. The exclusion criteria included a lack of high-quality MR images, and of an adequate sample for microRNAs extraction. Network analysis was applied to identify the biomarkers drivers of csPCa.

RESULTS

We have identified among the MRI biomarkers (i.e., PI-RADS score, ADC/normalized ADC, perfusion markers) those correlating with disease status (csPCa), tumor aggressiveness (ISUP category) and expression of miRNAs. Preliminary results have shown that ADC ($r=-0.51$, $p=0.02$), normalized ADC values ($r=-0.64$, $p=0.002$), and PI-RADS assessment score ($r=0.73$; $p=0.02$) strongly correlate with csPCa and specific miRNAs expression (i.e., miR-302a-5p, miR-520d-3p/miR-548a-3p). Once the driver biomarkers will be further validated, we are going to perform the analysis for the secondary objectives of the study.

CONCLUSION

s This approach will allow for accurate patient allocation to biopsy, and for stratification into risk group categories, reducing overdiagnosis and overtreatment.

CLINICAL RELEVANCE/APPLICATION

The study will provide evidence for a diagnostic paradigm shift that sees MRI biomarkers and molecular data as the prebiopsy triage of patients at risk.

W5B-SPGU-4 Utility of Diffusion Weighted Imaging-Based Radiomics Nomogram to Predict Pelvic Lymph Nodes Metastasis in Prostate Cancer

Participants
Xiang Liu, (*Presenter*) Nothing to Disclose

PURPOSE

To explore the feasibility of DWI-based radiomics for preoperative PLNM prediction in PCa patients at the nodal level

METHODS AND MATERIALS

The preoperative MR images of 1116 pathologically confirmed lymph nodes (LNs) from 84 PCa patients were enrolled. The subjects were divided into a primary cohort (67 patients with 192 positive and 716 negative LNs) and a held-out cohort (17 patients with 43 positive and 165 negative LNs) at a 4:1 ratio. Two PLNM prediction models were constructed based on automatic LN segmentation with quantitative radiological LN features alone (Model 1) and combining radiological and radiomics features (Model 2) via multiple logistic regression. The visual assessments of junior (Model 3) and senior (Model 4) radiologists were compared.

RESULTS

No significant difference was found between the area under curve (AUCs) of Models 1 and 2 (0.89 vs.0.90; $P = 0.573$) in held-out cohort. Model 2 showed the highest AUC (0.83) for PLNM prediction in the LN subgroup with a short diameter = 10 mm compared with Model 1 (0.78), Model 3 (0.66), and Model 4 (0.74). The C-index of the nomogram analysis (0.91) and decision curve analysis (DCA) curves confirmed the clinical usefulness and benefit of Model 2.

CONCLUSION

s A DWI-based radiomics nomogram incorporating the LN radiomics signature with quantitative radiological features is feasible for PLNM prediction in PCa patients, particularly for normal-sized LNM.

CLINICAL RELEVANCE/APPLICATION

A key advantage of this study is indicated by the result that the combined radiomics model has more predictive efficacy than senior

radiologists for differentiating malignant and benign normal-sized PLNM, a finding that could be helpful for patients with PCa to optimize decision-making and adjust adjuvant treatments.

Spatial Distribution of Prostate Cancer Detection using Multiparametric MRI

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - GU DPS

Participants
Fatemeh Zabihollahy, Los Angeles, CA (*Presenter*) Nothing to Disclose

PURPOSE

Multiparametric MRI (mpMRI) has significantly improved prostate cancer (PCa) diagnosis, but its spatial characteristic of tumor detection has not been fully understood. We aim to investigate the spatial correlations of the mpMRI performance in detecting clinically significant (cs)PCa with PI-RADS= 3 across different subjects.

METHODS AND MATERIALS

In this IRB approved, HIPAA compliant study cohort, 704 consecutive men underwent mpMRI prior to radical prostatectomy with thin-section whole-mount histopathology (WMHP) correlation at a single tertiary institution between 2010 and 2020 with annotation of true positive (TP), false negative (FN), and false-positive (FP) lesions. All WMHP and MRI-based findings were cognitively registered to the PI-RADS v2.1 based prostate sector map and the TP, FN, and FP lesions in each sector were assigned. Sector-based cancer prevalence (CP) and detection rate (DR) of mpMRI were then calculated as the number of csPCa divided by the whole number of csPCa lesions and TP/(TP+FN) in each sector, respectively. The correlation between DR and various locations of csPCa (GS= 7) tumors across the prostate sector map was evaluated using a chi-square test.

RESULTS

As shown in Figure 1 the CP and DR maps for csPCa lesions varied across sectors. csPCa lesions were most prevalent in the left and right posterior-lateral mid-gland peripheral zone (PZ), and the DR in the corresponding locations was significantly higher than the overall DR (70.2%; p-value<0.01). The most compromised DR in the right posterior basal transitional zone (TZ) and the left anterior apical PZ. The csPCa lesions in TZ were missed more than in the PZ (DR 63.3% vs. 69.3%; (p<0.01)) while the prevalence of csPCa was higher in PZ over TZ (CP of 64.5% vs. 23.2%). There was no significant difference in the laterality of CP and DR in the PZ. The csPCa lesions in the anterior PZ were also most likely to be missed by mpMRI (p-value<0.001).

CONCLUSION

s In a 704-patient cohort with mpMRI and WMHP with per lesion sector-based detection mpMRI was best in the PZ and least in the anterior TZ and PZ; attention to these sectors may further improve PCa diagnosis.

CLINICAL RELEVANCE/APPLICATION

The results may reduce the need for systematic prostate biopsy as it helps obtain samples from areas with the highest CP instead of removing samples from random areas of the prostate gland.

W5B-SPGU-2

MR-US fusion biopsy of the prostate assisted by artificial intelligence segmentation based on deep learning

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - GU DPS

Participants
Sung Il Hwang, MD, PhD, Seongnam-si, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

Performing target biopsies at the lesions suspected by a radiologist and by artificial intelligence (AI) segmented, to compare the cancer detection rates from these target lesions.

METHODS AND MATERIALS

This is a prospective, explorative study performed in a single institution with IRB approval. From Oct 2021 to Feb 2022, a total of 100 patients who requested for the fusion biopsy of the prostate were enrolled. Multiparametric MRI including diffusion weighted image and dynamic contrast enhancement was performed with 3.0T machine. Under Prostate Imaging Reporting and Data System (Pi-RADS) 2.1, a human index lesion with score over three was annotated by a uroradiologist. Automatic cancer detection and segmentation were done using PROMISE-I software, based on deep learning. The largest segmented lesion was marked as an AI Index lesion. If more than two lesions were segmented, a lesion with higher PI-RADS scoring or larger volume was chosen. Two core targeted biopsy was done for each index lesion by another uroradiologist. If human and AI index lesions are identical, only target biopsy with two cores was done, and marked as both human and AI index lesions. Twelve core systemic randomized biopsy was followed after target biopsy. Clinically significant cancer detection rates (CSCDR) per patient and per core were calculated and compared.

RESULTS

Overall CDR by the patient was 51% and CSCDR was 39%, respectively. In 52 out of 100 patients, the human and AI index lesion was identical and underwent fourteen cores of biopsy. In another 44 patients, either the index lesions from human and AI were different from each other (N=14), or only one index lesion by human (N=3)/ AI (N=27) was present. In the remaining four patients, neither human nor AI could detect lesion, resulting in systemic biopsy only. Core-based CSCDR from human index lesion was 44.9% (31/69) and CSCDR from AI was 33.3% (31/93) ($p < 0.05$). In a subgroup analysis of excluding PI-RADS score 2 lesions (N=27) from AI index lesions, CSCDR rose to 47.0% (31/66).

CONCLUSION

s Core-based CSCDR from the human index lesion was higher than from the AI index. False positive detection from AI was the main problem, necessitating expert PI-RADS scoring after automatic segmentation.

CLINICAL RELEVANCE/APPLICATION

Review by the expert is essential to decide target lesion from the segmented lesions by AI.

W5B-SPGU-3

Integration of MRI biomarkers with molecular profiling for prostate cancer early detection: a prospective cohort validation study

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - GU DPS

Participants
Martina Pecoraro, MD, Roma, Italy (*Presenter*) Nothing to Disclose

PURPOSE

(i) to comprehensively integrate MRI biomarkers, validated microRNAs, and clinical data to implement PCa early detection; (ii) to test different proposed diagnostic pathways to compare performance and patients' outcomes in terms of biopsy avoidance, accurate diagnosis of clinically significant cancer (csPCa), and reduction in overdiagnosis of clinically insignificant cancer (cisPCa); (iii) to build a risk-based diagnostic algorithm using the identified biomarkers.

METHODS AND MATERIALS

We prospectively enrolled 123 consecutive naïve patients with the suspicion of PCa. All patients underwent MRI and, according to PI-RADS categorization, target biopsy and blood sampling for molecular profiling. The exclusion criteria included a lack of high-quality MR images, and of an adequate sample for microRNAs extraction. Network analysis was applied to identify the biomarkers drivers of csPCa.

RESULTS

We have identified among the MRI biomarkers (i.e., PI-RADS score, ADC/normalized ADC, perfusion markers) those correlating with disease status (csPCa), tumor aggressiveness (ISUP category) and expression of miRNAs. Preliminary results have shown that ADC (r=-0.51, p=0.02), normalized ADC values (r=-0.64, p=0.002), and PI-RADS assessment score (r=0.73; p=0.02) strongly correlate with csPCa and specific miRNAs expression (i.e., miR-302a-5p, miR-520d-3p/miR-548a-3p). Once the driver biomarkers will be further validated, we are going to perform the analysis for the secondary objectives of the study.

CONCLUSION

s This approach will allow for accurate patient allocation to biopsy, and for stratification into risk group categories, reducing overdiagnosis and overtreatment.

CLINICAL RELEVANCE/APPLICATION

The study will provide evidence for a diagnostic paradigm shift that sees MRI biomarkers and molecular data as the prebiopsy triage of patients at risk.

W5B-SPGU-4

Utility of Diffusion Weighted Imaging-Based Radiomics Nomogram to Predict Pelvic Lymph Nodes Metastasis in Prostate Cancer

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - GU DPS

Participants
Xiang Liu, (*Presenter*) Nothing to Disclose

PURPOSE

To explore the feasibility of DWI-based radiomics for preoperative PLNM prediction in PCa patients at the nodal level

METHODS AND MATERIALS

The preoperative MR images of 1116 pathologically confirmed lymph nodes (LNs) from 84 PCa patients were enrolled. The subjects were divided into a primary cohort (67 patients with 192 positive and 716 negative LNs) and a held-out cohort (17 patients with 43 positive and 165 negative LNs) at a 4:1 ratio. Two PLNM prediction models were constructed based on automatic LN segmentation with quantitative radiological LN features alone (Model 1) and combining radiological and radiomics features (Model 2) via multiple logistic regression. The visual assessments of junior (Model 3) and senior (Model 4) radiologists were compared.

RESULTS

No significant difference was found between the area under curve (AUCs) of Models 1 and 2 (0.89 vs.0.90; P = 0.573) in held-out cohort. Model 2 showed the highest AUC (0.83) for PLNM prediction in the LN subgroup with a short diameter = 10 mm compared with Model 1 (0.78), Model 3 (0.66), and Model 4 (0.74). The C-index of the nomogram analysis (0.91) and decision curve analysis (DCA) curves confirmed the clinical usefulness and benefit of Model 2.

CONCLUSION

s A DWI-based radiomics nomogram incorporating the LN radiomics signature with quantitative radiological features is feasible for PLNM prediction in PCa patients, particularly for normal-sized LNM.

CLINICAL RELEVANCE/APPLICATION

A key advantage of this study is indicated by the result that the combined radiomics model has more predictive efficacy than senior radiologists for differentiating malignant and benign normal-sized PLNM, a finding that could be helpful for patients with PCa to optimize decision-making and adjust adjuvant treatments.

W5B-SPHN-1 Lateralization of Cerebral Blood Flow In the Auditory Pathway of Patients with Idiopathic Tinnitus: An Arterial Spin Labeling Study

Participants
Xiaoshuai Li, (*Presenter*) Nothing to Disclose

PURPOSE

To assess the lateralization of cerebral blood flow (CBF) in the entire auditory pathway of patients with idiopathic tinnitus and healthy controls (HCs) using 3D pseudocontinuous arterial spin labeling (pcASL).

METHODS AND MATERIALS

Thirty-six patients with idiopathic tinnitus and 43 age- and gender-matched HCs underwent 3D-pcASL scanning using 3.0T MRI system. Region of interest (ROI) analysis was performed on the auditory pathway of both groups. The clinical data of all subjects were analyzed.

RESULTS

In patients with idiopathic tinnitus and HCs, the CBF in the left primary auditory cortex (PAC) was significantly higher than that in the right, while the CBF in the right secondary auditory cortex, auditory associative cortex, and medial geniculate body was significantly higher than that in the left. In HCs, the CBF in the right inferior colliculus (IC) was significantly higher than that in the left, while no significant difference in CBF between the bilateral IC was found in tinnitus patients. Compared with HCs, tinnitus patients exhibited significantly higher CBF in the bilateral PAC (right: P = 0.005; left: P = 0.01) and lower CBF in the right IC (P = 0.013). The reduced CBF in the right IC was positively correlated with tinnitus severity (r = 0.506, P = 0.002).

CONCLUSION

s This study confirms the asymmetry of the entire auditory pathway and investigates the underlying neuropathology of idiopathic tinnitus from in terms of CBF.

CLINICAL RELEVANCE/APPLICATION

This study not only investigated the underlying neuropathology of tinnitus in terms of CBF but also may have implications for the rationale of tinnitus treatment protocols based on lateralized hyperactivity.

W5B-SPHN-2 Static And Dynamic Evaluation with MRI of Larynx and Oro-Pharingeal Cavity in Professional Opera Singers

Participants
Marco Di Girolamo, MD, (*Presenter*) Nothing to Disclose

PURPOSE

To assess the anatomical configuration of phonetic organs by MRI in professional opera singers with different vocal range.

METHODS AND MATERIALS

26 professional opera singers (12 men (7 tenors and 5 basses) and 14 women (8 sopranos and 6 mezzosopranos) were evaluated with MRI. We performed both static and dynamic study with MRI. The static study was performed with TSE T2-weighted axial scans at the level of larynx (TR:2000 ms; TE:120ms; slice thick:3mm) in order to evaluate the area of superior surface of vocal cord. In the dynamic study, the singers were asked to perform a prolonged vocalization at a confortable tonality of the fundamental vowel [a]. We performed a midsagittal Turbo Field Echo scan (TR:12ms; TE:6ms; fa:30°; acq.time:6s) at the level of the oro-pharyngeal cavity measuring the area of the mouth and pharyngeal lumen. These data underwent statistical evaluation using the Mann-Whitney U-test (non-parametric test) considering: 1) vocal tessitura; 2) size of the vocal cord; 3) area of the mouth and pharyngeal lumen during the utterance of the vowel [a].

RESULTS

The average size of the vocal cord was: 0.71 cm2 for sopranos; 1.20 cm2 for mezzosopranos; 1.58 cm2 for tenors; 2.88 cm2 for basses. The average area of mouth and pharyngeal lumen on midsagittal scan during the utterance of the vowel a was: 15.8 cm2 for sopranos; 14.6 cm2 for mezzosopranos; 23.6 cm2 for tenors; 32.2 cm2 for basses. We found that the differences in vocal cord size between sopranos and mezzosopranos (P: 0.0641) and between tenors and basses (P: 0.0833) are tendentially statistically significant. The variation in vocal tract size during the utterance of the vowel a between tenors and basses is considered tendentially statistically significant (P: 0.0833) while the difference between sopranos and mezzosopranos is not considered

statistically significant (P: 0.6434). The difference in the vocal register between soprano and mezzosoprano is less considerable in comparison with tenor and bass or with soprano and contralto.

CONCLUSION

s Our results demonstrate a correlation between the surface of the vocal cord and the configuration of vocal tract and the vocal tessitura of a singer.

CLINICAL RELEVANCE/APPLICATION

ong vocal cord and wide vocal tract are characteristic of singers with low-pitched voice types (bass, baritone, contralto) while short vocal cord and narrow vocal tract are characteristic of singers with high-pitched voice types (tenor, soprano).

W5B-SPHN-3 Clinicoradiological Characteristics in The Differential Diagnosis of Follicular-patterned Lesions of the Thyroid: A Multicenter Cohort Study

Participants
Haein Lee, Suwon, Korea, Republic Of (*Presenter*) Nothing to Disclose

PURPOSE

The preoperative differential diagnosis of follicular-patterned lesions is often challenging. This multicenter cohort study investigated the clinicoradiological characteristics relevant to the differential diagnosis of such lesions.

METHODS AND MATERIALS

From June to September 2015, 4,787 thyroid nodules (= 1.0 cm) with a final diagnosis of benign follicular nodule (BN, n=4461), follicular adenoma (FA, n=136), follicular carcinoma (FC, n=62), and follicular-variant of papillary thyroid carcinoma (FVPTC, n=128) were included from 26 institutions. The clinicoradiological characteristics of these groups were compared using logistic regression analyses, and the relative importance of those characteristics was determined using a random forest algorithm.

RESULTS

Compared to BN, distinguishing features of FA, FC, and FVPTC were patient age (odd ratio [OR], 0.969), lesion diameter (OR: 1.054), solid composition (OR: 2.262), hypoechogenicity (OR: 2.183), and halo (OR, 1.763) (all $P < 0.05$). Compared to FA, FC differed with respect to lesion diameter (OR: 1.039) and rim calcifications (OR: 16.692), while FVPTC differed with respect to patient age (OR: 0.966), lesion diameter (OR: 0.973), macrocalcifications (OR: 3.590), and non-smooth margin (OR: 2.477) (all $P < 0.05$). The five relative feature importance for differential diagnosis of FA, FC, and FVPTC from BN were lesion diameter, composition, echogenicity, orientation, and patient age. The most important relative features of FC and FVPTC from FA were rim calcifications and macrocalcifications, respectively.

CONCLUSION

s Although follicular-patterned lesions have overlapping clinical, radiological, and cytological features, the relative importance of those features as assessed in a large clinical cohort may provide information valuable to preoperative decision-making.

CLINICAL RELEVANCE/APPLICATION

1. Our multicenter cohort study showed that follicular-patterned neoplasms could be distinguished from BN based on their larger diameter, solid composition, hypoechogenicity, halo, and the younger age of patients associated with them. 2. Compared to FA, FC tumors were of larger diameter and characterized by rim calcifications whereas FVPTC were of smaller diameter and differed by their macrocalcifications, non-smooth margin, and the younger age of patients. 3. On the basis of our findings, the new risk stratification system for follicular-patterned lesions should be considered for a preoperative decision-making.

W5B-SPIN-1 GAN-based Contrast Media Reduction in MRI in A Large Animal Experiment

Participants
Johannes Haubold, MD, Essen, Germany (*Presenter*) Speaker, Siemens AG

PURPOSE

The aim was to establish virtual contrast enhancement in MRI with generative adversarial network (GAN) to reduce the amount of hepatobiliary contrast agent(CA) in a large animal model.

METHODS AND MATERIALS

120 exams were performed on a clinical 1.5 T MRI on six different occasions with 20 healthy Goettingen minipigs, 50% low-dose(lCM)(0.005mmol/kg, gadoxetate) and 50% with normal-dose(nCM)(0.025mmol/kg). These included arterial, portal venous, venous, and hepatobiliary contrast phases(20 and 30 minutes). One animal had to be excluded due to incomplete examinations. Three of the 19 animals were chosen at random and withheld for validation (18 examinations). The remaining 16 animals (96 examinations) were used to train a GAN for image-to-image conversion from lCM to nCM (vCM).Following that, ROI measurements in the abdominal aorta, inferior vena cava, portal vein, liver parenchyma, and autochthonous back muscles were obtained, and the vascular and parenchymal CNR was determined. In addition, the nCM and vCM data were shown in a visual-Turing-test(VTT) to three consultant radiologists, who had to assess whether they would have reported both sequences identical(pathologically consistent) and which sequence was the nCM sequence.

RESULTS

Pooled vascular ($p<0.0001$) and parenchymal ($p<0.0001$) CNR increased significantly from lCM to vCM and were not significantly different between vCM and nCM exams (vascular CNR (mean±SD): lCM 17.6±6.0, vCM 41.8±9.7 and nCM 48.4±12.2; parenchymal CNR (mean±SD): lCM 21.6±6,1, vCM 30.2±7.0, nCM 32.4±8.7). On median, the consultant radiologist indicated that the nCM and vCM sequences are pathologically consistent in 100 percent of the studies and correctly identified the normal-dose series in 59.5 percent of the instances.

CONCLUSION

s This feasibility study on healthy minipigs demonstrates that, GAN-based contrast enhancement can lower the amount of hepatobiliary CA on MRI by up to 80% while retaining equivalent image quality.

CLINICAL RELEVANCE/APPLICATION

GAN-based contrast enhancement can reduce costs and exposure of patients to gadolinium-based CA.

W5B-SPIN-2 Impact of AI for Pathology Detection From Knee MRI

Participants
Gaspard d'Assignies, MD, Paris, France (*Presenter*) Founder, Incepto Medical SAS;Employee, Incepto Medical SAS;Stockholder, Incepto Medical SAS

PURPOSE

To evaluate the impact of artificial intelligence (AI) models on diagnostic performances of a panel of readers for detecting meniscal and ligament tears from knee MRI.

METHODS AND MATERIALS

An evaluation dataset consisted of 200 knee MRI (mean age 52.4, 52% male), for which gold standard diagnosis for Medial and Lateral Menisci (MM and LM), Anterior Cruciate Ligament (ACL), and Medial Collateral Ligament (MCL) was established via expert consensus of 3 musculoskeletal radiologists.Six experienced readers were asked to each review 100 exams (stratified for pathology prevalence) without the help of the AI, and the remaining 100 assisted by the AI.The AI model was a CE marked product (keros 1.0 - Incepto medical (c)).Readers' performances were evaluated using sensitivity/specificity, while Receiver Operating Characteristic curves were used for the AI performances. Chi-square testing was used for statistical significance of performance comparisons.

RESULTS

Pathology prevalence for MM, LM, ACL and MCL were 40%, 18.5%, 40% and 20%, respectively.Readers' sensitivity (without / with AI) values for MM, LM, ACL and MCL were 0.858/0.908 (95% CI [0.799, 0.875]/[0.879, 0.927], p=0.088), 0.685/0.712 (95% CI [0.665, 0.747]/[0.641, 0.783], p=0.661), 0.783/0.917 (95% CI [0.734, 0.809]/[0.858, 0.95], p<1e-4), and 0.592/0.742 (95% CI [0.506, 0.684]/[0.686, 0.791], p=0.014), respectively.Readers' specificity (without / with AI) values for MM, LM, ACL and MCL were

0.836/0.906 (95% CI [0.801, 0.872]/[0.858, 0.95], p=0.005), 0.969/0.947 (95% CI [0.965, 0.981]/[0.932, 0.96], p=0.079), 0.972/0.894 (95% CI [0.959, 0.978]/[0.866, 0.915], p<1e-4), and 0.962/0.954 (95% CI [0.957, 0.972]/[0.947, 0.965], p=0.518), respectively.

CONCLUSION

s AI assistance led to an increased specificity for MM and an increased sensitivity for MCL. For ACL, it led to an increased sensitivity and a decreased specificity.

CLINICAL RELEVANCE/APPLICATION

AI algorithms appear to bring an overall positive impact on radiological performances. Additional care must be paid to balance sensitivity vs. specificity of the AI assistance according to the clinical relevance for the considered structure.

W5B-SPIN-3 Ultrasonic Texture Features as Radiomic Biomarkers for Screening Cardiac Remodeling and Dysfunction

Participants
Quincy Hathaway, PhD, (*Presenter*) Nothing to Disclose

PURPOSE

Point-of-care ultrasound (POCUS) workflows allow for rapid screening of cardiac abnormalities for guiding appropriate early triage and management. Morphometry and textural features (radiomics) in POCUS images could aid in the rapid automated expert-level screening of left ventricular (LV) myocardial remodeling and dysfunction without requiring any quantitative measurements.

METHODS AND MATERIALS

We developed Machine-learning (ML) models using three clinical cohorts that included 1,915 subjects: 1) an expert-annotated registry of POCUS (n=943, 80% training and 20% internal validation), 2) a prospective institutional POCUS cohort for external validation (n=275), and 3) a prospective external validation ML model on high-end ultrasound systems (n=484) for a head-to-head comparison of radiomics-based prediction with standardized quantitative measurements obtained during comprehensive echocardiography. With radiomic features from the parasternal long axis, we developed an explainable ML model and a direct image-derived black-box convolutional neural network (CNN) model. Echocardiography of wildtype (n=10) and Leptr-/- (n=8) mice were assessed longitudinally at 3 and 25 weeks, and radiomic features of importance were correlated with histopathological features of myocyte disarray and hypertrophy.

RESULTS

The receiver operating characteristic (ROC) area under the curve (AUC) for predicting expert annotated LV myocardial remodeling and dysfunction was higher for texture-based interpretable ML than the black-box, deep learning model (0.84, 0.73 and 0.75 vs. 0.53, 0.59, and 0.58; P=0.0001 for internal and external POCUS and high-end ultrasound validation studies, respectively). Furthermore, the radiomics model predicted time-to-event outcomes in the external POCUS (100% vs. 82% survival, P=0.0001) and high-end ultrasound studies (93% vs. 85% survival, P=0.0031). Leptr-/- obese mice revealed LV remodeling through increased cardiomyocyte diameter (>20% increase, compared to controls) that positively correlated with two radiomics biomarkers of importance extracted from the interventricular septum (r = 0.79 and 0.90, P=0.0001), respectively.

CONCLUSION

s Texture-based ML models can be applied to cardiac POCUS to mirror an expert physician’s ability to screen for the presence of LV myocardial remodeling and dysfunction without quantitative measurements.

CLINICAL RELEVANCE/APPLICATION

Traditional cardiac point-of-care ultrasound requires expert-level interpretation to assess clinical findings; our model can automate the interpretation of left ventricular structural and functional changes without quantitative measurements.

W5B-SPIN-4 Is It Time for Radiologists to Build AI? International Validation of Radiologist-trained AI Models to Identify Causes of Suboptimal Chest Radiographs

Participants
Giridhar Dasegowda, MBBS, Boston, MA (*Presenter*) Nothing to Disclose

PURPOSE

Generalizability of artificial intelligence (AI) models is a critical step towards its use in diverse clinical practices. Such efforts are hampered due to lack of data diversity in single study or country studies. Therefore, we assessed the performance of radiologist-trained AI models to differentiate suboptimal (sCXR) and optimal (oCXR) chest radiographs on a diverse multicenter data from 7 countries.

METHODS AND MATERIALS

Our IRB-approved study included 10,687 CXRs from adult patients (age > 18 years) from 7 countries (US, Brazil, Lebanon, India, Italy, Croatia, Iran: 14 imaging sites). The CXRs represented consecutive portable radiographs from each site. All de-identified CXRs were reviewed and annotated for the presence and causes of suboptimality on an AI server-based platform (CARPL AI). After annotation, all CXRs were uploaded into an AI building platform (Cognex Inc.) that allows non-programmers to build, train and test AI model for clinical applications. The platform allowed training (7508 CXRs: 3048 oCXR, 7508 sCXR from 7 sites, 2 country) and testing (3179 CXRs: 2490 sCXR, 689 oCXR from 7 other international sites) of 8 AI models for identifying various causes of sCXR. Receiver operating characteristics analyses were performed.

RESULTS

The AI models classified sCXR with missing apices, right CP angle and left CP angle lung with 98%, 96%, 98% accuracies, and AUCs (95% CI) of 0.84 (0.80-0.88), 0.92(0.89-0.95) and 0.93 (0.90-0.95), respectively. AI identified under- and over-exposure with 93% and 94% accuracy, with 0.93 AUC (95% CI 0.90-0.95) and 0.86 AUC (95% CI 0.82-0.90). The presence of low lung volume was identified with 92% accuracy, and 0.94 AUC (95% CI 0.91-0.96). Lungs obscured by overlying chin was identified with 95% accuracy and AUC of 0.94 (95% CI 0.91-0.96). The AI accuracy and AUC for patient rotation were 95% and 0.92 (95% CI 0.89-

0.95), respectively.

CONCLUSION

s The eight AI models had high accuracy and generalizable performance for identifying suboptimal CXRs across 14 sites from 7 countries across four continents.

CLINICAL RELEVANCE/APPLICATION

International generalizability evaluation of AI models can help overcome lack of data diversity and representations from single country or site studies, which helps prove model trustworthiness.

W5B-SPIN-5 DeepLiverNet 2.0: A Deep Transformer Model for Liver Stiffness Classification Using T2-Weighted MRI Data

Participants
Redha Ali, PhD, Cincinnati, OH (*Presenter*) Nothing to Disclose

PURPOSE

To develop an improved version of DeepLiverNet 1.0 for categorically classifying the degree of liver stiffening using anatomic T2-weighted MRI in children and young adults with known or suspected pediatric chronic liver disease.

METHODS AND MATERIALS

Clinical axial T2-weighted fast spin-echo fat-saturated MRI images and 2D MR elastography liver stiffness measurements were clinically acquired from 1236 children and young adult patients with known or suspected pediatric chronic liver disease. We propose DeepLiverNet 2.0 in order to improve upon our prior work DeepLiverNet 1.0, that classified patients into one of two groups, no/mild liver stiffening <3 kPa or moderate/severe liver stiffening =3 kPa, which derived from MR elastography (Fig. 1). Specifically, we replaced the prior model's transfer learning block with the state-of-art Swin Transformer for latent imaging feature extraction. Swin Transformer is a hierarchical transformer implemented by shifting window partitions between consecutive self-attention layers. Such sliding window schema enhances efficiency by limiting self-attention computation to non-overlapping local windows while allowing for cross-window connection. Model performance was assessed using ten-fold cross-validation.

RESULTS

The proposed DeepLiverNet 2.0 model was able to categorically classify the severity of liver stiffening with an accuracy [mean ± standard deviation] 82.7 ± 0.02%, sensitivity 73.3 ± 4.0%, specificity 87.7 ± 4.0%, and AUC 0.84 ± 0.04. It outperformed the DeepLiverNet 1.0 model by a significant margin of 0.08 on AUC (0.76 ± 0.01; $P < 0.0001$), as well as on accuracy (77.8 ± 1.0%; $P < 0.0001$), sensitivity (67.2 ± 4.0%; $P = 0.004$), and specificity (83.4 ± 4.0% $P = 0.03$).

CONCLUSION

s By updating our previously developed feature extraction module using a state-of-the-art Swin Transformer, we have demonstrated that the proposed DeepLiverNet 2.0 model has better capability than DeepLiverNet 1.0 to stratify the severity of liver stiffening using anatomic T2-weighted MRI data in children and young adults with known or suspected pediatric chronic liver disease. Extensive model optimization is likely to further improve performance.

CLINICAL RELEVANCE/APPLICATION

Our DeepLiverNet 2.0 AI model can categorically classify the severity of liver stiffening using anatomic T2-weighted MRI in children and young adults. Model refinements and incorporation of clinical features may soon decrease the need for MR elastography.

W5B-SPIN-1

GAN-based Contrast Media Reduction in MRI in A Large Animal Experiment

Wednesday, Nov. 30 12:45PM - 1:15PM Room: Learning Center - IN DPS

Participants
Johannes Haubold, MD, Essen, Germany (*Presenter*) Speaker, Siemens AG

PURPOSE

The aim was to establish virtual contrast enhancement in MRI with generative adversarial network (GAN) to reduce the amount of hepatobiliary contrast agent(CA) in a large animal model.

METHODS AND MATERIALS
